This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based on healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data, and other factors unique to the patient. The publisher does not provide medical advice or guidance, and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings, and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used, or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Norfolk, Virginia

REMEMBRANCES

Dr. James F. Glenn MD, FACS, FRCS (Hon)

Pioneer in urology, leader, surgeon, scientist, mentor, and friend—all these describe James F. Glenn's life as a leader in academic medicine. Jim was born in Lexington, Kentucky, on May 10, 1928 and died in Lexington on June 10, 2009. After graduation from the University School in Lexington, Jim studied at the University of Rochester where he graduated with a bachelor of arts degree in 1949. He was accepted at and entered the Duke University School of Medicine graduating with honors in 1952 where he was elected a member of Alpha Omega Alpha. After completion of 2 years as a surgical house officer at the Peter Bent Brigham Hospital in Boston, he returned to North Carolina as a U.S. air force flight surgeon commanding the 3308th hospital. He was influenced by Dr. Edwin Alyea and Dr. John Dees to return to Duke as a urology resident completing his training in urology in 1959. Jim was asked to stay as a faculty member but recalls that he wanted to "spread my wings" and accepted a faculty position at Yale. Following 2 years on the Yale faculty, he once again returned to North Carolina joining William Boyce at Wake Forest as an associate professor.

When Dr. Edwin Alyea chose to step down as Duke's chief of urology, Jim Glenn was chosen as his successor at age 34, then the youngest chief of urology in the country. Once at Duke, Jim blossomed into the leader and mentor that set the course for his career. With his prodigious energy and unconquerable spirit, Jim created one of the most outstanding urology programs in the United States. Known for research, training and clinical excellence, and a reputation that he established continues today. He created an active alumni network called Duke Youthful Society of Urology Residents Interested in Advancement (DYSURIA). He recognized the acute needs of academic programs for philanthropy and created Committee for Urologic Research, Education and Development (CURED) and raised an endowment to fund urologic research and education. He was among the first to recognize the need for educating community urologists and created a regional meeting and quarterly visiting professors open to all urologists in the community. Jim was editor of *Glenn's Urologic Surgery*, now in its eighth edition; it continues to guide both urology trainees and practitioners in surgical procedures from simple to complex.

One of his greatest contributions was his mentorship ability. He was the "godfather" to countless urologists in private practice and academic positions. He trained and mentored future chairs and chiefs at University of Chicago, Emory, Duke, University of North Carolina, University of California-Davis, University of South Florida, and the National Cancer Institute. He also trained chiefs of pediatric urology at Mayo Clinic, Texas Children's Hospital, DuPont Hospital for Children-Jacksonville, and the University of Cincinnati. In his essay for a Duke alumni publication, he stated, "We were a coherent and cohesive coterie of friends, a family with unified goals."

In 1980, Jim moved from urology to academic administration accepting the position as dean of the Emory University School of Medicine where he was instrumental in choosing many clinical chairs and expanding the facilities and research funding. He then moved to the Mount Sinai School of Medicine in New York where he served as president of the Mount Sinai Medical Center from 1983 until 1987. After leaving Mount Sinai, he returned to his home town of Lexington, Kentucky, and served in positions at the University of Kentucky Medical Center including executive director of the Markey Cancer Center (1989–1993), interim chair of the department of surgery (1996–1997), and associate dean for clinical affairs and chief of staff (1993–1995). He served his community as board chairman of the Lexington Cardinal Hill Rehabilitation Hospital and was chair of the Lexington History Museum Board. He funded the Glenn Building at Transylvania College and endowed professorships in urology at the University of Kentucky and Duke University.

Including the American Surgical Association, Jim was a member and officer of many prestigious national and international organizations. He was founding member and president of the Society of University Urologists and president of the Southeastern Section of the American Urological Association, American Association of Genitourinary Surgeons, Clinical Society of Genitourinary Surgeons, Society for Pediatric Urology, The Society of Pelvic Surgeons, and Société Internationale d'Urologie. His honors include the medal of the Société Internationale d'Urologie, its highest honor, Hugh Hampton young award from the American Urological Association as well as its lifetime achievement award. He was honored by the British Association of Urological Surgeons with the St. Paul's Medal for professional contributions and was an honorary fellow of The Royal College of Surgeons of England.

All of these positions and honors, however, do not define the man. Jim Glenn was a caring but focused leader. His humor was legendary. No one who knew Jim could forget the lengthy jokes and humorous stories that he told at many events and the singing of his presidential address at the Clinical Society of Genitourinary Surgeons. His humorous approach to even the most difficult situations put his peers and understudies at ease and demonstrated his ability reach all people. Jim was the consummate mentor. He continued to support, promote, and advise his former residents, faculty, and friends throughout their careers. His steadfast support and sage advice were his lasting legacy.

Culley C. Carson III, MD

PREFACE

The preface for the last edition (seventh) of *Glenn's Urologic Surgery* was written by Dr. Glenn shortly before his death. Having reviewed it with a view to making changes, I find that there are none to make. He said all that needed to be said, and therefore, both Sam and I feel we have no more to add. Enjoy!

Tom Keane, MD, BCh, FRCSI, FACS

In 1969 when the first edition of *Urologic Surgery* was published, the avowed purpose of the work was to present authoritative expositions of various surgical procedures, authored by acknowledged experts in the field. It was the conviction of the editors that there were atlases and textbooks that presented urology well, but there were no volumes on surgical technique, and that urology is—first and foremost—a surgical specialty.

In developing that initial effort, I was joined (and guided) by my good friend and wise mentor William H. Boyce, superb clinician, outstanding scientist, and master surgeon. Between us, we were able to recruit some of the most respected urologic surgeons to contribute to the volume. Over the years, that tradition has continued, and I am forever grateful to all of my colleagues who have given of their time, talent, and expertise to the several iterations of this book.

Having observed my 81st birthday and retired from active clinical practice, I recognize that the time has come to pass the responsibility to others, and I happily do so. Two friends—Sam D. Graham Jr., MD, former Chairman of Urology at Emory University and former Director of the Johns Cancer Center in Richmond, Virginia, and Thomas E. Keane, MD, Chairman of Urology at the Medical University of South Carolina, Charleston—have already demonstrated their proficiency in co-editing previous editions. Both Dr. Graham and Dr. Keane are products of the Duke system, as I am.

As our French friends say, "Vive urologie!"

James F. Glenn, BA, MD, DSc, FACS, FRCS

CONTENTS

Editors
Contributors
Remembrances
Preface

SECTION I

ADRENAL, RENAL, URETER, PELVIS

Jerome P. Richie

1 Anatomy of the Adrenal Glands, Kidney, Ureter, and Pelvis
Kristin C. Turza and Sam D. Graham, Jr.

2 Open Partial Nephrectomy
Paul Russo, Roy Mano, and Simon Kimm

3 Radical Nephrectomy
Chad R. Ritch, Sam S. Chang, and Michael S. Cookson

4 Intracaval Tumors
William C. Faust and John A. Libertino

5 Donor Nephrectomy: Laparoscopic Techniques
Jim C. Hu and Eric G. Treat

6 Laparoscopic/Robotic Nephrectomy and Partial Nephrectomy
Jean-Christophe Bernhard, Charles Metcalfe, and Inderbir S. Gill

7 Minimally Invasive Nephroureterectomy
Alon Z. Weizer and Jeffrey S. Montgomery

8 Laparoscopic Renal Procedures: Renal Cystectomy, Biopsy, and Nephropexy
Michael Maddox and Benjamin R. Lee

9 Laparoscopic Ablation of Small Renal Masses
Daniel Ramirez and Jeffrey A. Cadeddu

10 Laparoscopic and Robotically Assisted Pyeloplasty in Adults
J. Stuart Wolf, Jr.

11 Laparoscopic Adrenalectomy
Arvin K. George and Louis R. Kavoussi

12 Renal Trauma
Jill C. Buckley and Jack W. McAninch

13 Renal Transplantation
John M. Barry

14 Ureteric Complications Following Kidney Transplantation
H. Albin Gritsch and Eric G. Treat

15 Renal Autotransplantation
Venkatesh Krishnamurthi and David A. Goldfarb

16 Miscellaneous Laparoscopic Urologic Procedures: Lymphoceles, Calculus, Varicocele, Ureterolysis
Sri Sivalingam, Sean P. Hedican, and Stephen Y. Nakada

SECTION II
BLADDER

Stephen J. Savage

17 Anatomy of the Bladder
Clinton W. Collins and Adam P. Klausner

18 Simple and Partial Cystectomy
Ryan S. Levey and Jonathan C. Picard

19 Radical Cystectomy in Men
Mohamed A. Ghoneim and Ahmed M. Harraz

20 Radical Cystectomy in Women
Miriam Hadj-Moussa, Joanne Lundgren, Cheryl T. Lee, and Todd M. Morgan

21 Bladder Diverticulectomy
Sarah Fraumann Faris and Sam S. Chang

22 Bladder Augmentation
Stephen Mark

23 Management of the Distal Ureter for Nephroureterectomy
Gavin N. Wagenheim and Surena F. Matin

24 Vesicovaginal Fistula
Hajar I. Ayoub and O. Lenaine Westney

25 Intestinourinary Fistulas
Ryan L. Mori, Eric A. Klein, and Kenneth W. Angermeier

26 Vesical Trauma and Hemorrhage
Chad M. Gridley and Christopher D. McClung

27 Interstitial Cystitis/Bladder Pain Syndrome
Michael J. Ehlert and Kenneth M. Peters

28 Minimally Invasive Bladder Procedures: Radical Cystectomy, Partial Cystectomy, Urachal Excision, Diverticulectomy
Andre Luis de Castro Abreu, Sameer Chopra, and Inderbir S. Gill

SECTION III
PROSTATE

Sandip M. Prasad

29 Anatomy of the Prostate
Jonathan Paul Manley, Edward W. Rowe, and Christian Andreas Bach

30 Surgery for Benign Prostatic Obstruction
Musaab Yassin, Sandip M. Prasad, and Hashim Hashim

31 Open Radical Retropubic Prostatectomy
David Gillatt and Sandip M. Prasad

32 Radical Perineal Prostatectomy
Sam D. Graham, Jr. and Thomas E. Keane

33 Robotically Assisted Laparoscopic Radical Prostatectomy
Sandip M. Prasad, David Gillatt, and Magnus Annerstedt

34 Brachytherapy for Localized Prostate Cancer
Eva Marie Suarez, Harry S. Clarke, and David T. Marshall

35 Imaging, Innovation, and Novel Therapies
Andrew D. Hardie, G. Joel DeCastro, and Sandip M. Prasad

SECTION IV
URETHRA

Eric S. Rovner

36 Anatomy of the Urethra
Lawrence M. Dagrosa and E. Ann Gormley

37 Female Urethral Reconstruction for Fistula and Female Urethral Diverticulum
Ahmed M. El-Zawahry and Eric S. Rovner

38 Surgical Management of the Incompetent Bladder Outlet in the Patient with a Neurogenic Bladder
Teresa L. Danforth and David A. Ginsberg

39 Anterior Urethral Stricture Disease
Hunter Wessells

40 Surgery for Urethral Trauma Including Urethral Disruption
Timothy J. Tausch, Jay Simhan, and Allen F. Morey

41 Carcinoma of the Urethra (Male and Female)
Eugene J. Pietzak and Thomas J. Guzzo

42 Injectable Therapies for Incontinence in Women
Stephen Mock, Melissa R. Kaufman, W. Stuart Reynolds, and Roger R. Dmochowski

43 Urethral Slings
Alex Gomelsky

44 Abdominal Retropubic Approaches for Female Incontinence
Leslie M. Rickey

45 The Artificial Urinary Sphincter
Angelo E. Gousse, Hari S. G. R. Tunuguntla, Neal Patel, and Izak Faiena

46 The Male Sling for Postprostatectomy Incontinence: Current Concepts and Controversies
Ying H. Jura and Craig V. Comiter

47 Sacral Neuromodulation
Christopher F. Tenggardjaja and Sandip Vasavada

48 Surgical Treatment of Pelvic Organ Prolapse
Ariana L. Smith, Polina Reyblat, and Ja-Hong Kim

SECTION V
TESTIS, EPIDIDYMIS, VAS DEFERENS, AND SEMINAL VESICLES

Marc Goldstein

49 Anatomy of the Epididymis, Vas Deferens, and Seminal Vesicle
Akanksha Mehta

50 Seminal Vesicle and Ejaculatory Duct Surgery
Brooke A. Harnisch and Jay I. Sandlow

51 Vasectomy
Douglas G. Stein

52 Vasovasostomy and Vasoepididymostomy

Matthew Wosnitzer and Marc Goldstein
53 Microsurgical Varicocelectomy
Marc Goldstein
54 Epididymectomy
Khalid Alrabeeah and Peter Chan
55 Ejaculation Induction Procedures
Darius A. Paduch, Lindsay Dow, and Robert John Lischer
56 Anatomy of the Testis
Mark Sigman
57 Sperm Retrieval Techniques
Kelly A. Chiles and Peter N. Schlegel
58 Simple Orchiectomy
Jonathan L. Silberstein
59 Radical Inguinal Orchiectomy
Daniel J. Lee and Douglas S. Scherr
60 Organ-Preserving Surgery in Testicular Tumors
Axel Heidenreich
61 Retroperitoneal Lymph Node Dissection
Simon Kimm and Joel Sheinfeld
62 Torsion of the Testicle
Diana K. Bowen and Robert E. Brannigan
63 Scrotal Trauma and Reconstruction
K. Jeff Carney and Gerald H. Jordan

SECTION VI

PENIS AND SCROTUM

67 Surgical Treatment of Peyronie’s Disease
Brooke Edwards and Ramón Virasoro
68 Priapism
Arthur L. Burnett II and Nate Readal
69 Penile Prosthesis Implantation
Robert M. Coward and Culley C. Carson
70 Penile Vascular Surgery
Jack M. Zuckerman and Kurt McCammon
71 Penile Trauma
Judith C. Hagedorn and Daniel I. Rosenstein
72 Penile Replantation
Jairam R. Eswara and Steven B. Brandes
73 Hydrocele and Spermatocele

Ali A. Dabaja and Cigdem Tanrikut

74 Congenital Curvature
Erik Grossgold and Jeremy Tonkin

75 Ileal Conduit Urinary Diversion
Samuel C. Haywood and Eric A. Klein

SECTION VII

URINARY DIVERSION

Urs E. Studer

76 Transverse Colonic Conduit
Michael Rink and Margit Fisch

77 Managing the Patient with Orthotopic Bladder Substitution
Gianluca Giannarini and Urs E. Studer

78 Orthotopic Urinary Diversion Using an Ileal Low-Pressure Reservoir with an Afferent Tubular Segment
Fiona Burkhard and Urs E. Studer

79 Ileal Neobladder
Richard E. Hautmann

80 Colonic Orthotopic Bladder Substitution
Joachim W. Thüroff and Ludger Franzaring

81 Continent Catheterizable Reservoir Made from Ileum
Hassan Abol-Enein and Mohamed A. Ghoneim

82 Continent Catheterizable Reservoir Made from Colon
Hubertus Riedmiller, Elmar W. Gerharz, and Arkadius Kocot

83 Ureterosigmoidostomy and Mainz Pouch II
Michael Rink and Margit Fisch

84 Palliative Urinary Diversion
Stephan Degener, Burkhard Ubrig, and Stephan Roth

SECTION VIII

PEDIATRICS

H. Gil Rushton

85 Wilms Tumor
Mark D. Tyson and Michael L. Ritchey

86 Renal Fusion and Ectopia
Ross M. Decter and Amy S. Burns

87 Transureteroureterostomy
Aaron D. Martin and H. Gil Rushton

88 Pyeloplasty
Megan S. Schober, Kevin M. Feber, and Evan J. Kass

89 Megaureter
Christopher J. Long, J. Christopher Austin, and Douglas A. Canning

90 Prune Belly (Triad) Syndrome
David B. Joseph

91 Childhood Rhabdomyosarcoma
Frank J. Penna and Martin A. Koyle

92 Vesicoureteral Reflux
Mark R. Zaontz and Christopher J. Long

93 Endoscopic Treatment of Vesicoureteral Reflux
Angela M. Arlen and Andrew J. Kirsch

94 Ureteroceles
Richard N. Yu, Chester J. Koh, and David A. Diamond

95 Urachal Anomalies and Related Umbilical Disorders
Leslie T. McQuiston and Anthony A. Caldamone

96 Vesical Neck Reconstruction
John C. Pope IV and John H. Makari

97 Surgery for Posterior Urethral Valves
Rosalia Misseri and Kenneth I. Glassberg

98 Hypospadias
Laurence S. Baskin

99 Complete Primary Repair for Exstrophy
Richard W. Grady

100 Exstrophy and Epispadias—Modern Staged Approach
Ezekiel E. Young, John P. Gearhart, and Brian M. Inoyuye

101 Pediatric Cryptorchidism, Hydroceles, and Hernias
Angela M. Arlen and Christopher S. Cooper

102 Pediatric Laparoscopic and Robotic Pyeloplasty
Pasquale Casale and Walid A. Farhat

103 Pediatric Laparoscopic Nephrectomy and Partial Nephrectomy
Glenn M. Cannon, Jr. and Richard S. Lee

104 Urogenital Sinus and Cloacal Anomalies
Richard C. Rink, Jeffrey A. Leslie, and Martin Kaefer

105 Surgery to Correct Ambiguous Genitalia (46XX Disorder of Sexual Development)
Anthony J. Casale

106 Circumcision, Concealed Penis, and Scrotal Abnormalities
Irene M. McAleer and George W. Kaplan

107 Augmentation Cystoplasty in Children
Nora G. Lee and Hans G. Pohl

108 The Mitrofanoff and Malone Antegrade Continence Enema Procedures in Pediatric Urinary Tract Reconstruction
Mark P. Cain

SECTION I ■ ADRENAL, RENAL, URETER, PELVIS

Section Editor: JEROME P. RICHIE

CHAPTER 1 ■ ANATOMY OF THE ADRENAL GLANDS, KIDNEY, URETER, AND PELVIS

KRISTIN C. TURZA AND SAM D. GRAHAM, JR.

ADRENAL

The adrenal glands are paired and located high in the retroperitoneum, on the anterior craniomedial aspect of the kidney (Figs. 1.1 to 1.3). Distinct in appearance from the surrounding fat and pancreas by their golden color, the adrenals each weigh approximately 4 to 5 g. Glandular weight and size may change with prolonged illness or prolonged adrenocorticotropic hormone (ACTH) stimulation. The atrophic gland is thin and pale compared to the normal or hyperplastic gland. The left gland has a semicircular or crescent shape. The right gland has an inverted pyramidal or V shape. The adrenal gland consists of the cortex and medulla and arise from mesodermal (cortex) and ectodermal (medulla) elements in the medial aspect of the coelomic cavity.

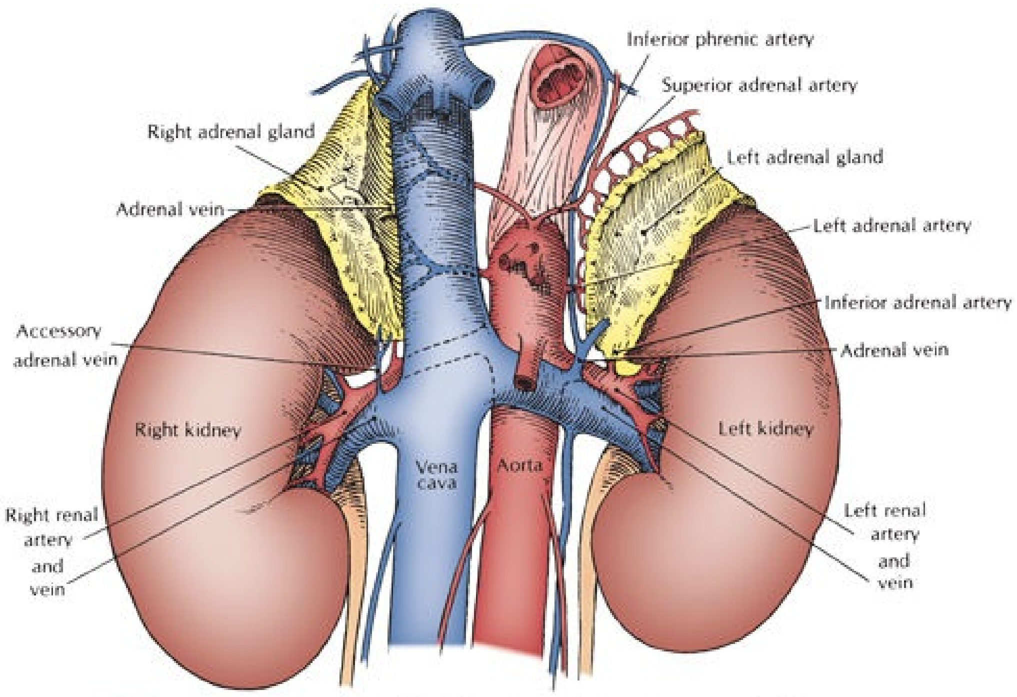

FIGURE 1.1 The anatomic relationship of the adrenal glands to the aorta and inferior vena cava. Multiple arterial vessels entering the glands indicate the rich arterial supply, while a single central adrenal vein illustrates the limited and relatively constant venous damage.

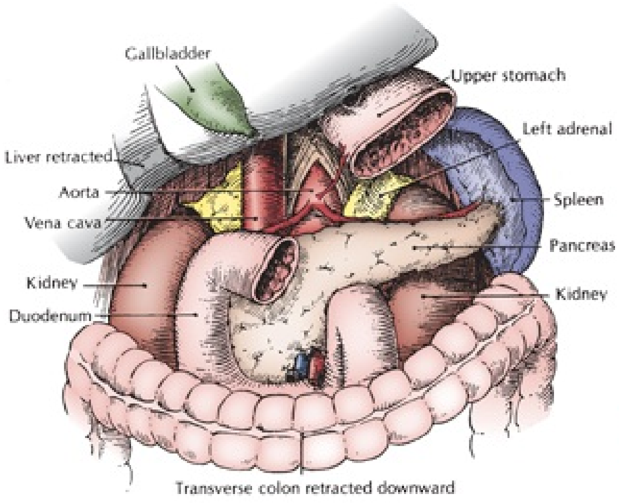

FIGURE 1.2 An anterior view of the abdomen illustrating the anatomic relationship of the adrenal glands to the surrounding gastrointestinal tract and organs.

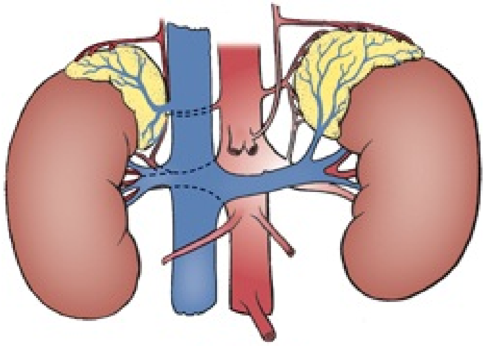

FIGURE 1.3

Embryology

The cortex and medulla each have a unique embryologic derivation. The coelomic mesoderm, specifically the dorsal cells of the blastema cord at the medial aspect of the mesonephric bodies, gives rise to the cortex. Of note, the ventral cells of these bodies are the origin of the interstitial cells of the testis or the theca cells of the ovary. The medulla is derived from neural crest cells, which migrate from the same primordial neural crest giving rise to the sympathetic chain. The 8-week embryo has massive adrenals, approximately the size of the kidney, and they remain enlarged and very vascular until birth. Rapid regression occurs in the adrenal size during the first month. The large adrenal size with hypervascularity may predispose to adrenal hemorrhage in the newborn as well as misdiagnosis for Wilms tumor or neuroblastoma. The medullary tissue within the gland imparts a unique tripartite structure of the head (most medial), body, and tail (most lateral). Each adrenal gland resides within the Gerota fascia with the kidney. However, in the case of renal ectopy, the adrenal remains in its natural position.

Ectopic adrenal tissues may develop in certain locations of the body. Although rare, they may undergo neoplastic changes or hyperplasia. Ectopic adrenal tissues in most cases consist of cortex only; rarely do they contain cortex and medulla. The embryologic relationship in the urogenital ridge predisposes to adrenal ectopy in the retroperitoneum, the testis, the spermatic cord, and the region of the celiac ganglion.

Vascular Anatomy

The arterial supply remains variable; the main sources include primarily the branches from the aorta, inferior phrenic artery, and renal artery. The multiple small-caliber arterial branches must be appreciated for hemostasis during surgery. Controlling the venous drainage, although less variable, can be challenging, especially when operating on large adrenal masses, which may obscure visualization. The right adrenal vein is short and empties directly into the inferior vena cava (IVC) in its most posterolateral aspect. Bleeding from this site can be profuse and even life-threatening if not identified and controlled immediately. The left adrenal vein comparatively is smaller than the right and exits anteroinferiorly, draining into the ipsilateral renal vein.

Contiguous Structures

Preventing intraoperative injury to contiguous structures rests on the surgeon having a thorough knowledge of the anatomic relationships of the adrenal gland (see Fig. 1.2). The right adrenal gland lies superior to the upper pole of the right kidney, posterolateral to the IVC. Dissection of the right adrenal gland is limited medially by the duodenum and superiorly by the right hepatic lobe. Access to the right adrenal gland is more easily obtained by entering the retroperitoneum behind the liver. The right hepatic lobe can be mobilized from the colon and diaphragm by transecting the triangular, coronary, and hepatocolic ligaments, allowing visualization of the right adrenal gland just superior to the upper pole of the right kidney. Mobilization of the duodenum is also required for easier identification of the right adrenal vein. This step is critical when resecting large pheochromocytomas because early access to the adrenal vein is essential. Using the Kocher maneuver, the duodenum can be retracted medially, enabling access to the IVC and thorough dissection of the right adrenal vein. With the right adrenal vein controlled, an avascular plane is developed laterally on the gland resulting in quick and bloodless removal. The main arterial trunks and small-caliber arteries can be easily controlled with electrocautery and/or surgical clips.

The left adrenal gland is usually more medial than the right, and it lies on the upper pole of the left kidney, just lateral to the aorta. The left adrenal gland lies in close contact with the spleen and stomach, and it is crossed on its anteroinferior surface by the body of the pancreas and splenic artery and vein. A special technical effort must be made to prevent inadvertent injury to the tail of the pancreas and/or capsule of the spleen. Releasing the splenocolic ligament allows free mobilization of the spleen, and gentle blunt dissection allows medial mobilization of the left abdominal viscera and adequate exposure of the left adrenal gland. The left adrenal vein is usually isolated in the anteroinferior aspect of the gland, and control of this vein is usually less of a problem, with minimal blood loss (see Fig. 1.3). The lowest extent of this gland is close to the renal vessel, which remains at risk of injury during adrenalectomy.

KIDNEY

The abdominal wall is composed of three layers of muscle and fascia that are derived from the same embryonic muscle sheets as the intercostal muscles. Each muscle is invested by its own layer of deep fascia and innervated by intercostal nerves. The external oblique fibers are oriented anteriorly and inferiorly, attaching posteriorly to the iliac crest, and the anterior fibers attach to the linea alba in the midline (Fig. 1.4A). The internal oblique fibers are oriented anteriorly and superiorly (Fig. 1.4B). Posteriorly, the internal oblique fibers attach to the lower four ribs and anteriorly they attach to the linea alba. In the upper abdomen, the internal oblique fascia splits to enclose the rectus muscle, whereas inferiorly, the fascia only covers the rectus muscle anteriorly. The ilioinguinal and iliohypogastric nerves are found in the internal oblique fascia anterior to the internal oblique muscle. The transversus abdominis are horizontally oriented fibers that attach to the linea alba (Fig. 1.4C).

The ribs are supported by the intercostal muscles and fascia, as well as the costovertebral (costotransverse) ligament, which must be divided if the rib is to be retracted inferiorly (Fig. 1.5).

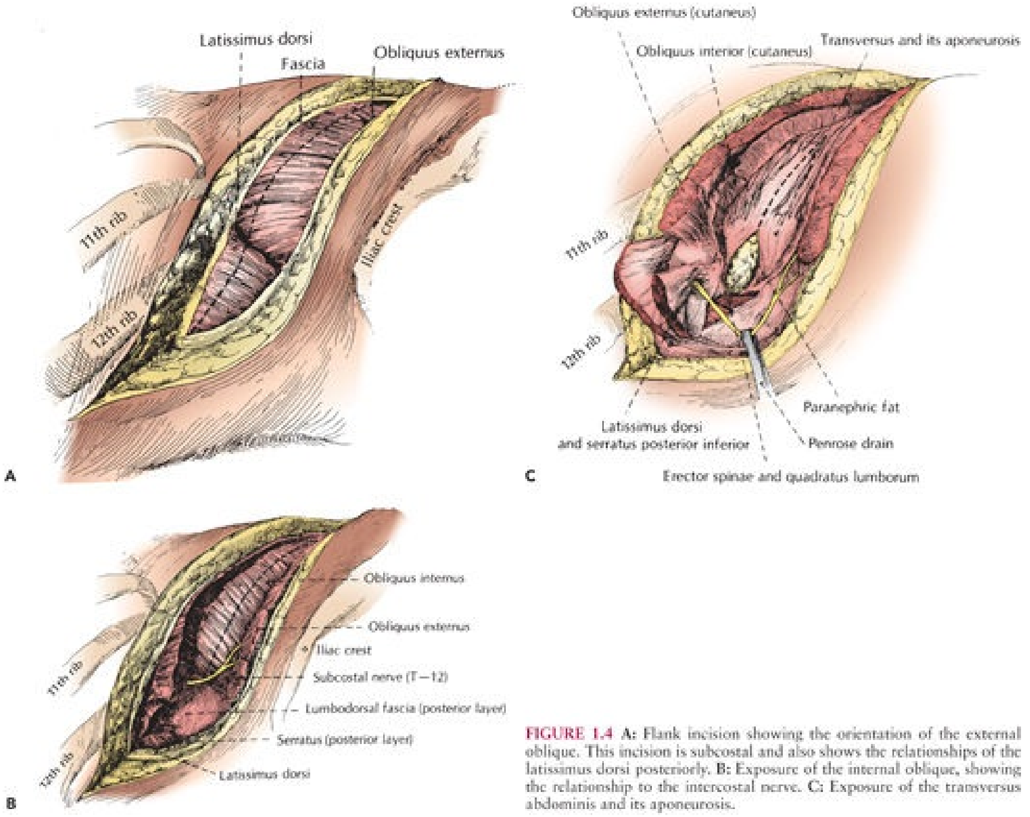

FIGURE 1.4 **A:** Flank incision showing the orientation of the external oblique. This incision is subcostal and also shows the relationships of the latissimus dorsi posteriorly. **B:** Exposure of the internal oblique, showing the relationship to the intercostal nerve. **C:** Exposure of the transversus abdominis and its aponeurosis.

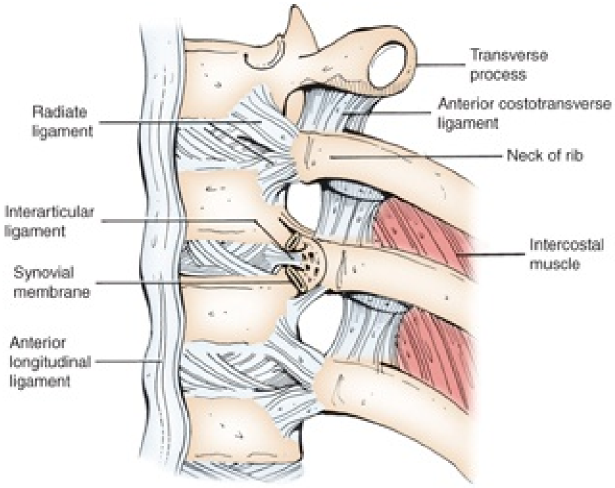

FIGURE 1.5 Costovertebral (costotransverse) ligaments extend from the transverse process of the vertebra immediately above the rib to the neck of the rib. In order to gain exposure during a thoracolumbar or supracostal approach, this must be divided to allow the rib to rotate inferiorly.

The kidneys are located on either side of the vertebral column in the lumbar fossa of the retroperitoneum and vary in length in adults from 11 to 14 cm, or from approximately 3.0 to 4.5 times the height of the second lumbar vertebrae (see Fig. 1.1). A normal adult kidney weighs 135 to 140 g. The right kidney tends to be lower in the retroperitoneum than the left because of the liver's position. The parenchyma of the kidney is covered by a thin transparent capsule, which in turn is covered by a layer of perinephric fat enclosed in a distinct layer of fascia (Gerota fascia) (Fig. 1.6). The capsule is attached to Gerota fascia by fibrous trabeculae (1). Gerota fascia is completely fused superiorly and laterally, but it is open inferiorly and to some extent medially, where it is adherent to the adventitia of the renal vessels, aorta, and IVC. Gerota fascia extends above the kidney to form a special compartment for the adrenal gland (2). Posteriorly, Gerota fascia is connected to the sheaths of the psoas and quadratus lumborum muscles by connective tissue septae. Anteriorly, Gerota fascia is closely applied to the peritoneum. On the left, the hilum of the spleen is attached to the ventral aspect of the kidney by a double layer of peritoneum known as the splenorenal ligament (2).

The kidney contains a cortex and medulla. The cortex is the site of ultrafiltration and erythropoietin production, and it contains renal columns (columns of Bertin) and corpuscles (composed of the glomerulus and Bowman capsule). Columns of Bertin contain renal vessels traversing to the peripheral cortex. This anatomic feature is important during percutaneous collecting system access performed via a posterolateral needle approach into the posterior calyx along Brödel line (avascular plane between the posterior and anterior arterial divisions) through a renal pyramid to avoid potential vascular injury associated with sticking the columns (3). The medulla is not a contiguous layer within the kidney; instead, it is divided into pyramids, consisting of tubules that transport urine from the cortex to the calyces. Nephrons are the basic functional unit of the kidney and consist of a glomerulus and tubules (proximal, distal, and loop of Henle). The nephrons drain into collecting ducts and coalesce ultimately in the ureter.

Vascular Anatomy

The main renal arteries branch from the lateral aorta at approximately L2. Generally, the renal arteries divide into segmental branches at the junction of the middle and final third of their course. A single left artery most commonly lies dorsal to the renal vein, and a long right renal artery lies dorsal to the vena cava and renal vein. Up to 35% of kidneys have an accessory renal artery, with 1.5% having more than one accessory artery (2). As the renal artery approaches the hilum, it has two branches, the inferior suprarenal (adrenal) and the ureteric arteries (Fig. 1.6). At the hilus, the main renal artery divides into an anterior and posterior branch, which further divide into segmental arteries. The kidney can be divided into four segments based on the arterial supply (Fig. 1.7). Both the apical and basilar segmental arteries supply each respective pole of the kidney anteriorly and posteriorly. The largest segment is the anterior segment, which is supplied by two segmental arteries and extends posteriorly to the avascular plane where it meets the posterior segment (4).

Peritoneum

FIGURE 1.6 Retroperitoneal anatomy showing Gerota fascia in sagittal section.

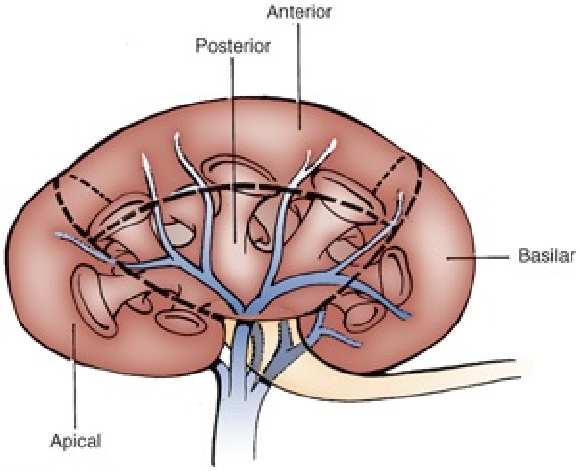

FIGURE 1.7 Segmental anatomy of the kidney. The relatively avascular plane between the anterior and posterior segments is the line of Brödel. In general, calyces tend to extend from the renal pelvis to the central mass of the segment they supply.

The renal veins directly join the vena cava. The right renal vein is usually less than one-half the length of the left renal vein and has no significant branches. The left renal vein, however, is usually joined by the adrenal and inferior phrenic vein superiorly, the gonadal vein inferiorly, and frequently by lumbar vein(s) posteriorly (Fig. 1.8). These collaterals are of great importance in patients in whom the vena caval ligation or resection is contemplated.

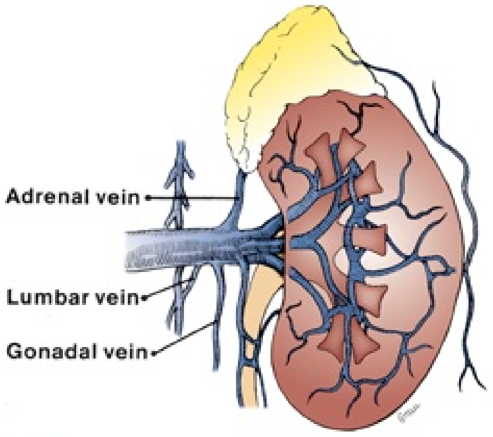

FIGURE 1.8 The complex and varied anatomy of the left renal vein. Note that there may be one or even two lumbar veins from the renal vein posteriorly, allowing alternative venous flow if the vena cava is occluded.

The renal vein is usually the most anterior structure in the renal hilum. Posterior to the vein is the renal artery, and the most posterior structure in the hilum is the renal pelvis. The hilum is filled with fibrofatty tissue that can usually be easily dissected from these structures to allow access into the renal sinus (Fig. 1.9).

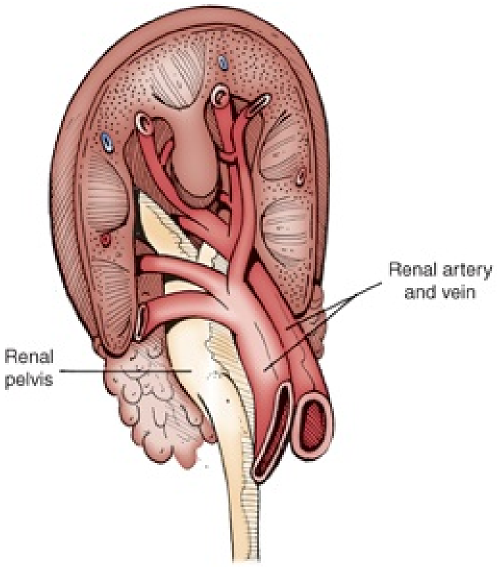

FIGURE 1.9 Transverse section of kidney showing relative anatomy of vascular structures in the renal hilum.

Lymphatic Anatomy

Parenchymal and capsular lymphatics merge and drain into the right lumbar or para-aortic chains, respectively. These lymphatics become part of the cisterna chylae superior to the renal artery.

Nervous Innervation

The kidney is innervated by sympathetic preganglionic fibers from T8 to L1 with subsequent course to the celiac and aorticorenal ganglia. An autonomic plexus surrounds the renal artery and contains postganglionic fibers. Sympathetic efferent fibers reach renal vasculature, tubules, and juxtaglomerular cells. Sympathetic stimulation decreases renal blood flow and glomerular filtration and increases sodium and water absorption and renin production. Fibers from the vagus nerve constitute the parasympathetic innervation and terminate in the same autonomic plexus. Parasympathetic stimulation results in vasodilation.

Contiguous Structures (Fig. 1.10)

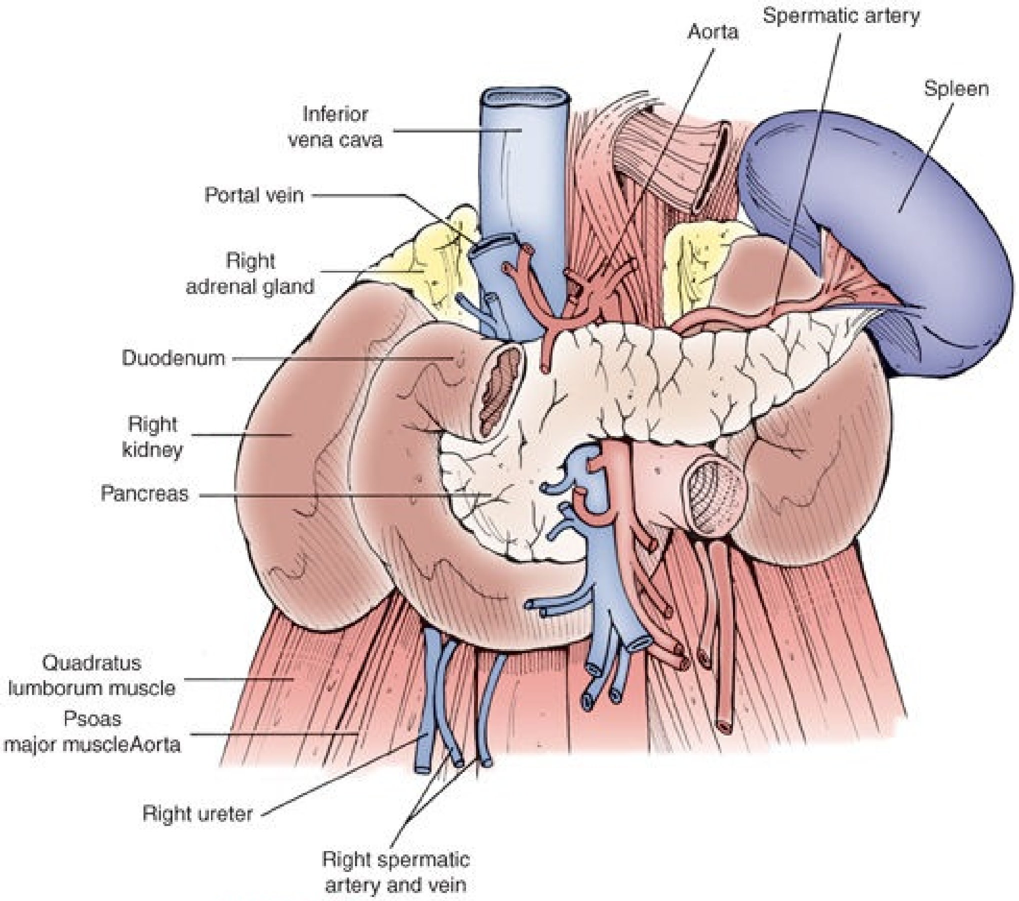

FIGURE 1.10 The kidney in relation to contiguous structures.

Posterior to the kidney lie the psoas major and quadratus lumborum muscles. Posteriorly and superiorly, the upper pole of each kidney is in contact with the diaphragm. The pleura is also adjacent to the upper poles of both kidneys, usually extending down below the level of the 12th rib posteriorly and to the 11th rib anteriorly (1). This is important to bear in mind intraoperatively or during percutaneous procedures because violating the pleural space is a potential complication. With respect to their rotational axis, the lower pole of both kidneys is anteriorly displaced and located lateral to the upper pole.

Embryologically, when the gut rotates, this leaves the posterior parietal peritoneum covering the upper three-fourths of the right kidney, which is directly related to the hepatorenal pouch of Morrison. The duodenum is fixed to the original peritoneal covering of the lower pole of the right kidney by fusion of the embryonic dorsal mesentery to the posterior parietal peritoneum (2). On the left, the rotation of the foregut causes a fusion of the embryonic mesogastrium with the original peritoneal covering of the upper anterior kidney, thereby causing the relationship of the left kidney to the omental bursa (2). The midportion of the left kidney loses its contact with the peritoneum due to growth of the tail of the pancreas.

Superiorly, the anteromedial surface of the right kidney is in contact with the right adrenal gland. The liver overlies the anterior two-thirds of the right kidney, and the hepatic flexure of the colon overlies the lower one-third of the right kidney. The second portion of the duodenum overlies the renal hilum. In >90% of patients, the right kidney is lower than the left (2).

The medial surface of the left kidney is also in contact with the left adrenal gland. Other structures anterior and in close approximation to the left kidney are the spleen, the tail of the pancreas, the stomach, and the splenic flexure of the colon.

CHAPTER 2 OPEN PARTIAL NEPHRECTOMY

PAUL RUSSO, ROY MANO, AND SIMON KIMM

Over the last 20 years, partial nephrectomy (PN) has emerged as a critical operation for the treatment of renal cortical tumors (1). Advances in complex stone surgery (anatrophic kidney splits, hilar clamping, ice slush, collecting system repair), trauma surgery (renorrhaphy, proximal renal hilar control, vascular repair), and kidney donor transplantation (renoprotective solutions, ice slush) set the stage for the development of contemporary controlled open PN (2,3). The rapid development of the modern imaging modalities of ultrasound, computerized tomography (CT), and magnetic resonance imaging (MRI), often ordered for nonspecific abdominal or musculoskeletal complaints or during unrelated cancer care, leads to the detection of small, asymptomatic renal masses (1), which today account for 70% of all newly diagnosed renal tumors with a median tumor size of <4 cm (T1a). Approximately 20% of these tumors are benign (i.e., oncocytoma, fat poor angiomyolipoma), 25% are indolent malignancies with limited metastatic potential (i.e., papillary type 1, chromophobe, cystic renal cell carcinoma [RCC]), and 54% are the more potentially malignant clear cell carcinoma, but at the T1 size (<7 cm), metastasis would be realized in less than 10% of patients (1). These factors, which when taken together, led to the expansion of elective PN in the late 1990s (4). Once reserved only for the essential indications of tumors in an anatomically or functionally solitary kidney, today PN can effectively achieve the same local tumor control as radical nephrectomy (RN) while maximally preserving renal function and preventing or worsening preexisting chronic kidney disease (CKD) (5). Based on common preexisting medical conditions such as diabetes, hypertension, and cigarette smoking–induced vascular disease, CKD is present in up to 30% of patients with renal cortical tumors prior to operation and is associated with subsequent cardiovascular events, increased rates of hospitalization, and worse overall survival (6). The historical use of RN for all renal tumors, regardless of size, must now be considered obsolete. We have replaced the large and painful 11th rib flank incision associated with flank bulge and hernia in up to 50% of cases (7) with a mini-flank surgical incision (8,9) which, when coupled with our rapid recovery clinical pathway (10), is a highly effective approach to PN and leads to a median 2-day hospital length of stay. This approach is an excellent alternative to the expensive and technically complex minimally invasive (laparoscopic and robotic assisted laparoscopic) PN.

INDICATIONS FOR SURGERY

In the past 20 years, PN has transitioned from an operation only performed for *essential* conditions (tumor in a solitary kidney, bilateral tumors, tumor in patient with preexisting medical disease) to now include *elective* conditions (tumor in a patient with a normal contralateral kidney). Initially, elective PN was restricted to tumors of 4 cm or less (11–13), but with increasing experience, surgeons approached T1b and T2-T3a tumors (14–17) when technically feasible with similar oncologic outcomes compared to RN. With the advantage of intraoperative ultrasound (18), it is now also possible to resect impalpable endophytic, renal sinus, multifocal, and perihilar tumors which previously would have been treated only by RN.

PN may also be advocated as a salvage procedure after failed thermal ablation attempts, as "redo" procedures for recurrent renal tumors in both the sporadic and hereditary RCC setting, and uncommonly as a cytoreductive procedure in metastatic patients with a small renal tumor prior to the initiation of systemic therapy. These indications pose a greater surgical challenge than primary PN with more potential for blood loss and conversion to RN if, for technical reasons, PN cannot be executed. In essence, today, all patients with kidney tumors are scrutinized closely for consideration of PN, and only those where the majority of the kidney is replaced by tumor or those with massive tumors with regional adenopathy and/or renal vein/inferior vena cava extension will undergo RN.

ALTERNATIVE THERAPIES

Patients with small renal tumors are eligible for active surveillance, or surgery (PN or RN) by either open or minimally invasive approaches. In general, for older patients (>75 years) or those with serious medical comorbidities and a limited life expectancy, active surveillance is recommended due to the low likelihood of disease progression in the patient's lifetime and significant risks associated with surgical intervention (19,20). Active surveillance, even with small renal tumors, is more difficult to propose in young and healthy patients with a long life expectancy because on rare occasions, rapid tumor growth and metastatic disease can ensue. Thermal ablation (radiofrequency ablation [RFA], cryoablation) procedures are associated with far greater rates of persistent and recurrent disease (21), and patients deemed likely candidates for ablation are generally the same that we recommend for active surveillance.

PREOPERATIVE PLANNING AND PATIENT PREPARATION

Preoperative assessment begins with a careful history, with a special emphasis on medical comorbidities affecting the cardiovascular and renal function, and a thorough physical examination. Correctable and potentially life-threatening cardiovascular disease should be addressed (i.e., carotid endarterectomy, coronary revascularization) prior to PN. A baseline calculation of estimated glomerular filtration rate (eGFR) should be done using the following web link for the MDRD or CKD-EPI equation (http://www.nephron.com/MDRD_GFR.cgi). Preoperative renal protocol CT imaging must have noncontrast views in search of microscopic fat or pseudo enhancement with volume averaging to exclude benign angiomyolipoma and hemorrhagic cyst, respectively, which would warrant nonoperative management (22). A contrast-enhanced study (MRI, CT, or renal perfusion/excretion nuclear scan) is required to document bilateral renal function. Renal ultrasound with Doppler imaging is an effective way to assess the lesion for vascular flow (23), can fully characterize cystic lesions, and serves as a template for intraoperative ultrasound in order to locate small, endophytic, impalpable subcortical renal tumors (18). In general, preoperative renal tumor biopsy is considered only when this information could dramatically change management if, for example, an infiltrative mass is identified and a renal lymphoma is suspected.

We conduct in-depth discussions describing the anticipated degree of surgical difficulty in completing an anticipated PN, the renal functional result, and a full description of potential complications including bleeding, infection, urinary fistula, the need for a prolonged perinephric drainage, and conversion to RN, if for technical reasons, a PN cannot be executed. A preoperative nomogram can reassure patients with small renal masses that a favorable long-term prognosis is achievable with an effective resection (24). A nephrometry scoring system (R.E.N.A.L.) can categorize the degree of surgical difficulty for a planned PN (25). The likelihood of a subsequent ipsilateral (<5%) or contralateral (<5%) tumor recurrence in a patient's lifetime and the need for lifetime kidney imaging is also discussed.

The anticipated length of the hospital stay and postoperative recovery are described. The importance of walking on the first postoperative day (14 laps around the floor is a mile) to prevent deep venous thrombosis and deep breathing with incentive spirometry to prevent atelectasis and pneumonia is stressed. We rapidly advance patients to a regular diet with conversion to oral pain medication and continued vigorous walking by the second day. The vast majority of patients are discharged on the second postoperative day (10). This regimen of vigorous walking continues at home with a switch to over-the-counter pain medications as soon as possible. We encourage three protein-rich meals per day to maximize healing and continued walking at least 30 minutes twice per day with avoidance of heavy lifting for 3 months.

SURGICAL TECHNIQUE

Supra-11th Rib Mini-flank Surgical Incision

The traditional 11th rib flank incision provided wide exposure, but patients complained of significant postoperative pain, prolonged recovery, and for up to 50%, an uncomfortable and unsightly flank bulge usually caused by denervated muscle often with associated paresthesia and neuralgic pain (7). For the surgeon, rib resection and closure of this large incision also added significant operating time. We developed the "mini-flank" supra-11th rib incision as an effective alternative to standard flank incision or laparoscopic PN (8,9).

The patient is placed in the standard flank position (Fig. 2.1). An 8- to 10-cm extraperitoneal incision is made between the bed of the 10th and 11th ribs (Fig. 2.2). Intercostal ligaments are sharply divided, allowing for further separation of the ribs and rapid exposure to the retroperitoneum without rib resection (Fig. 2.3). The latissimus dorsi, external oblique, and internal oblique muscles are transected, and the transversus abdominis is divided in the direction of its fibers while preserving the intercostal neurovascular bundle. Using blunt dissection, the peritoneal cavity is mobilized medially, the perinephric soft tissues laterally, and the diaphragmatic fibers and pleural superiorly. A small incision in the plane between the soft tissues overlying the psoas muscle (Fig. 2.4A) and Gerota fascia is then bluntly developed, creating a flap of peritoneum (Fig. 2.4B) that is retracted medially and exposes the kidney, ureter, and ipsilateral great vessel (vena cava on the right, aorta on the left). The Bookwalter retractor (Codman and Shurtleff, Inc, Raynham, Massachusetts) is placed using the bladder blade to retract the 10th rib and peritoneal flap superiorly and medially which allows the kidney and perinephric soft tissues to move caudally into the wound. The short right-angle blade retracts the 11th rib laterally. Following blunt dissection of the intestinal contents, deeper malleable blades are placed to expose the great vessels by retracting intestines medially (Fig. 2.5). The ureter is isolated with a yellow vessel loop (Fig. 2.6A), and careful division of lymphatic channels and soft tissues allow isolation of the renal artery and vein with red and blue vessel loops, respectively (Fig. 2.6B). For tumors located in a polar position, once the renal hilar vessels are isolated, it is not necessary to mobilize the opposite pole from the surrounding soft tissues (and adrenal for upper pole). We do not perform mass renal pedicle clamping with vascular clamps during cold ischemia. On the left side, the gonadal and adrenal veins are usually ligated and divided to liberate the tethered renal vein to allow enhanced upward lifting of the kidney and improved access to the renal artery. The upward mobilization of the kidney decreases venous bleeding later during the tumor resection and facilitates identification and repair of rents in renal sinus veins (Fig. 2.7). The upper pole of the kidney is separated from the adrenal using blunt dissection, and perforating vessels are ligated and divided with the LigaSure (Covidien, Mansfield, Massachusetts).

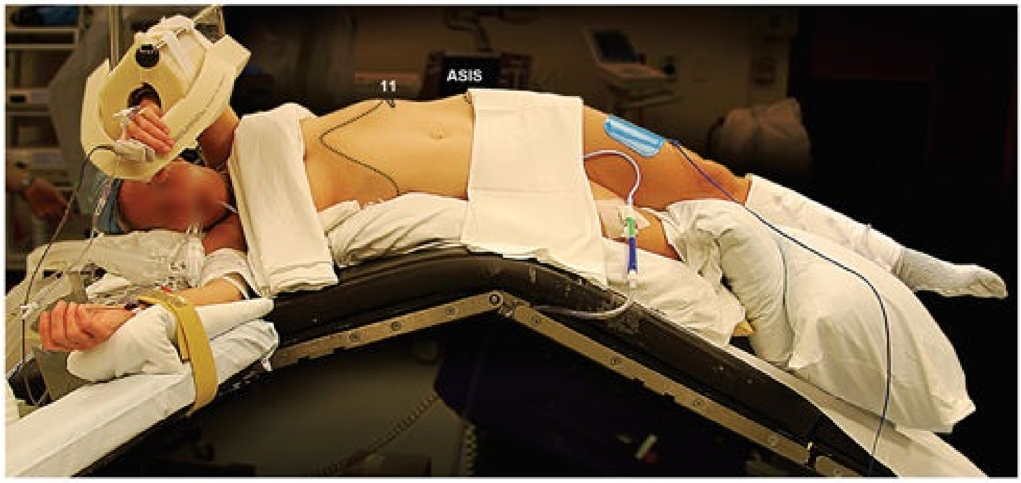

FIGURE 2.1 Patient positioning. The patient is carefully positioned in standard flank position, using approximately 50 to 60 degrees of flank elevation. The patient should be centered on the operating table with the upper brim of the iliac crest below the table break to avoid direct gluteal pressure. An axillary roll is placed. A beanbag is used to hold the patient in position. After rolling to the flank position, the legs are flexed and separated by two pillows, avoiding adduction strain on the upside leg. The leg in contact with the table is flexed to a greater degree with additional padding placed at the hip, knee, and ankle pressure zones. The downside arm is cushioned on an armboard with the elbow flexed. The upside arm is suspended in a foam cradle in neutral position. The patient is secured to the table at the hip with 2-inch fabric tape. Padding is used on the skin such that the adhesive surface of the tape does not come in contact with the skin. A padded safety strap is used to further secure the lower extremities. ASIS, anterior superior iliac spine.

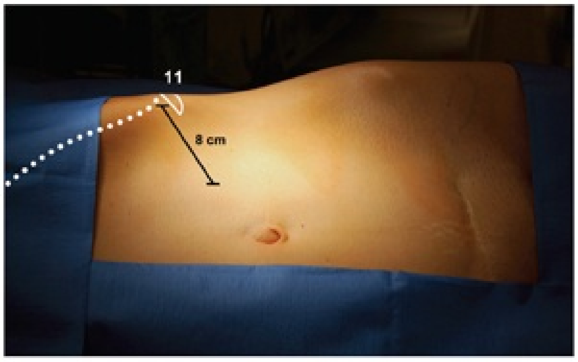

FIGURE 2.2 Mini-flank incision. An 8- to 10-cm extraperitoneal incision is made between the bed of the 10th and 11th ribs. *White broken line*, lower boundaries of the thoracic cage.

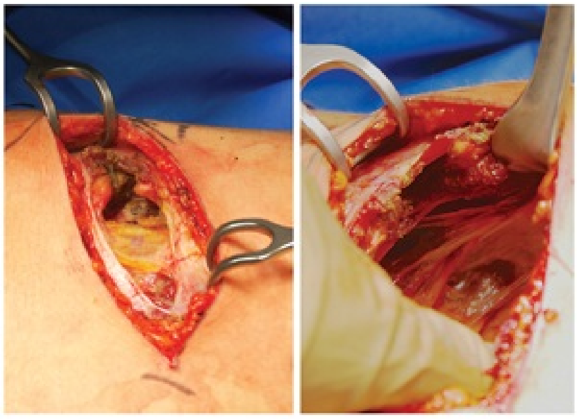

FIGURE 2.3 Intercostal ligaments are cut, allowing more space between ribs and easy access to retroperitoneum. The latissimus dorsi, external oblique, and internal oblique muscles are transected, and the transversus abdominus is divided in the direction of its fibers.

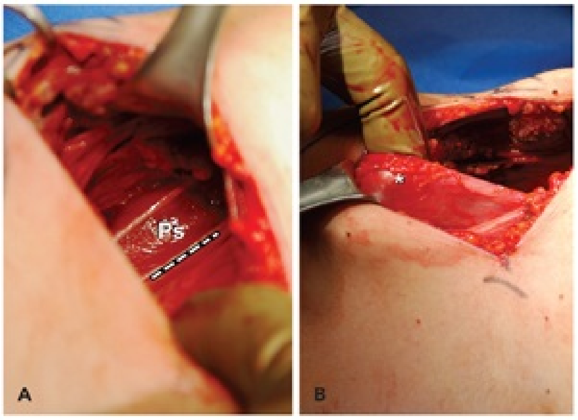

FIGURE 2.4 **A:** A small incision is made in the soft tissues posterior to Gerota fascia which overly the psoas muscle (*Ps*). **B:** Gerota fascia is then bluntly developed and gathered with the peritoneum to create a flap of tissue (*asterisk*) that is retracted medially for exposure.

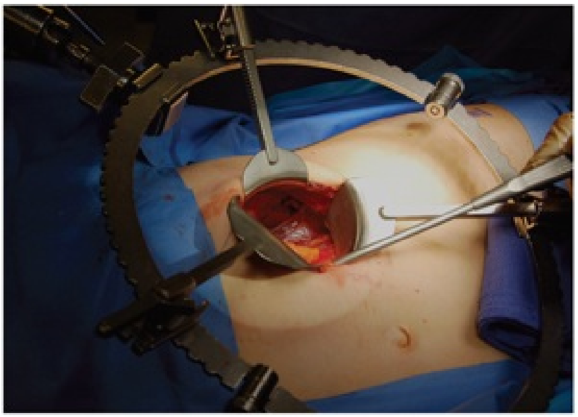

FIGURE 2.5 The Bookwalter retractor is deployed to assist in exposure. Superior and medial retraction of the 10th rib and peritoneal flap is provided by the bladder blade. The short right-angle blade provides lateral retraction of the 11th rib. Right-angle or malleable blades provide inferior and medial retraction.

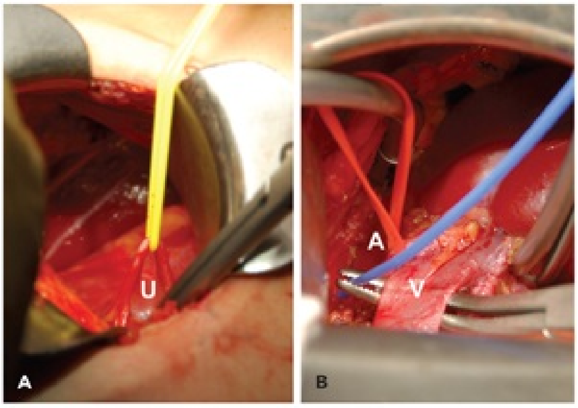

FIGURE 2.6 **A:** The ureter (*U*) is isolated with a yellow vessel loop. **B:** The renal artery (*A*) and renal vein (*V*) are identified and isolated.

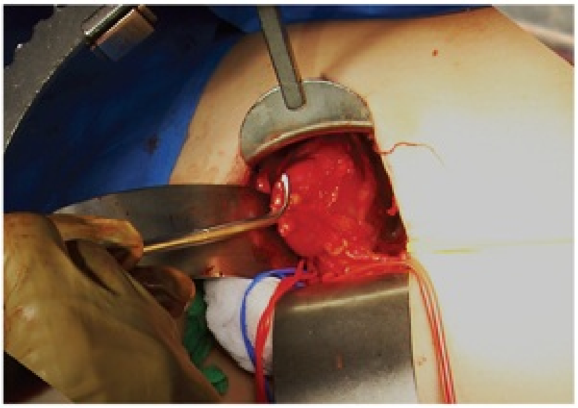

FIGURE 2.7 Upward mobilization of the kidney facilitates identification and control of the renal hilum and decreases venous bleeding during tumor resection.

Tactics for Tumor Resection during Partial Nephrectomy

Following isolation of the renal hilar vessels, careful visual and intraoperative ultrasound (Fig. 2.8) inspection of the renal surface is performed in order to confirm the location and depth of the tumor and identify any satellite lesions, or evidence of branch renal vein or collecting system tumor invasion (18). The surgeon needs to plan a resection strategy based on the location of the tumor, its depth within the kidney, and the presence of segmental arteries or arterial branches that may feed the tumor directly. If the tumor has a polar location with a segmental artery feeding that region, a bulldog clamp can be applied to the feeding artery and, if ischemia covers the tumor bearing area of the kidney, resection can proceed with this form of “regional ischemia,” whereas the rest of the kidney is normally perfused. Similarly, for a tumor that is polar in location, exophytic, and with no renal sinus extension, a Satinsky clamp can be applied to the renal cortex beneath the tumor while resection and cortical hemostasis is obtained without hilar clamping in another form of regional ischemia (Fig. 2.9). For tumors substantially involving either renal pole with sinus fat invasion, a more substantial polar PN is performed. In this setting, arteries, veins, and collecting system elements of the renal sinus will be sizeable with special care to ligate them separately and avoid large, deep bites within the renal sinus which can inadvertently fuse arteries to veins and lead to iatrogenic arteriovenous fistula and delayed bleeding events.

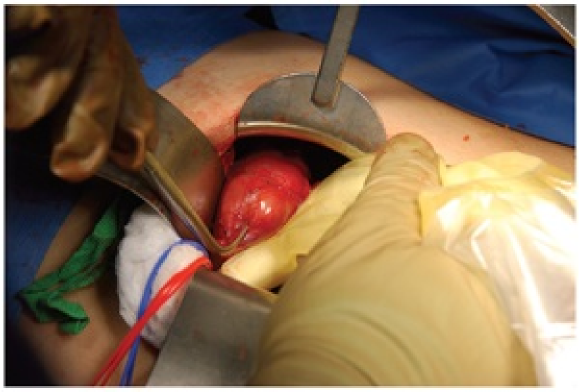

FIGURE 2.8 Intraoperative ultrasound is used to localize the tumor, assess tumor extent, and identify satellite lesions.

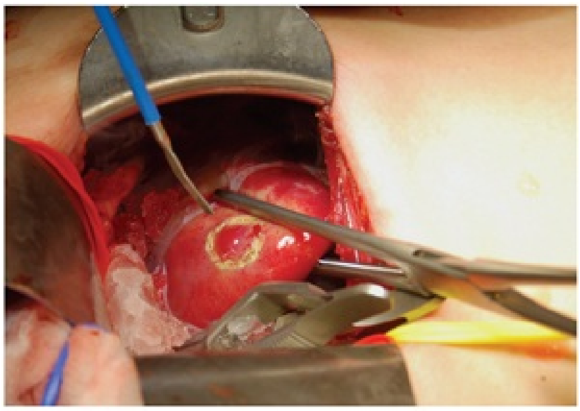

FIGURE 2.9 Regional ischemia provided using straight Satinsky clamp.

For patients with large, endophytic, or perihilar tumors, renal artery occlusion with a bulldog clamp is required to limit blood loss during the resection and to improve visibility. Renoprotective measures, including mannitol infusion (12.5 g per 200 mL of normal saline given 30 minutes prior to clamping) and ice slush, are routinely used. It is unnecessary to place the kidney in a plastic bag prior to applying the ice slush because the small surgical mini-flank incision does not cause the patient significant hypothermia. We always apply renoprotective ice slush hypothermia (Fig. 2.10) if renal artery occlusion is required and see no rationale in open PN for using warm ischemia alone as advocated by some, even if the PN can be rapidly completed.

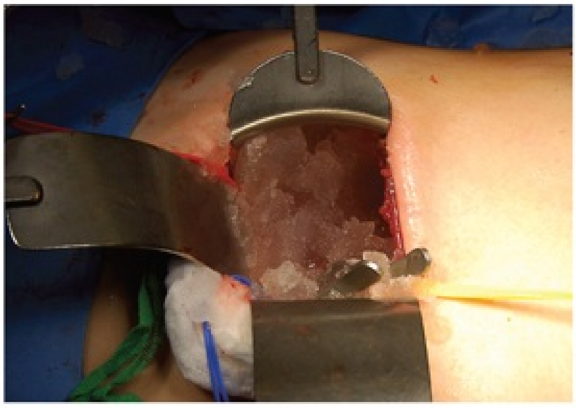

FIGURE 2.10 Iced saline slush hypothermia. Pictured are two bulldog clamps used to clamp the main renal artery and an accessory renal artery.

Following renal hilar clamping, the renal cortex is scored with a 1-cm margin using the electrocautery, and scissor dissection (Fig. 2.11) is used within the renal parenchymal plane (pink kidney tissue) with care not to get too close to the renal tumor’s pseudo capsule (yellowish/golden tissue for conventional clear cell, brownish for oncocytoma, grayish for chromophobe tumors, yellowish/tan for papillary tumors). If dissection is too close to the tumor, readjustment to a deeper plane of dissection is made. A Penfield dissector held by the first assistant gently retracts away the tumor from the operating surgeon and allows the surgeon to avoid the tumor pseudo capsule. We do not “enucleate” the tumor within its pseudo capsule. As the PN proceeds, 3-0 and 4-0 absorbable sutures are used to separately close any open small veins, arteries, and breaches in the collecting system that are encountered (Fig. 2.12). A search for venous bleeding can be accomplished by simply dropping the kidney into the wound (closer to the central venous pressure) and then raising it again. The surgical specimen is inspected to be certain the resection is complete with a rim of surrounding renal and soft tissue and no fractures in the resection margin. The deep tumor surgical margin is marked with a silk suture to orient the specimen which is then sent for a frozen section.

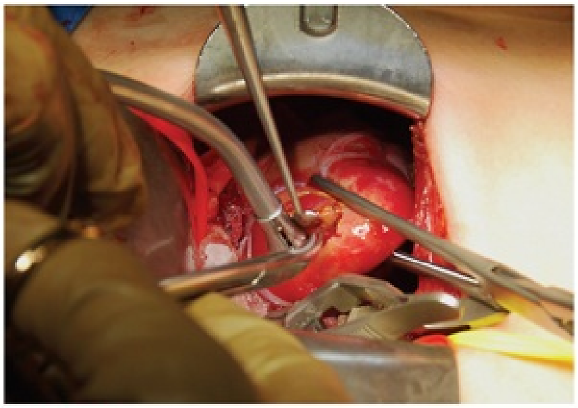

FIGURE 2.11 Sharp scissor and Penfield nerve dissector dissection of the tumor, keeping the plane of surgical dissection within the normal kidney tissue.

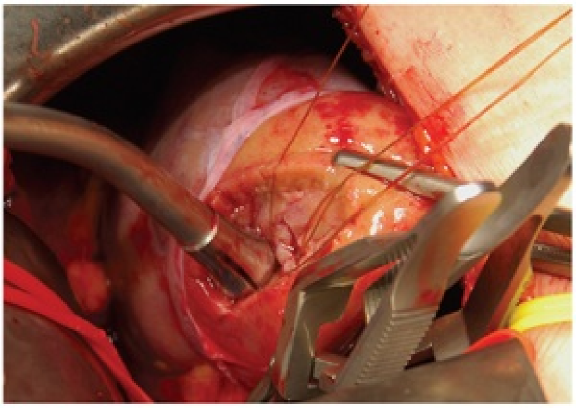

FIGURE 2.12 Direct collecting system repair with 3-0 and 4-0 absorbable sutures (chromic pictured here).

Endophytic and renal sinus based tumors are especially challenging to locate and require careful correlation with preoperative CT and intraoperative ultrasound. Renal sinus tumors can emanate from the renal cortex facing the renal sinus and be attached by a small area of the cortex and otherwise float freely within the sinus without invasion of vascular or collecting system elements. The renal sinus can be accessed through a horizontal cortical incision in the avascular plane (Brödel line) using anatrophic techniques developed in the past for intact removal of staghorn calculi (Fig. 2.13). The tumor is identified on its lateral border and circumferentially dissected with a rim of surrounding cortex. Penfield or Cobb dissectors are used to gently lift the tumor out of the sinus with the final dissection of the actual renal cortical attachment performed sharply. This deep renal cortical attachment is marked with a silk suture as the deep margin to orient the specimen for the pathologist. Surprisingly, little collecting system reconstruction and vascular closure is required in many renal sinus tumor resections.

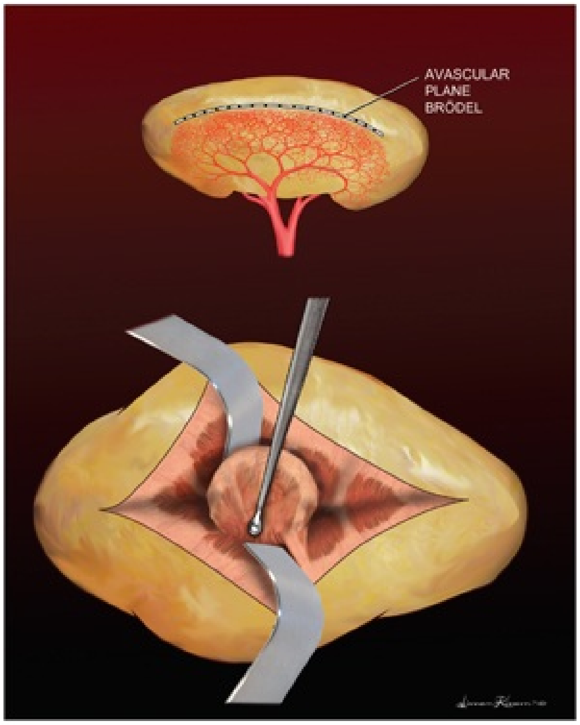

FIGURE 2.13 Endophytic and renal sinus based tumors can be accessed through a horizontal cortical incision in the avascular plane (Brödel line) using anatrophic techniques.

Reconstruction

Following tumor resection, reconstruction of the surgical bed, a combination of hemostasis and repair of any rents in the collecting system, is performed. Using 2.5× optical loupes, fine forceps are used to gently probe the bed for any collecting system rents which, if found, are closed with either interrupted or running 3-0 absorbable sutures. Care is taken to carefully locate and ligate sometimes minute distal arterial branches which can bleed profusely once the main arterial clamp is released. During reconstruction within the sinus, care is taken to include renal papilla with a corresponding calyx and not occlude the stem of a calyx during suture repair, events which could lead to a protracted urinary leak and/or calyceal diverticulum. The cut renal cortex is coagulated using the argon beam coagulator (ABC) (Fig. 2.14A).

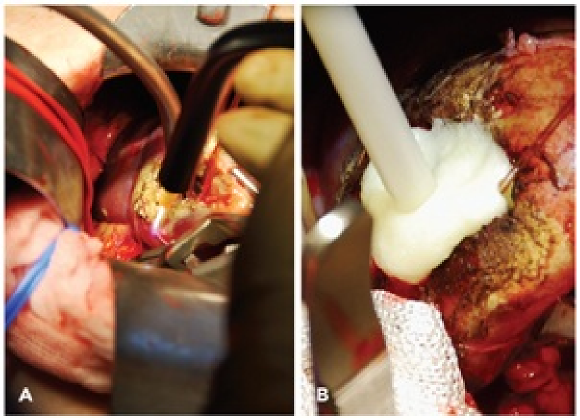

FIGURE 2.14 The ABC is used for hemostasis on the renal cortical surface (**A**), and FloSeal, Surgicel, and perinephric fat are used in the renal cortical resection cavity (**B**).

The resection cavity is then filled with the hemostatic agents FloSeal (Baxter, Deerfield, Illinois) and Surgicel (Johnson and Johnson, New Brunswick, New Jersey) along with any available perinephric fat (Fig. 2.14B). The renal capsule is reapproximated using 0-chromic blunt-tipped liver sutures pledgeted with Surgicel to prevent tearing of the renal cortical capsule and further bleeding (Fig. 2.15). The renal artery is unclamped, and gentle pressure over resection bed is applied for 3 to 5 minutes. If the collecting system was entered, a closed suction Jackson-Pratt drain (Allegiance Healthcare, McGaw Park, Illinois) is placed through a separate stab wound in the retroperitoneal space posterior to the kidney. For exophytic tumors excised completely without entry into collecting system, the drain can be safely omitted (26). If venous oozing from the resection bed persists, another 5-minute period of gentle compression is applied. However, if brisk red arterial bleeding is observed, careful inspection of the bed by cutting one or more liver sutures and ligation of any arterial bleeders is performed. Reclamping of the renal artery is avoided to prevent renal reperfusion injury. The surgical incision is closed in two layers using no. 1 polydioxanone (PDS) for the fascia and 4-0 subcuticular suture for the skin (Fig. 2.16).

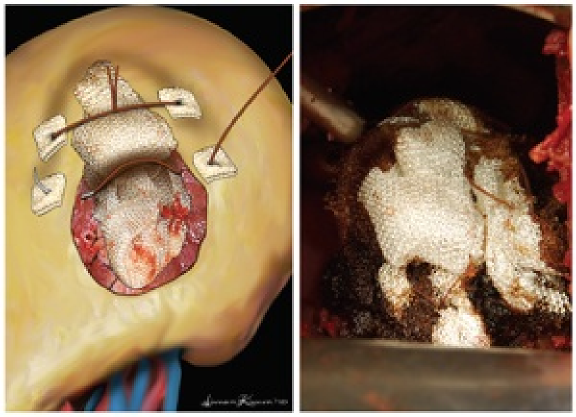

FIGURE 2.15 The renal capsule is reapproximated using 0-chromic blunt-tipped liver sutures pledgeted with Surgicel.

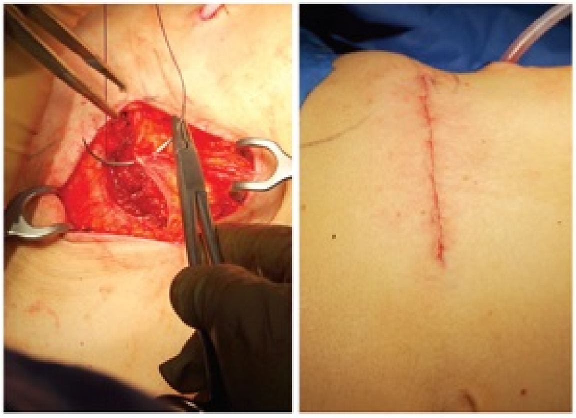

FIGURE 2.16 Closure of surgical incision in two layers using no. 1 PDS, and reapproximation of the skin incision using 4-0 absorbable sutures in a subcuticular fashion.

COMPLEX APPLICATIONS OF PARTIAL NEPHRECTOMY

As our experience with PN has increased, more challenging referrals for PN are being made for tumors which in previous years would have been managed by RN. For patients with sporadic and hereditary bilateral tumors, tumor histologic concordance between the two kidneys is 70% (27–29). We approach the kidney with the largest tumor burden first because it carries the greater oncologic threat (30). The notion of performing the smaller PN first in order to “support” the larger contralateral tumor bearing kidney is no longer applicable because both can now usually be approached by PN. If the pathology of the larger tumor is indolent with limited or no metastatic potential, such as renal oncocytosis or multifocal chromophobe renal cancer, a strong case for nonoperative management with careful observation alone for the contralateral renal tumor can be made (31).

For patients with multifocal tumors, many of which are minute in size, careful visual inspection and intraoperative ultrasound to examine the entire kidney is required. We initially resect as many of the minute tumors as possible using fine scissors or a no. 15 scalpel blade with hemostasis obtained using the ABC. Larger multifocal tumors may require formal PN using cold ischemia. During the resection of centrally located hilar and perihilar tumors abutting proximal major renal arteries and veins, especially in patients with essential indications, a complete resection, even if the surgical margin is close, should be attempted because a microscopically positive surgical margin does not necessarily translate into a local tumor recurrence or worse cancer specific survival (32). For patients with a renal tumor in a solitary kidney, PN can achieve the dual goals of local tumor control and preservation of renal function. When prolonged renal artery ischemia and postoperative acute tubular necrosis (ATN) is anticipated, a preoperative renal medicine consult and placement of a tunneled subclavian dialysis catheter is prudent (33–35) in case postoperative hemodialysis is required before the kidney begins to function again.

During PN, an intrarenal muscular branched vein tumor thrombus, often seen on intraoperative ultrasound, may be encountered. This finding is associated with a worse prognosis than previously appreciated (36), yet PN can still be done using basic vascular surgical principles of proximal and distal vascular control and milking the thrombus back from the vein before dividing it. Similarly, with extension of a renal tumor into the collecting system (37), reconstructive urology principles, up to and including a pyeloplasty are used following the complete excision. Again, care must be taken during the reconstruction not to exclude a papilla from the renal calyceal system which can lead to a prolonged urinary fistula in the absence of retrograde pyelogram evidence of urinary extravasation. Most such leaks close spontaneously but may take weeks or months to do so. We generally do not place indwelling ureteral stents after collecting system repairs because postoperative urinary fistula can be accentuated by reflux of urine from the contralateral kidney. In the rare and difficult circumstance of resection of a tumor involving the majority of a low-capacity intrarenal pelvis where pyeloplasty is no longer an option, closure of the proximal renal pelvis with ureteral calycostomy can achieve proper drainage from the kidney. In this case, we do place a double-J ureteral stent and a closed suction drain.

“Redo” PN can be difficult due to scar tissue involving the renal hilum and is associated with greater operative time, blood loss, and more complications. Meticulous dissection around the renal hilum can lead to a successful repeat PN in the vast majority of cases (38). Treatment failures following thermal ablation procedures are now being referred for salvage PN. If the residual lesions are small and the patient is elderly, frail, or comorbidly ill, we recommend active surveillance which likely would have been our preference over thermal ablation initially. If the patient is young and otherwise well, PN is attempted. Patients are forewarned that PN may be unsuccessful due to extensive fibrosis and scarring with and conversion to RN is a real possibility (39,40).

Medical oncologists may refer patients with metastatic renal cancer whose primary tumor is amenable to a cytoreductive PN. For patients with compromised renal function, PN makes sense; however, if the patient has sufficient renal functional reserve, a strong case can be made for a cytoreductive RN to avoid potential postoperative wound complications associated with the targeted agents that could delay the systemic chemotherapy. Long-term concerns for renal functional decline and potential late cardiovascular morbidity may not be as relevant in this patient population with a generally poor overall prognosis (41–43).

Results

Initial reports in the 1990s of PN for tumors of 4 cm or less indicated equivalent oncologic control to RN (4,44,45) with later reports from the United States and abroad confirming the oncologic equivalency (11–13,46). Expansion of PN to tumors of 4 to 7 cm and later to carefully selected larger size (>7 cm) and higher stage (T2-T3a) did not appear to compromise oncologic efficacy when compared to RN (16,17). In addition, evidence was mounting that when PN was compared to RN for the management of small renal masses, RN was associated with elevated postoperative serum creatinine (47,48) and the development of or worsening of preexisting CKD, which is prevalent in the United States and associated with cardiovascular events and worse overall survival (6). Despite the accumulating clinical evidence supporting the use of PN for small renal masses by guidelines committees (49,50), RN remains overused in the United States and abroad, particularly in elderly patients and women (51–53).

The mini-flank incision is well tolerated by patients and, when coupled with a rapid recovery clinical pathway, is associated with a short hospital stay. In our initial report of 167 consecutive patients undergoing a mini-flank PN, excellent and rapid exposure of the kidney was achieved and only 3.6% of patients reported a flank bulge after 18 months of follow-up with one patient requiring incisional hernia repair (8). In a follow-up report of 280 additional cases, length of stay was 4 days and a flank bulge was reported in less than 2% (9). Muscle atony/bulge at the incision site without hernia is disconcerting for the patient and can be ameliorated or improved completely by exercises that twist the upper torso and core muscles (using an exercise bar, broom, or golf club). For the rare flank hernia, repair with synthetic mesh is more effective than primary closure which is likely to lead to recurrent hernia. With the advent of clinical postoperative pathways emphasizing early ambulation, progression to regular diet, and early switch to oral pain medications, length of stay for PN has been further reduced to 2.6 days (10).

Complications of Open Partial Nephrectomy

Complications related to PN generally fall in the three major categories of urinary fistula, bleeding, and infection. With more complex PN being performed, more complications will be encountered. If PN is performed without entry into the collecting system, urinary fistula is unlikely and the perinephric drain can be omitted and thereby eliminate drain-related patient discomfort as well as a portal for nosocomial infection (26). Factors associated with persistent urinary fistula beyond the immediate and expected postoperative period include tumor in a solitary kidney, prolonged operating time, greater blood loss, endophytic tumor, and collecting system repair. Approximately 4% of patients will have a urinary leak of more than 2 weeks, and investigations such as CT urography and retrograde pyelography can reveal anatomic findings that are actionable. For example, a perinephric drain may heal directly into the kidney and become a virtual nephrostomy tube. Simply backing out the drain can lead to rapid resolution of the fistula. Occasionally, kinks in the proximal ureter from mobilization can lead to preferential leakage of urine from the surgical bed. Placement of a stent can straighten out the ureter and lead to rapid resolution of the fistula. A disconcerting finding in a patient with urinary fistula that is not declining is an intact renal pelvis and calyceal system as seen by retrograde pyelogram in the absence of any contrast extravasation. This implies either an obstructed intrarenal calyx or a renal papilla that is producing urine but without a corresponding calyx to collect the urine. In the former case, a combined percutaneous antegrade and endoscopic retrograde approach is often required to reestablish continuity of the obstructed calyx and the renal pelvis. In the latter case, over an extended time (weeks to months), the renal papilla will stop producing urine and the leakage will end. We have no experience with attempting to destroy this undrained papilla with RFA or cryoablation. We stress excellent nutrition, exercise, and rest in the postoperative period as means to promote wound healing following PN. On rare occasions in patients who apparently have healed, passage of surgical debris or a small stone can cause ureteral obstruction and a delayed leak through the newly healed surgical bed which can present with pain and flank fullness necessitating placement of a percutaneous drain.

Pseudoaneurysm or iatrogenic arterial venous fistula forms when surgical repair of vascular rents fuses arteries and veins with direct communication developing between the two. On rare occasions, a palpable thrill can be noticed over the resection site at the end of a PN. In this case, immediate reexploration of the surgical bed with ligation of the communicating vessels or completion RN is performed. These can present with delayed postoperative bleeding, perinephric hematoma with pain, ureteral colic, gross hematuria, hypotension, flank mass, or flank discoloration from dissecting blood. Following appropriate resuscitation, CT renal protocol is performed which will reveal arterial contrast pooling with or without perinephric hematoma, a finding that should initiate an urgent request for selective renal artery angiogram and coil embolization. The interventional radiologist should make every effort to occlude tertiary and quaternary branches of the renal artery as close to the pseudoaneurysmal pocket as possible in order to limit collateral damage to viable, healthy renal tissue. Memorial Sloan Kettering Cancer Center (MSKCC) reported 15 pseudoaneurysms (1%) during a 7-year period including 7 of 1,160 (0.6%) in open PN. Fourteen of 15 patients were successfully treated with embolization, but 1 patient with a coagulopathy required a completion RN (54).

Follow-up after Partial Nephrectomy

In an attempt to standardize the follow-up after nephrectomy, the American Urologic Association recently published guidelines based on tumor stage. All patients should undergo interval history and physical examination and laboratory testing including blood urea nitrogen (BUN)/creatinine, urinalysis, and eGFR. Low-risk patients (pT1, N0, Nx) should undergo a baseline abdominal scan (CT or MRI) within 3 to 12 months following surgery. If the initial scan is negative, abdominal imaging (US, CT, or MRI) may be performed yearly for 3 years, based on the individual risk for recurrence. In addition, low-risk patients are recommended to undergo yearly chest X-ray (CXR) to assess for pulmonary metastases for 3 years and, if clinically, indicated beyond that period. Moderate-to-high–risk patients (pT2-4N0 or any N+ stage) should undergo baseline chest and abdominal scans (CT or MRI) within 3 to 6 months following surgery, with continued imaging every 6 months for 3 years at least and annually thereafter to year 5. Imaging beyond 5 years may be performed at the discretion of the clinician (55). At MSKCC, after 2 years without evidence of disease recurrence, we refer patients to our “survivorship” clinic where long-term renal cancer follow-up, general medical care, and oncologic screening is provided. As much as possible, renal ultrasound and CXR are used in follow-up unless specific patient signs or symptoms need to be directly addressed by specific imaging studies.

CONCLUSIONS

PN is an essential operation for the management of small renal masses increasingly detected by cross-sectional imaging usually obtained for the evaluation of nonspecific abdominal or musculoskeletal complaints. PN provides equivalent oncologic control for the T1 tumor as does RN while at the same time preventing or delaying CKD and its potential for late cardiovascular morbidity and mortality. This kidney functional preserving effect is amplified by the fact that approximately 45% of patients will have a benign or indolent tumor resected with little or no metastatic potential. A mini-flank supra-11th rib approach is a highly effective operation that should be part of every renal surgeon's arsenal. This approach provides rapid exposure to the kidney, is useful for both straightforward and complex operations, is cost-effective, and is now associated with a median surgical length of stay of 2 days and a marked reduction in flank bulge. Increasingly, challenging PN is being performed, and despite concerns for postoperative complications, the dual goals of oncologic control and preservation of renal function are achieved. Potential complications of postoperative bleeding, infection, and urinary fistula can occur, but most are managed with conservative measures that ultimately preserve the kidney.

CHAPTER 3 RADICAL NEPHRECTOMY

CHAD R. RITCH, SAM S. CHANG, AND MICHAEL S. COOKSON

Renal cell carcinoma (RCC) is the most common malignancy of the kidney and accounts for about 5% of all adult neoplasms in men and 3% in women. The estimated number of new cases of RCC in the United States in 2012 was 65,150 with a projected 13,680 deaths, and this incidence is expected to continue to increase as a result of the expanded use of radiographic imaging coupled with the aging population (1).

There has been an increase in incidence of RCC and a concomitant decrease in renal mass size and stage at presentation, likely related to the increased use of imaging. This shift in epidemiology has encouraged the American Urological Association (AUA) to develop guidelines specifically addressing the management of the clinical stage I renal mass (2). As such, several treatment options exist for select patients with incidentally discovered renal masses. However, radical nephrectomy remains the mainstay for curative treatment in the majority of patients. In fact, a recent randomized controlled trial by the European Organization for Research and Treatment of Cancer (EORTC 30904) has brought into question the survival benefit of partial nephrectomy for tumors <5 cm as compared to radical nephrectomy (3). Although these findings need to be corroborated, radical nephrectomy remains a standard treatment for most renal tumors to which other options should be compared.

The role of open radical nephrectomy in the management of RCC has changed somewhat over the last decade. Pure laparoscopic, hand-assisted laparoscopic, and robotic radical nephrectomy have emerged as less invasive alternatives to open surgery in the management of low- to moderate-volume (8 to 10 cm or smaller), localized RCCs without local invasion, renal vein involvement, or lymphadenopathy.

However, this has placed an increased emphasis on the performance of open radical nephrectomy in a higher percentage of patients who have either comorbid illnesses or advanced tumors that preclude a minimally invasive approach. Furthermore, the beneficial impact of cytoreductive nephrectomy has increased the clinical situations in which open radical nephrectomy may be performed in the setting of metastatic disease (4).

This chapter focuses on the open surgical approach for radical nephrectomy.

DIAGNOSIS

Typically, RCCs are characterized on computerized tomography (CT) scan by a solid parenchyma mass with a heterogeneous density and enhancement with IV contrast injection (between 15 and 40 Hounsfield units). However, despite modern imaging, some benign tumors and complex cysts may be indistinguishable from cancer and confirmed only after surgical excision or biopsy. As such, the use of percutaneous biopsy has increased in the diagnosis and management of some renal masses and is now included in the AUA guideline (2). Prior concerns of poor accuracy and needle tract seeding have been dismissed by contemporary reports demonstrating low false-negative rates and almost no reports of seeding (2).

Clinical staging in patients suspected of RCC usually includes a contrast-enhanced CT scan of the abdomen, which may include CT angiography as well as three-dimensional reconstructions, and magnetic resonance imaging (MRI) is used on occasion, depending on the clinical scenario.

INDICATIONS FOR SURGERY

The indication for radical nephrectomy is a clinically localized solid renal mass in a patient with a normal contralateral kidney. Patients with solitary kidneys, renal insufficiency, or bilateral renal masses should be considered candidates for nephron-sparing surgery. Partial nephrectomy is acceptable for T1 lesions in the "elective" setting (2). However, for larger lesions, radical nephrectomy remains the treatment of choice. A thorough preoperative history and physical examination should be performed before the procedure. If significant comorbidities are suspected, preoperative consultation with the appropriate physician is recommended. In an elective radical nephrectomy, the patient should be expected to physically withstand the operation, have a reasonable overall performance status, and have a 5-year life expectancy.

Routine lymphadenectomy remains controversial during radical nephrectomy. In fact, the recommendation against the role of routine lymphadenectomy at the time of radical nephrectomy is supported by data from a prospective, randomized controlled trial (EORTC 30881), which found a low incidence of lymph node metastases and no survival advantage with complete lymph node dissection (5). This study has been criticized for a low number of men at risk for nodal metastases but nevertheless adds support to this argument, and currently, lymphadenectomy is offered to selected high-risk individuals.

Radical nephrectomy in combination with immunotherapy for metastatic RCC (i.e., cytoreductive nephrectomy) has been demonstrated to improve survival among patients with metastatic RCC over immunotherapy alone (4,6). The tyrosine kinase inhibitor (TKI) class of medications has surpassed immunotherapy as the standard systemic therapy for metastatic disease (7). However, the concept of cytoreductive nephrectomy is still applied in the setting of TKI treatment for metastatic RCC. Accordingly, radical nephrectomy is offered to patients with a resectable primary tumor in the setting of metastatic disease as an initial treatment strategy prior to systemic therapy. Radical nephrectomy may also be performed for palliation, such as for patients with intractable pain or life-threatening hemorrhage who fail conservative treatment despite the presence of metastases. The role of radical nephrectomy among patients with a solitary metastatic site is controversial; however, modest 5-year survival rates have been reported in selected patients, with best results reported in patients with solitary pulmonary metastases (8).

Although local extension of primary RCC into the perinephric fat, vena cava, or ipsilateral adrenal gland may portend a worse prognosis, in the absence of metastatic disease, these factors alone should not dissuade the surgeon from attempting a radical nephrectomy. Similarly, regional lymphadenopathy should not exclude a patient from undergoing a radical nephrectomy. In addition, radical nephrectomy has been successfully performed in the setting of direct extension of the tumor into adjacent organs such as the liver, colon, spleen, pancreas, or psoas muscle. However, surgical removal in this setting is technically difficult and is associated with a higher morbidity and a potentially poor prognosis. Therefore, it should be attempted only after careful preparation and in cooperation with appropriate surgical consultants.

ALTERNATIVE THERAPY

Surgery remains the only effective and potentially curative form of therapy for primary RCC. Along this line, the main challenge to radical nephrectomy in the near future appears to be from more conservative surgical approaches, including nephron-sparing surgery and minimally invasive approaches. Retrospective series of elective partial nephrectomy, enucleation, and wedge resection have demonstrated equivalence in terms of cancer control and may afford potential advantages in terms of preserved renal function and quality of life in properly selected patients (9–11). However, results from EORTC 30904 demonstrated that overall survival was higher in patients undergoing radical nephrectomy (3).

Radical nephrectomy is also being performed through laparoscopic approaches, including hand-assisted techniques, which again have shown equivalent cancer control and significant advantages in terms of reduced pain, shorter convalescence, and improvements in quality of life (12).

Open radical nephrectomy continues to play an important role in the management of RCC, and it is essential that any surgeon who employs minimally invasive techniques be well versed in its performance.

SURGICAL TECHNIQUE

There are a variety of factors that influence the choice of incision during radical nephrectomy. These include location of the affected kidney, tumor size and characteristics, body habitus, and physician preference. There are advantages and disadvantages to each incision, and it is important to be familiar with several approaches to the kidney as no one incision is appropriate in all settings. The most commonly used incisions for radical nephrectomy are the flank, thoracoabdominal, and transabdominal (subcostal or chevron) (Fig. 3.1).

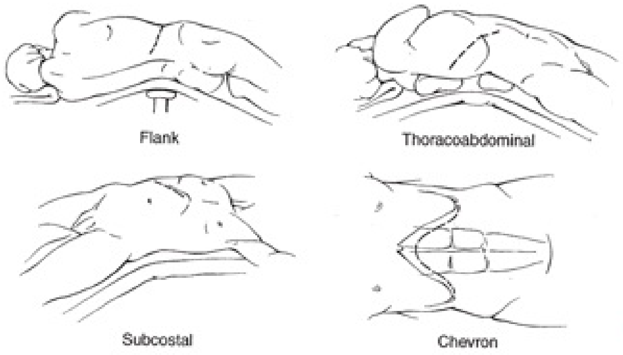

FIGURE 3.1 Types of incisions during radical nephrectomy.

Flank Incision

The flank approach can be advantageous for several reasons. First, it allows direct access to the retroperitoneum and kidney, and the entire procedure can often be performed in an extrapleural and extraperitoneal fashion. In addition, the incision is anatomic in that it follows the track of the intercostal nerves with minimal risk of denervation. However, in large tumors, tumors involving the upper pole, or situations where vena cava access is critical, a flank approach is often suboptimal. Although a flank approach may be performed through a subcostal incision, an 11th- or 12th-rib incision is superior for exposure of the upper pole and ipsilateral adrenal gland during radical nephrectomy.

The patient is positioned in the lateral decubitus position with the upper chest at about a 45-degree angle. An axillary roll is placed under the patient to cushion against pressure on the brachial plexus, and the elbows are padded to prevent ulnar nerve injury. The upper arm is draped across the body and placed on a Mayo stand or padded support. The lower leg is flexed at 90 degrees, and the upper leg is extended over one or two pillows. The kidney rest is raised and the table is flexed to elevate the flank and adjusted to make the flank horizontal to the floor. A beanbag or inflatable mattress may be helpful, and if utilized can be activated to further support the patient. The patient is then padded and secured with wide adhesive tape and safety straps.

An 11th- or 12th-rib incision is made based on several factors, including the kidney position, the cephalad extent of the tumor, and the patient's body habitus. A general rule is to incise over the rib so that, when extended medially, the incision will be over the renal hilum. The incision is then made off of the tip or over the rib from the posterior axillary line to the tip and extended medially as far as necessary, usually stopping short of the lateral border of the rectus abdominis (Fig. 3.2). The latissimus dorsi is divided, and the upper portion of the incision is carried down to the rib or near its tip. The incision is usually created between the ribs in the intercostal space, and additional exposure may be obtained by incising the costovertebral ligament. With larger tumors and depending on patient body habitus, a partial rib resection may be accomplished as shown in Figure 3.3. An Alexander periosteal elevator is used to deflect the periosteum from the bone to avoid injury to the intercostal bundle located under the inferior portion of the rib. A Doyen elevator is then used to strip the periosteum from the entire undersurface of the rib to be resected. Next, a rib cutter is used to divide the proximal segment of the rib. The posterior layer of the periosteum is then incised carefully, and the pleura is protected superiorly.

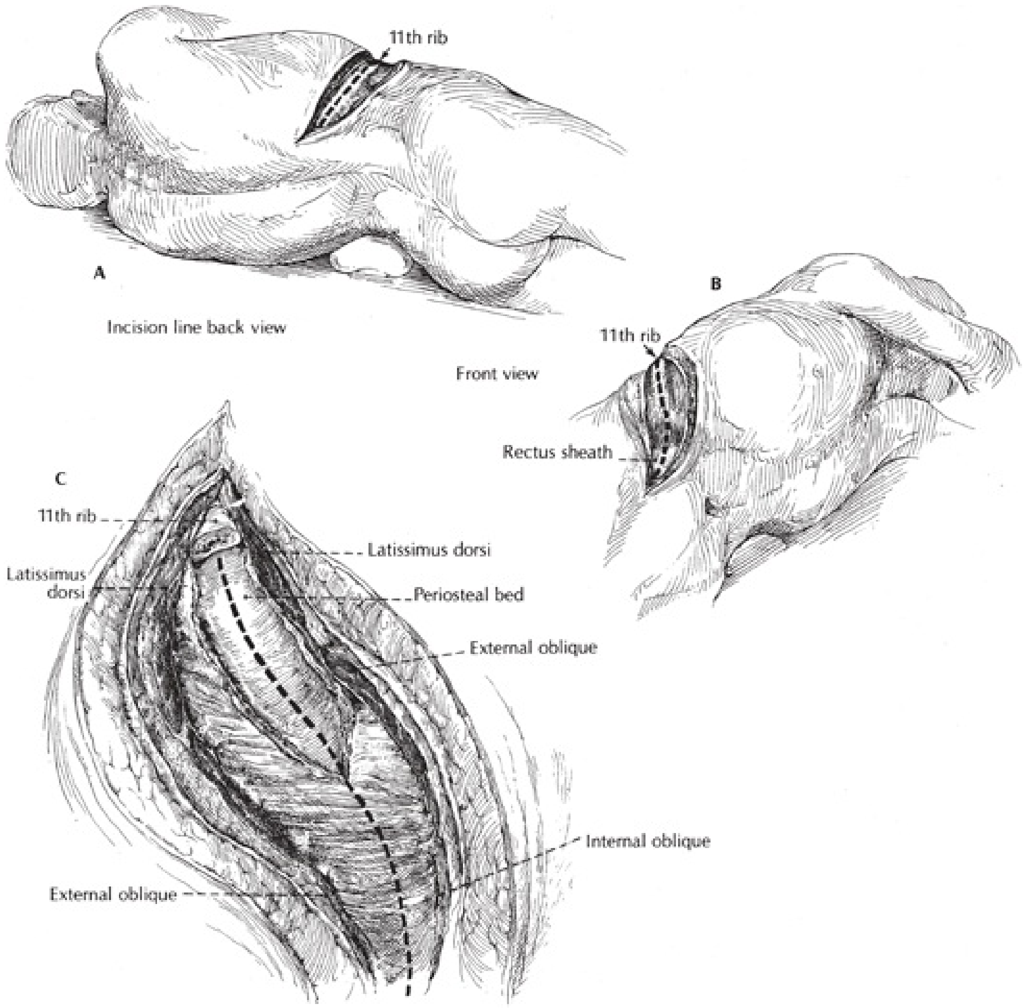

FIGURE 3.2 Technique of 11th-rib resection. **A and B:** The incision is made over the 11th rib. **C:** After division of the latissimus dorsi and external oblique muscles, subperiosteal resection of the rib is performed. *(continued)*

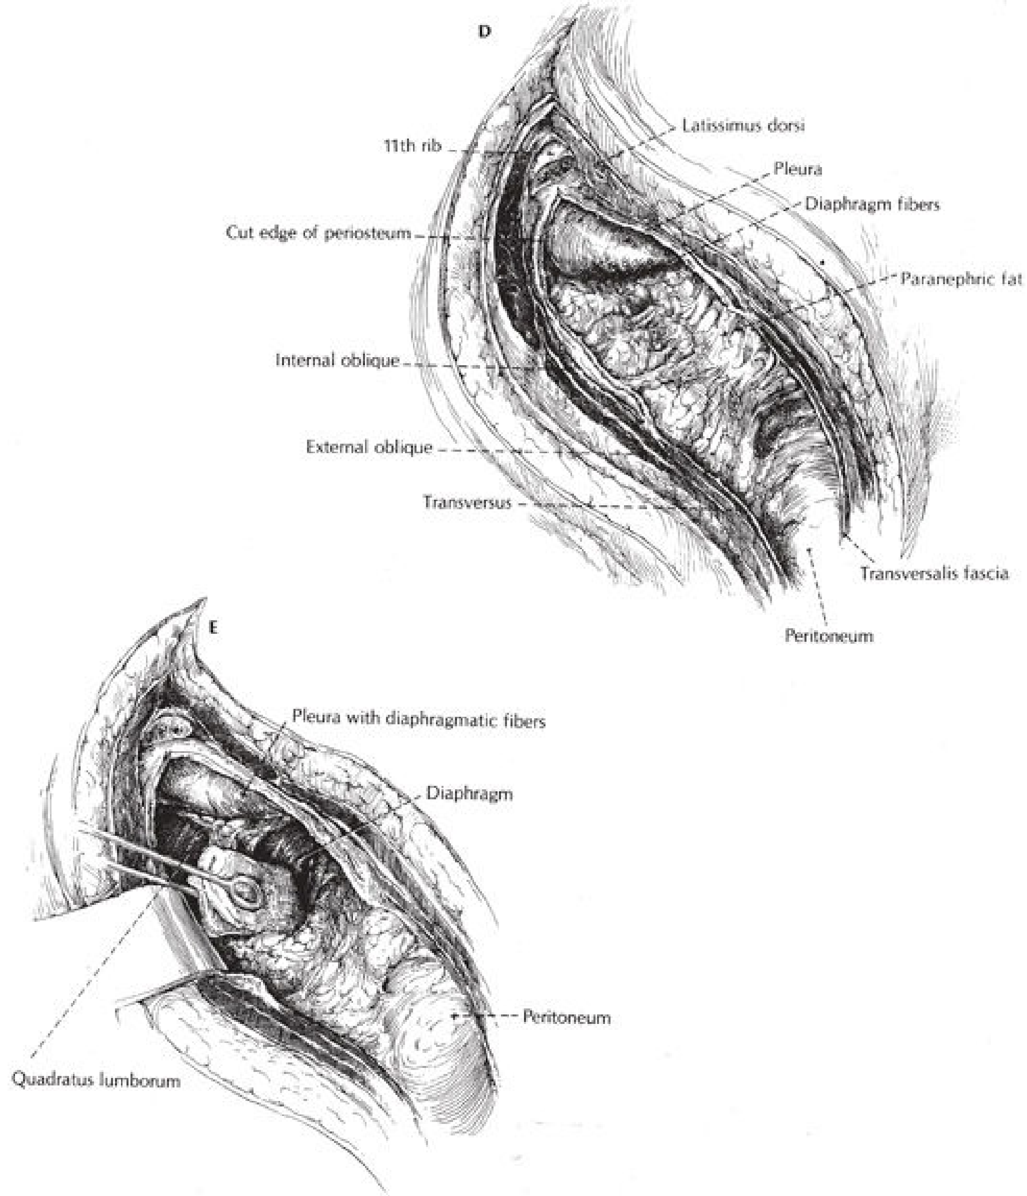

FIGURE 3.2 (*continued*) **D:** The incision is carried through the periosteum posteriorly and the internal oblique and transversus muscles medially, exposing the paranephric space. A tongue of pleura lies in the upper portion of the wound. Diaphragmatic slips that come into view are divided, and the pleura can be retracted upward. **E:** The paranephric fat is dissected bluntly.

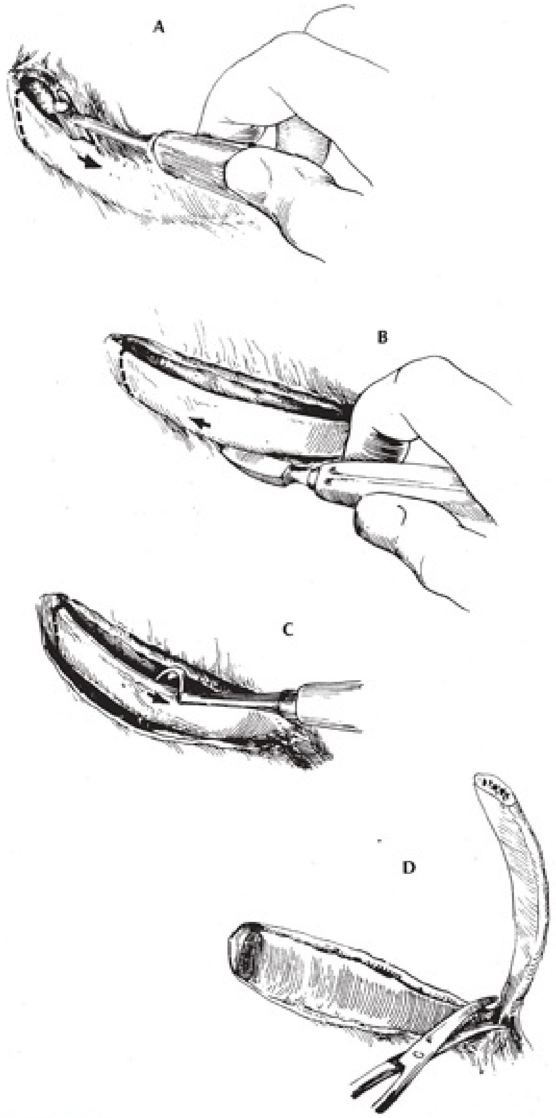

FIGURE 3.3 Rib resection technique. **A:** After exposure of the rib, the intercostal muscles are stripped from the upper and lower rib surfaces with an Alexander–Farabeuf costal periosteotome. **B:** The rib is freed from the periosteum by subperiosteal resection or from the pleura with a periosteum elevator. **C:** A Doyen costal elevator is slipped beneath the rib to free it. The proximal and distal portions of the rib are immobilized with Kocher clamps, and the rib is divided proximal to its angle with a right-angled rib cutter. **D:** The costal cartilage is cut free with scissors. The cut surface of the rib is inspected for spicules, which are removed with a rongeur and covered with bone wax.

Anteriorly, the external and internal oblique muscles are divided and the transversus abdominis muscle is split in the direction of its fibers, taking care not to enter the peritoneum. The peritoneum is swept medially, and the intermediate stratum of the retroperitoneal connective tissue is incised sharply to expose the perinephric space. Approaching this in a posterior fashion with early identification of the psoas muscle helps keep proper orientation. A self-retaining retractor such as a Balfour, Bookwalter, Omnitract, or Finochietto rib spreaders helps maintain exposure. A radical nephrectomy is then performed.

The wound is closed after checking to ensure that no injury to the pleura has occurred (see "Complications"). The table flex is released and the kidney rest is lowered. The posterior layer consisting of the fascia of the transversus abdominis and the internal oblique is closed in a running fashion with no. 1 polydioxanone suture (PDS) or Prolene. The anterior layer of external oblique fascia is closed with a running no. 1 PDS or Prolene. Alternatively, interrupted figure-of-eight sutures of no. 1 Vicryl can be used for both layers. The skin is closed in accordance with the surgeon's preference.

Thoracoabdominal Incision

The thoracoabdominal approach allows for excellent exposure of large tumors as well as upper-pole tumors, in particular on the left. In addition, it affords easy access to the adrenal gland and thoracic cavity. The patient is positioned with the hips flat and with the break of the table located just above the iliac crest. The pelvis can be torqued up to about 30 degrees if necessary. The patient's ipsilateral shoulder is rotated 45 degrees, and the ipsilateral arm is extended over the table and properly supported on a Mayo stand or padded armrest (Fig. 3.4). It is important to properly pad all pressure points, including between the legs and the contralateral shoulder. The kidney rest may be elevated to accentuate the proper extension, and the break in the table is made to optimize the incision. After positioning, the patient is secured with wide adhesive tape and safety straps.

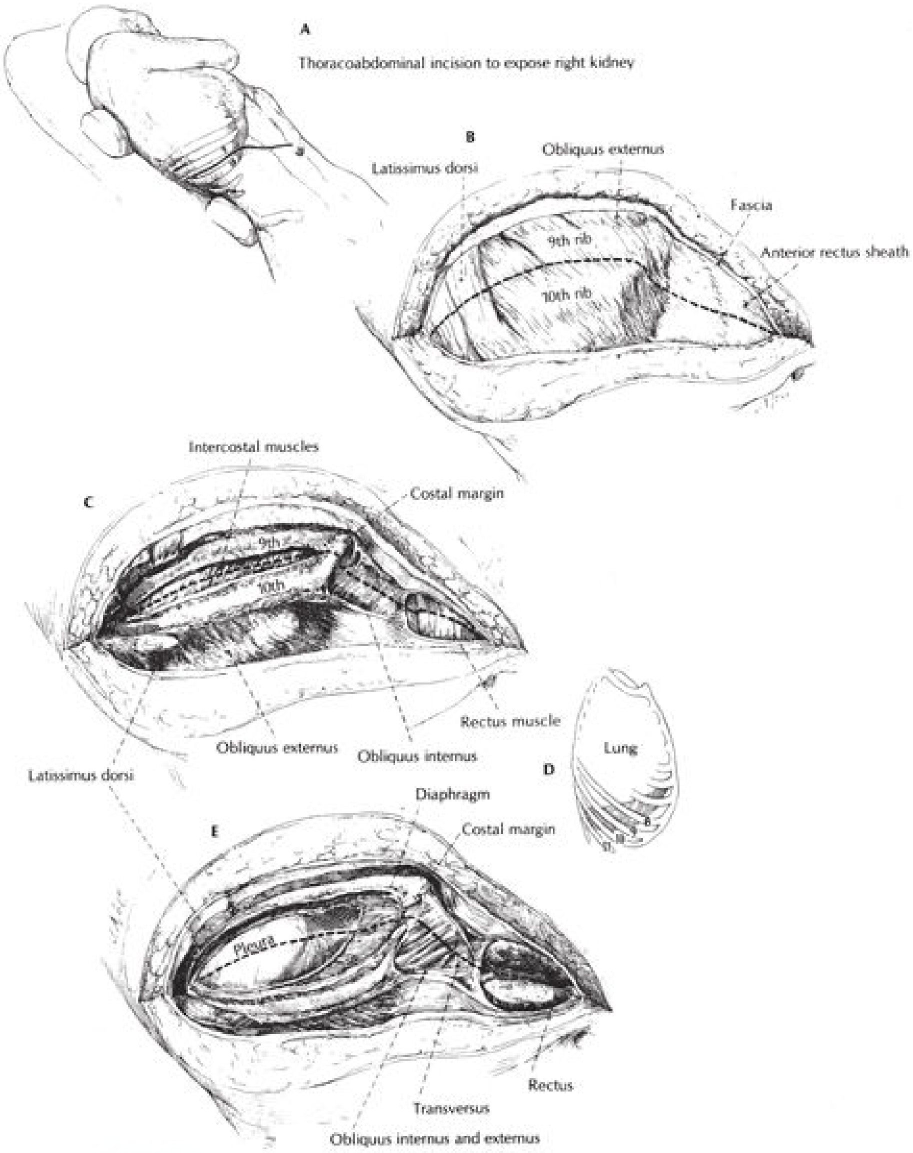

FIGURE 3.4 Thoracoabdominal incision. **A:** The patient is placed in a semirecumbent position using sandbags. If the chest is entered through the ninth intercostal space, the incision extends from the midaxillary line across the costal margin at the intercostal space to the midline or across it just above the umbilicus. **B:** The anterior rectus sheath and the external oblique and latissimus dorsi muscles are divided. **C:** The intercostal muscles parallel the direction of the three abdominal layers and are divided. The costal cartilage and the internal oblique and rectus muscles are incised. If more exposure is desired, the linea alba and opposite rectus can be divided. **D:** The pleural reflection (*shaded areas*) lies progressively closer to the costal margin in the more cephalic intercostal spaces. **E:** The pleura, reflecting as the costophrenic sinus near the costal margin, is exposed beneath the intercostal muscles. The diaphragm can be seen inferior and dorsal to the pleura. The pleura is opened with care to avoid injuring the lung, which comes into view with inspiration. After the lung is packed away gently, the diaphragmatic surface of the pleura is seen. The diaphragm is incised on its thoracic surface, avoiding the phrenic nerve. (*continued*)

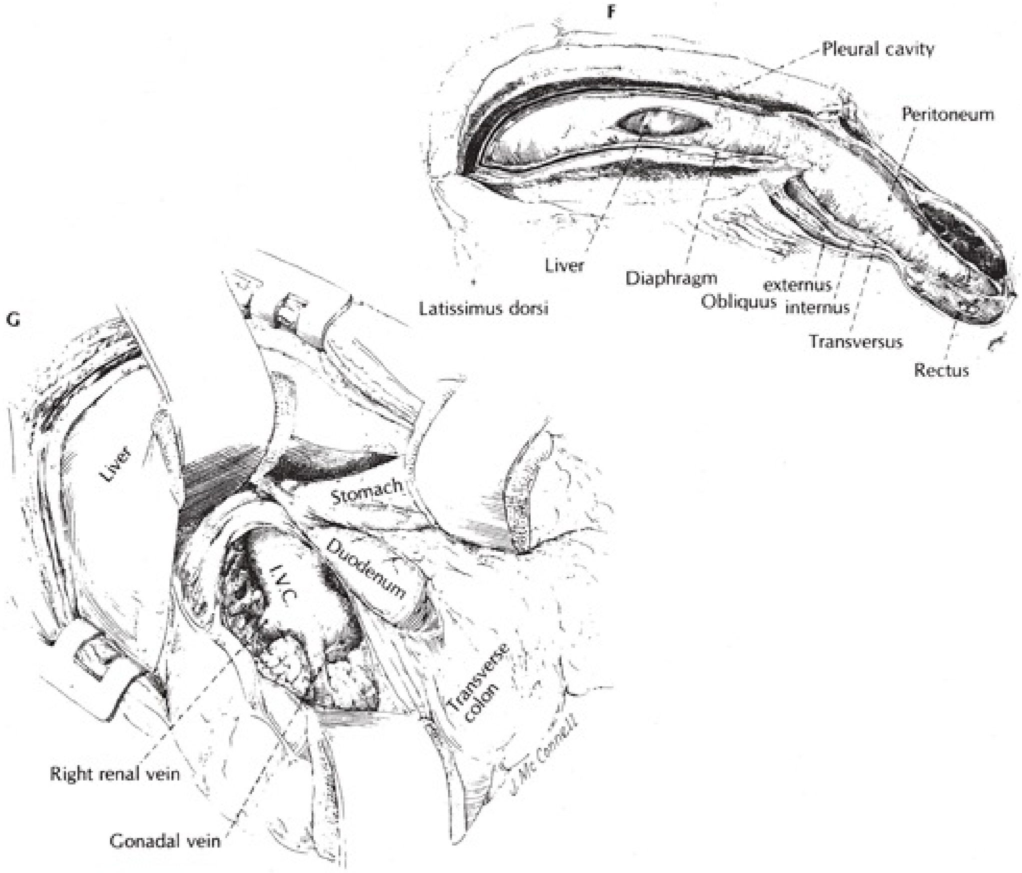

FIGURE 3.4 *(continued)* **F:** The transversus abdominis muscle is divided, exposing the peritoneum with the liver lying beneath it. **G:** The peritoneum is incised, and a rib-spreading retractor (Finochietto) is inserted, enabling upward displacement of the liver (or the spleen on the left) into the thoracic cavity and giving wider access to the posterior peritoneum than in an anterior abdominal incision.

The thoracoabdominal incision is made over the bed of the 8th, 9th, or 10th rib, depending on the surgeon's preference based on patient and tumor characteristics. The incision may be made between the ribs, or a portion of the rib may be removed. The incision is made over the rib beginning at the posterior axillary line. The incision is carried medially across the costal cartilage margin to the midline and then carried down the midline to the umbilicus. Alternatively, the medial portion of the incision may be carried across the midline or combined with a low midline to form a T shape. The latissimus dorsi is divided, and the upper portion of the incision is carried down to the rib. At this point, a rib resection can be performed as previously described (see Fig. 3.3).

The peritoneum may be entered by incising the external and internal obliques, the transversus abdominis, and the ipsilateral rectus abdominis. Next, the costochondral cartilage at the inferior portion of the upper thoracic incision is divided, and the chest is entered along the entire length of the periosteal bed. The pleural space is entered, and care should be taken not to injure the lung. The lung is protected, and the diaphragm is divided in the direction of the muscle fibers, which helps avoid injury to the phrenic nerve. A self-retaining retractor such as a Balfour, Bookwalter, Omnitract, or Finochietto rib spreaders is properly padded and placed to maintain exposure. A radical nephrectomy is then performed.

After completion of the radical nephrectomy, the table flex is removed and the diaphragm is closed with interrupted 2-0 permanent sutures with knots placed on the inferior (peritoneal) side. After a 20Fr to 18Fr chest tube has been inserted through a separate incision and properly positioned, the ribs are reapproximated with 2-0 absorbable sutures. The thoracic portion of the incision is closed with interrupted figure-of-eight 1-0 Vicryl sutures through all layers of the chest wall. The medial portion of the intercostal muscle closure should include at least a small portion of the diaphragm. An intercostal nerve block is administered before closure and may be accomplished by injecting approximately 10 mL of 1.0% lidocaine or 0.5% bupivacaine hydrochloride into the intercostal space of the incision and two interspaces above and below. The costal cartilage can be reapproximated with 0 chromic sutures. This is essential to prevent “clicking” of the ribs, which is oftentimes bothersome to the patient. The posterior rectus fascia, the fascia of the transversus abdominis, and the internal oblique muscles are closed with a running no. 1 PDS. The anterior rectus and the external oblique fascia are closed with either a running or interrupted no. 1 PDS. Skin closure is determined by surgeon preference. The chest tube is secured in place with a 0 silk and taped securely in place.

Transabdominal (Chevron or Anterior Subcostal) Incision

Anterior incisions offer several advantages, including excellent exposure of the renal pedicle and access to the entire intraperitoneal contents and contralateral retroperitoneum. With the patient in the supine position, the operative side is elevated slightly with a flank roll and the patient hyperextended to accentuate the line of incision. An incision is made from near the tip of the 11th or 12th rib on the ipsilateral side two fingerbreadths below the costal margin and extended medially to the xiphoid process. The incision is then gently curved across the midline and as far laterally as necessary for exposure up to near the tip of the contralateral 11th rib.

On occasion, only a portion of the contralateral side will be incised just across the rectus abdominis. The incision is carried down to the anterior rectus fascia, which is then divided (Fig. 3.5). Next, the external and internal oblique fascia and muscles are divided and the fibers of the transversus abdominis split. The rectus muscle and posterior rectus sheath are divided with electrocautery by placing a straight clamp underneath and gently elevating it. The peritoneal cavity is then entered, and the falciform ligament is ligated between two Kelly clamps, divided, and ligated. To facilitate exposure, use of a self-retaining retractor such as a Bookwalter (oval or segmented) or an Omni-Flex is helpful. A radical nephrectomy is then performed.

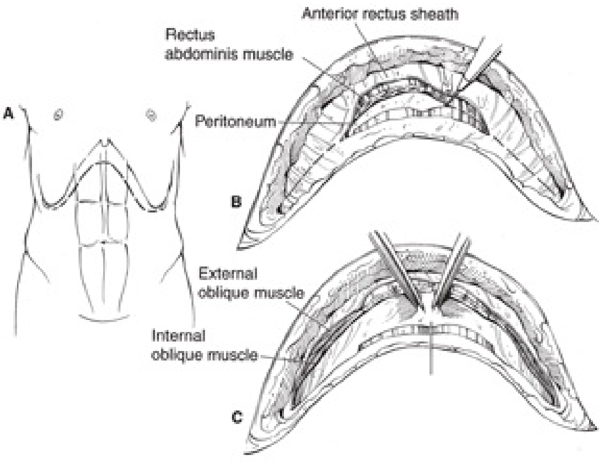

FIGURE 3.5 Transabdominal chevron incision. **A:** With the patient in the supine position and slightly hyperextended, an incision is made two fingerbreadths below the costal margin to just below the xiphoid process and then curved gently down across to the tip of the opposite 11th rib. **B:** The subcutaneous tissue and the anterior rectus sheath are divided bilaterally. A Kelly or an Army-Navy retractor is insinuated under the rectus muscle, and the muscle is divided with electrocautery. **C:** The external oblique and internal oblique muscles are divided, and the transversus abdominis is split. The peritoneal cavity is entered in the midline by tenting up on the peritoneum and incising sharply with Metzenbaum scissors.

Closure of the wound is performed after the table is returned to the horizontal position. The wound is then closed in two layers. The posterior layer consisting of the fascia of the transversus abdominis and the internal oblique laterally along with the posterior rectus fascia medially is closed with two running no. 1 PDS sutures, each starting at the lateral aspect and running medially to the midline. The anterior layer of external oblique and anterior rectus fascia is closed in a similar fashion with no. 1 PDS. On occasion, it is helpful to place a U stitch of no. 1 Prolene at the apex of the chevron incision (at the location of the linea alba) before closure, including the rectus fascia on either side of the midline, securing this suture after the anterior fascia has been approximated. The skin is then closed according to the surgeon’s preference.

Radical Nephrectomy

Irrespective of the choice of incision, certain caveats are universal for the safe and successful completion of a radical nephrectomy. They include a systematic approach with careful mobilization of Gerota fascia and careful vascular control. For a flank approach, the posterior peritoneum lateral to the colon is incised along the length of the descending colon (left side) or ascending colon (right side) and reflected medially. For left-sided exposure, the lienorenal ligament is incised to mobilize the spleen cephalad. On the right side, the hepatic flexure of the colon is mobilized. The ureter is identified and encircled with a vessel loop. The gonadal vein is ligated and divided routinely on the left and when necessary on the right. The plane between the mesentery of the colon and Gerota fascia (often referred to as the gonadal space) is then developed using a combination of sharp and blunt dissection. On the right side, kocherizing the duodenum is essential and exposes the vena cava. Using blunt and/or sharp dissection with electrocautery, the retroperitoneal fat overlying the renal vessels is separated, exposing the renal hilum. It is often helpful to ligate and divide the ureter before attempting to expose the renal hilum to allow for mobilization and upward displacement of the lower pole of the kidney.

The dissection is then carried cephalad along the vena cava (right side) or aorta (left side). On the right side, the right renal vein is identified exiting from the vena cava, isolated, and encircled with a right-angle clamp and a 0 silk suture and tagged. After identification of the renal artery (exposure from the anterior approach may be enhanced by the use of a vein retractor on the renal vein), the artery is dissected free and cleaned for a distance of approximately 2 to 3 cm. With a right-angle clamp, the renal artery is encircled, and 2-0 silk ties are passed (Fig. 3.6). The sutures are then separated and tied, allowing a safe distance for division of the artery, and it is preferable to leave two ties on the aortic side. A right-angle clamp is placed under the artery to be divided and gently elevated, and the artery is cut with either a knife (no. 15 blade) or Metzenbaum scissors. The right renal vein is then ligated with two 0 silk sutures and one additional 2-0 suture ligature on the side of the vena cava. Alternatively, the vessels may be encircled with a vessel loop as opposed to a suture, and the renal artery and vein can then be individually ligated using a stapling device with vascular load.

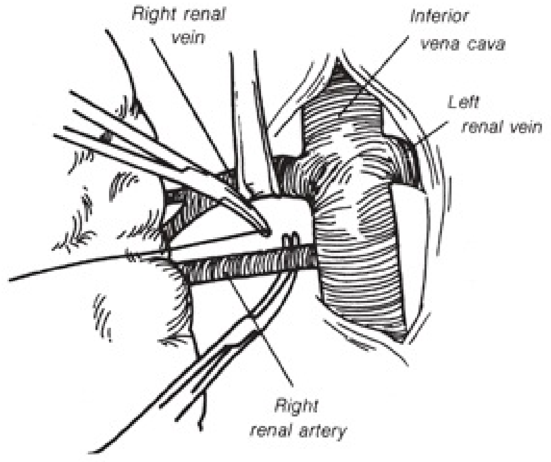

FIGURE 3.6 The right renal artery is identified by palpation beneath the vein. After identification with a right-angle clamp, the artery is cleaned in the same manner as the vein. With a right-angle clamp beneath the artery, a suture is passed on a tonsil clamp to the mouth of the right-angle clamp, and the suture is passed around the artery. (Reprinted with permission from Donohue RE. Radical nephroureterectomy for carcinoma of the renal pelvis and ureter. In: Crawford ED, Borden TA, eds. *Genitourinary Cancer Surgery*. Philadelphia: Lea & Febiger, 1982:101.)

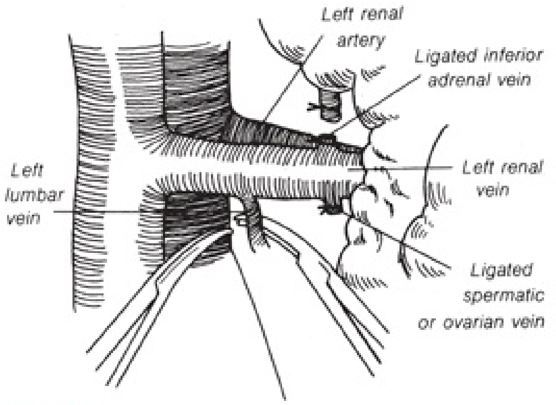
On the left, the renal vein is isolated as it courses over the aorta. The left adrenal and gonadal veins are identified emanating from the left renal vein, and, if present, a posteriorly directed lumbar venous tributary is noted. A right-angle clamp is passed around the renal vein, followed by a 0 silk suture proximal to the tributaries, and tagged. The venous tributaries are then individually ligated and divided with 2-0 or 3-0 silk where necessary, leaving the 0 silk suture on the main renal vein tagged (Fig. 3.7). The left renal artery and vein are then ligated similarly to the technique described previously for the right side. As with the right side, the vessels may alternatively be ligated with a stapling device.



Left renal artery
Ligated inferior adrenal vein
Left lumbar vein
Left renal vein
Ligated spermatic or ovarian vein

FIGURE 3.7 The same technique for ligation is employed on the left side. A suture is passed around the lumbar vein proximally and distally after the vein has been cleaned, and the vein is ligated. Sutures are passed around the main renal vein but are not tied until after the branches have been ligated. The artery is identified above the vein and cleaned, isolated, and ligated, and the proximal end is sutured with a 5-0 cardiovascular silk suture. (Reprinted with permission from Donohue RE. Radical nephroureterectomy for carcinoma of the renal pelvis and ureter. In: Crawford ED, Borden TA, eds. *Genitourinary Cancer Surgery*. Philadelphia: Lea & Febiger, 1982:101.)

Depending on the location of the tumor, prior to control of the renal hilum, Gerota fascia may be initially mobilized posteriorly and superiorly using a combination of sharp and blunt dissection, or this can follow ligation and division of the renal vessels. Small clips placed along the superior and medial border are useful to control any potential bleeding during this portion of the procedure. These should be avoided anywhere near the renal hilum as they may prove problematic if bleeding is encountered. The adrenal hilum is then dissected from caudal to cranial with the aid of either clips or straight clamps and ties. On the right side, the short posteriorly located right adrenal vein should be anticipated as it exits directly from the vena cava. When encountered, the right adrenal vein is isolated, ligated, and divided. The specimen is then delivered and meticulous hemostasis is achieved.

OUTCOMES

Complications

The potential for bleeding during radical nephrectomy necessitates careful patient preparation and preoperative planning to significantly reduce the chance of bleeding. Any medications that interfere with platelet function or clotting should be discontinued. A preoperative hematocrit should be obtained, and a type and screen are in general recommended. In patients with significant anemia or in those in whom significant blood loss is anticipated, a type and cross-match for possible transfusion should be performed. The patient should have either two large-bore peripheral IV lines or a central venous line to allow for rapid infusion of fluids or blood products if necessary.

Bleeding during radical nephrectomy may be from a variety of locations, including the renal hilum, collateral tumor vessels, or adjacent structures. Venous bleeding is usually the most problematic. The first maneuver is to apply direct pressure to the area of bleeding and allow for appropriate resuscitation before additional maneuvers are considered. The point of bleeding is then carefully exposed and controlled by a suture ligature. In the case of vena caval injury, pressure can be applied carefully with sponge sticks, and then an Allis or Satinsky clamp may be carefully placed; a vascular 5-0 or 6-0 Prolene suture is used to oversew the defect. Lumbar veins should be exposed by gentle retraction of the vena cava, appropriately clamped, ligated with vascular silk suture, and divided. Renal artery bleeding may be controlled by direct pressure on the aorta proximally and distally until adequate exposure can be obtained, and the artery is then ligated. Only in certain circumstances will a pedicle clamp or en bloc ligation be necessary.

Adrenal tears may result in significant hemorrhage during radical nephrectomy, in particular on the right side, where the short adrenal vein enters into the vena cava directly posterior. Control of the right adrenal vein should be attempted only after control of the vena cava, adequate exposure, and proper suction. The vein is then ligated with a 2-0 or 3-0 silk tie or vascular Prolene. Venous bleeding from a torn adrenal gland can be oversewn with a running suture or stopped by placement of surgical clips. However, removal of the ipsilateral adrenal may be the most expeditious method of controlling bleeding.

Failure to recognize a rent in the pleura during flank incision will result in a pneumothorax. Filling the flank wound with sterile water or saline and administering a deep inspiratory breath may help recognize small openings in the pleura. Small tears recognized intraoperatively can be managed by closing the pleura with a 3-0 chromic purse-string suture over a 12Fr or 14Fr Robinson catheter. Before it is removed, all air is aspirated from the pleural cavity either by suction or by placing the Robinson catheter under water and administering a deep inspiratory breath. The air is evacuated from the pleural space and the tube is removed while the purse-string suture is simultaneously tied in place. Alternatively, the Robinson catheter can be temporarily left in place with the chromic suture secured and the fascial layers closed around the catheter, which exits from the corner of the wound. Just before skin closure, after all air has been evacuated under water seal as described earlier, the catheter is removed. The latter technique is helpful when the pleura is attenuated or contains multiple small holes that are not easily closed. Alternatively, a 22Fr or 24Fr chest tube may be placed and left to suction and removed postoperatively.

An upright end-expiratory chest X-ray is obtained after all flank incisions to ensure that no significant pneumothorax exists. A small (usually <15%), asymptomatic pneumothorax can be followed conservatively with serial chest X-rays and oxygen therapy. In a symptomatic or large pneumothorax, aspiration of the pleural space using a needle or a central venous catheter (Seldinger technique) introduced just over the rib in the anterior fourth or fifth interspace can be therapeutic. However, if these attempts are not successful, a chest tube should be inserted and placed on suction.

Injuries to the colon during radical nephrectomy are uncommon. In locally advanced tumors with suspected extension into either the colon or mesentery, patients should undergo a preoperative mechanical and antibiotic bowel preparation. Segmental colon resection and primary anastomosis should be possible in most cases. Inadvertent injury to the colon during radical nephrectomy can usually be repaired primarily; however, in situations where there is gross spillage of fecal contents or a devascularized segment, a diverting colostomy should be considered, and a general surgery consultation is advisable. Defects in the mesentery of the colon should be closed to prevent internal herniation of peritoneal contents.

Right radical nephrectomy is also associated with the potential for injury to the duodenum and liver. The duodenum must be carefully mobilized, and care must be taken to properly pad retractors to prevent injury to the bowel and adjacent structures, including the head of the pancreas. The second portion of the duodenum may be injured during a right radical nephrectomy. Duodenal hematomas should only be observed, but rapidly enlarging hematomas will require control of the bleeding, and an intraoperative general surgery consultation should be obtained. Duodenal lacerations should be repaired in multiple layers with interrupted nonabsorbable sutures for the mucosal and serosal layers (1). When possible, an omental wrap may provide additional support, and all patients should be managed with a nasogastric tube during the postoperative period.

Bleeding from superficial liver lacerations may be controlled with Bovie electrocautery or an argon beam electrocoagulator. More significant bleeding may be repaired with absorbable horizontal mattress sutures utilizing a Surgicel or Gelfoam bolster. Deep liver lacerations, which may involve the hepatic ducts, could result in bile leakage and should be drained following repair; an intraoperative general surgical consultation is strongly recommended. Direct invasion of the liver by RCC is rare; however, resection including en bloc removal is possible in selected cases. If a major lobectomy or a partial hepatectomy is to be performed because of either direct extension or major hemorrhage, a general surgeon should be present to assist in its performance.

Splenic injury is one of the most common intraoperative complications during a left nephrectomy, with an incidence as high as 10% in some series. Most superficial lacerations or tears can be managed conservatively without the need for splenectomy. Although minor tears may require only some gentle pressure and the application of a Gelfoam or Surgicel bolster with spray thrombin, closure of a moderate splenic capsular tear is facilitated through the use of nonabsorbable sutures over bolsters of Surgicel. Major hemorrhage secondary to severe splenic lacerations may require splenectomy (13).

The splenic artery and vein are controlled by compressing these structures, which are located in the splenic hilum near the tail of the pancreas. Initially, this can be accomplished manually by compressing the tail of the pancreas between the thumb and forefinger. Once bleeding has been temporarily controlled, the spleen is mobilized by dividing the splenocolic and splenorenal ligaments as well as taking down the peritoneal attachments to the diaphragm. The short gastric vessels are then ligated, and the hilum of the spleen is dissected free from the tail of the pancreas. The splenic artery and vein are ligated and divided. The pancreas should be inspected closely to rule out inadvertent injury. Following splenectomy, patients will have a reduced resistance to *Streptococcus pneumoniae*, *Haemophilus influenzae* type b (Hib), and *Neisseria meningitidis* and should therefore receive pneumococcal and meningococcal vaccines as well as HibTITER postoperatively. Pneumococcal revaccination is required every 6 years, whereas meningococcal and Hib vaccination are not routinely readministered.

RESULTS

Surgical excision remains the only effective and potentially curative therapy for clinically localized RCC. Pathologic staging remains the best prognostic variable in terms of patient survival, and the most commonly used staging system is the 2009 American Joint Committee on Cancer recommendations (TNM) classification (14). The 5-year survival rate for patients with organ-confined tumors treated with radical nephrectomy for T1N0M0 tumors is between 80% and 100%, whereas that for T2N0M0 tumors is 50% to 80% (8). For those patients with T3aN0M0 (tumor invading into the renal vein, perinephric or renal sinus fat), T3bN0M0 (tumor invading into the IVC below the diaphragm), and T3cN0M0 (tumor invading the IVC above the diaphragm or into the wall of the IVC) carcinomas, the 5-year survival rates are 40% to 70%, 30% to 50%, and 20% to 40%, respectively (8). Finally, patients with locally advanced (T4) or node-positive disease (N1-3,M0) have a 5-year survival rate between 0% and 20% (8).

CHAPTER 4 ■ INTRACAVAL TUMORS

WILLIAM C. FAUST AND JOHN A. LIBERTINO

A unique feature of renal cell carcinoma (RCC) is its predilection to involve venous structures. Tumor extension can grow intraluminally along the renal vein and propagate into the inferior vena cava (IVC) up to and including the right atrium and occurs in 4% to 10% of cases. Although this does worsen the prognosis, if tumor spread has not occurred to the lymph nodes or otherwise metastasized, these tumors can be controlled surgically using a variety of approaches.

STAGING

In 2010, the American Joint Committee on Cancer published updated guidelines on RCC staging. In those guidelines, as pertains to intracaval tumors, pathologic T3a lesions are those that involve the renal vein or its segmental branches or invades renal sinus or perirenal fat. Pathologic T3b lesions are those that involve the IVC with the most proximal extent below the diaphragm, and T3c lesions are those that extend above the diaphragm. These classifications were modified according to research that showed that proximal extent of tumor thrombus had significant effect on cancer-specific survival (1) and has since been confirmed in larger multi-institutional studies (2).

Various other surgical staging systems have been proposed to define the extent of tumor thrombus and aid in surgical planning including the Neves system, the Novick system, and the Hinman system. At our institution, the Neves system is found to be a rationally organized and commonly used. It is broken down by level of cephalad extent of tumor (Fig. 4.1).

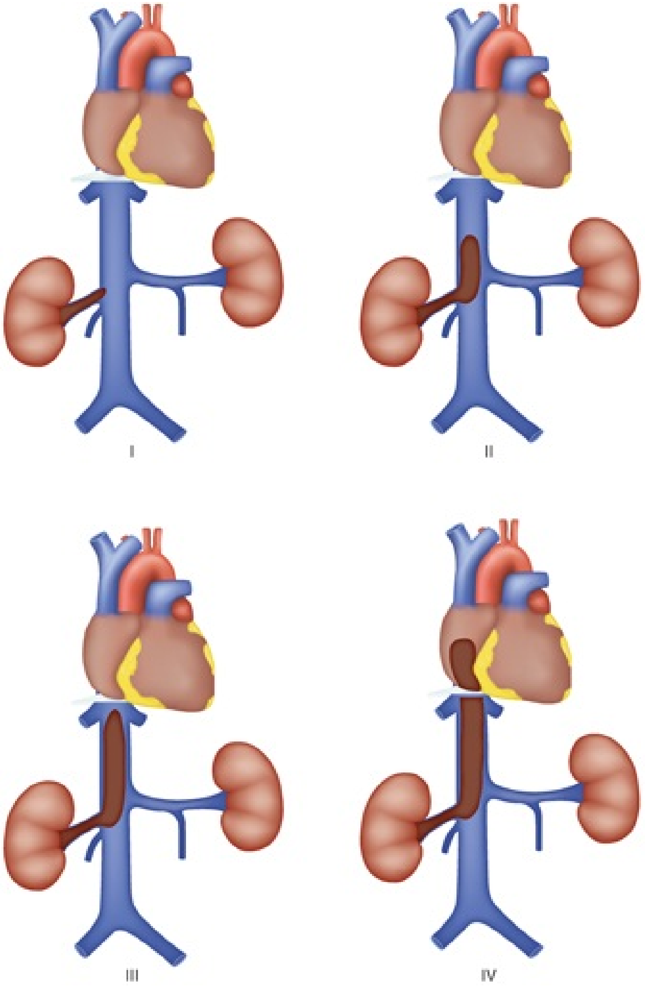

FIGURE 4.1 Classification of venous tumor thrombus extension—level I renal vein, level II infrahepatic IVC, level III retrohepatic IVC, and level IV supradiaphragmatic IVC. (Adapted with permission from Wang GJ, Carpenter JP, Fairman RM, et al. Single-center experience of caval thrombectomy with renal cell tumor extension into the inferior vena cava. *Vasc Endovascular Surg* 2008;42(4):335–340. Copyright © 2008, SAGE Publications.)

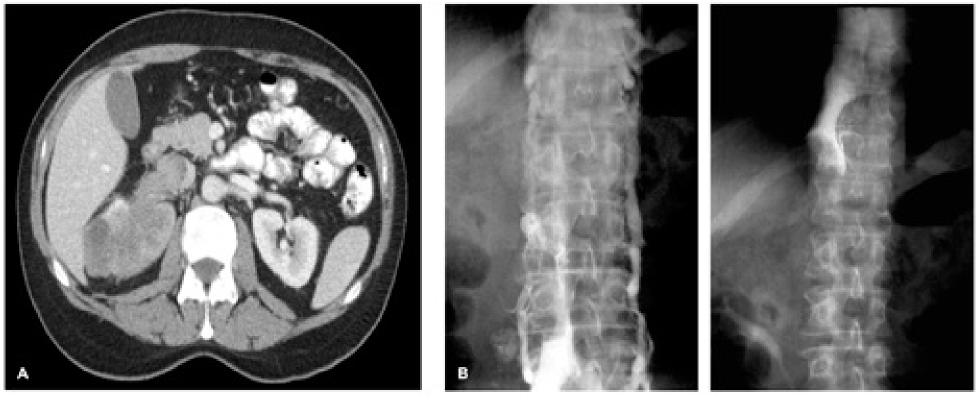
DIAGNOSIS

Preoperative imaging is critically important to plan the surgical approach and determine the need for cardiopulmonary bypass prior to resection. A variety of modalities exist to accurately diagnose the extent of tumor thrombus. Three-dimensional multiplanar computerized tomography can provide not only information about the extent and level of tumor thrombus but also the presence of collateralizations, lumbar venous anatomy, renal arterial anatomy, local surgical staging, and anatomic factors. Magnetic resonance venography is another useful technique routinely used to evaluate venous thrombus involvement (Fig. 4.2A–C). Transthoracic and transabdominal ultrasound can also be useful in patients who cannot undergo abdominal imaging. Finally, for patients undergoing renal artery angioembolization prior to resection, traditional inferior venacavography can be performed simultaneously. This, however, has limited benefit for evaluating the cephalad extent in cases of complete occlusion of the IVC.



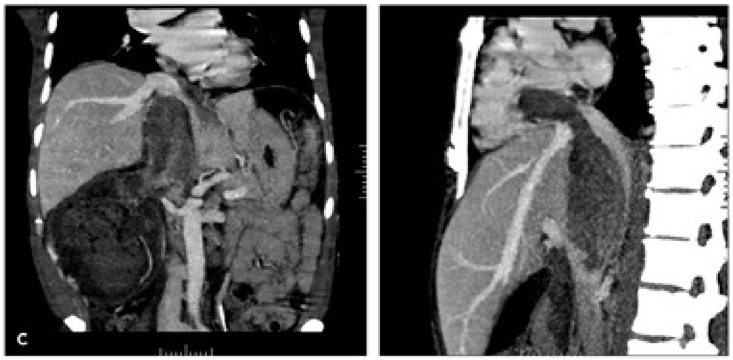


FIGURE 4.2 A: Contrast-enhanced upper abdominal computerized tomography with thrombus seen in renal vein. **B:** Preoperative cavogram demonstrating filling defect at the T10 level consistent with tumor thrombus in a patient with a large right renal mass. **C:** Coronal and sagittal magnetic resonance imaging scan demonstrates tumor extending to the level of the diaphragm (left) and further into the right atrium (right).

PREOPERATIVE ANGIOEMBOLIZATION

Renal artery embolization has evolved over the years from initially a palliative procedure to a preoperative adjunct to resection of locally advanced renal tumors. Preoperative renal angioinfarction facilitates dissection of the renal tumor as a result of local tissue edema from hypoxia and tissue necrosis. It also limits the amount of manipulation on the renal vein prior to resection because the vein may be transected prior to controlling or occluding the renal artery. It has been postulated that preoperative angioinfarction may decrease the extent of tumor thrombus while minimizing venous collateralization (3). It is the practice of the senior author to routinely perform preoperative angioembolization prior to surgical resection for RCC with venous thrombus involvement.

SURGICAL APPROACH

Surgical approaches to intracaval tumor thrombi are subject to extent of IVC involvement, body habitus, prior surgical history, and surgeon comfort. The goal of any surgical approach should be to maximize exposure of the great vessels and involved renal tumor. Tumors that involve the renal vein only typically can be managed with a thoracoabdominal incision in a fashion similar to organ-confined tumors. For right-sided infrahepatic tumors, a thoracoabdominal approach can still be used and provides adequate exposure of the infrahepatic IVC. Left-sided infrahepatic, all retrohepatic, and all supradiaphragmatic IVC tumor thrombi are approached using an upper abdominal chevron incision with the addition of either a median sternotomy or more recently a mini-access right fourth rib parasternal incision to access the right atrium and supradiaphragmatic IVC.

After induction of general anesthesia and intubation intraoperative monitoring is performed by placing a right internal jugular central venous MAC two-lumen catheter. Through this, a Swan-Ganz pulmonary artery catheter is introduced and floated into the pulmonary artery. Two large-bore peripheral intravenous lines are placed and if peripheral access is poor, a second 9Fr central venous catheter is placed in the contralateral great vessels. A Belmont Rapid Infuser is available in cases of large volume blood loss, and two Cell Saver devices are used to recycle blood products.

Prior to incision, transesophageal echocardiography is performed to evaluate for tumor thrombus propagation that would necessitate cardiopulmonary bypass. Accurate intraoperative hemodynamic monitoring is critical during the procedure, especially when using cardiopulmonary bypass. Another useful device for intraoperative monitoring is the real-time electrical impedimetric monitoring of blood coagulation factors, which allows for continuous resuscitation of blood loss and coagulopathy by anesthesia.

For tumor thrombus at or above 2 cm below the hepatic vein confluence, cardiopulmonary bypass and deep hypothermic cardiac arrest are routinely used to ensure a bloodless field in resecting these tumors. Although this approach is associated with risks of systemic anticoagulation and central nervous system impairments, it is the opinion of the senior author that these risks are justified to provide adequate access of the cephalad portion of tumor thrombus to prevent embolization or inadvertent disruption of the caval–atrial junction in milking techniques.

Infrahepatic Inferior Vena Cava Thrombus

The patient is positioned in the supine position with arms extended at 90 degrees. After induction of general anesthesia and placement of anesthetic intraoperative monitoring device, a Foley catheter is placed and the abdomen from the xiphoid to pubis is clipped free of hair and prepped with 2% chlorhexidine ChloraPrep solution from the lower rib cage to the pubis.

For right-sided tumors, a thoracoabdominal approach is used. For left-sided tumors, a chevron incision is made from the tip of the 11th rib to the tip of the contralateral 11th rib. For both right- and left-sided tumors, the initial portion of the procedure is controlling the IVC with limited manipulation to prevent possible dissemination of tumor thrombus. The peritoneum is entered, and the ascending colon and hepatic flexure are mobilized medially along the line of Toldt. The duodenum is kocherized exposing the right renal vein and IVC. A Bookwalter retractor is the used to provide maximal exposure. A series of short body wall retractors are placed at the 9 o’clock, 6 o’clock, and 4 o’clock position of the wound to retract oblique musculature, subcutaneous tissue, and skin. The duodenum and colon are retracted medially by using a malleable retractor with a moistened laparotomy pad. The liver is retracted cephalad either using a Harrington retractor or malleable retractor with laparotomy pads. Care must be taken to avoid damage to the porta hepatis.

The IVC is then exposed. The cephalad extent of tumor thrombus is palpated with care to prevent embolization from overzealous palpation. The right gonadal vein is identified and ligated between silk ties to prevent troublesome back bleeding during cavotomy and thrombectomy. For tumor at the junction of the renal vein and IVC or with a small caval extension, a DeBakey clamp is applied to the IVC, the thrombus removed, and the IVC is reconstructed (Fig. 4.3A–D). With larger caval extension, circumferential dissection of the IVC as well as the right and left renal vein is carried out so as to provide for placement of Rummel tourniquets. Lumbar veins as well as minor hepatic veins are identified and ligated to prevent back bleeding. Many times, renal angioembolization will produce an inflammatory response that precludes the need for arterial mobilization, and ligation of the renal artery is deferred until after IVC thrombectomy is performed. Complete occlusion of the renal artery is confirmed, however, by visually inspecting the renal vein as well as palpating the renal artery for persistent flow. If any doubt exists regarding the completeness of arterial occlusion, then renal artery dissection must take place prior to cavotomy to prevent unnecessary bleeding.

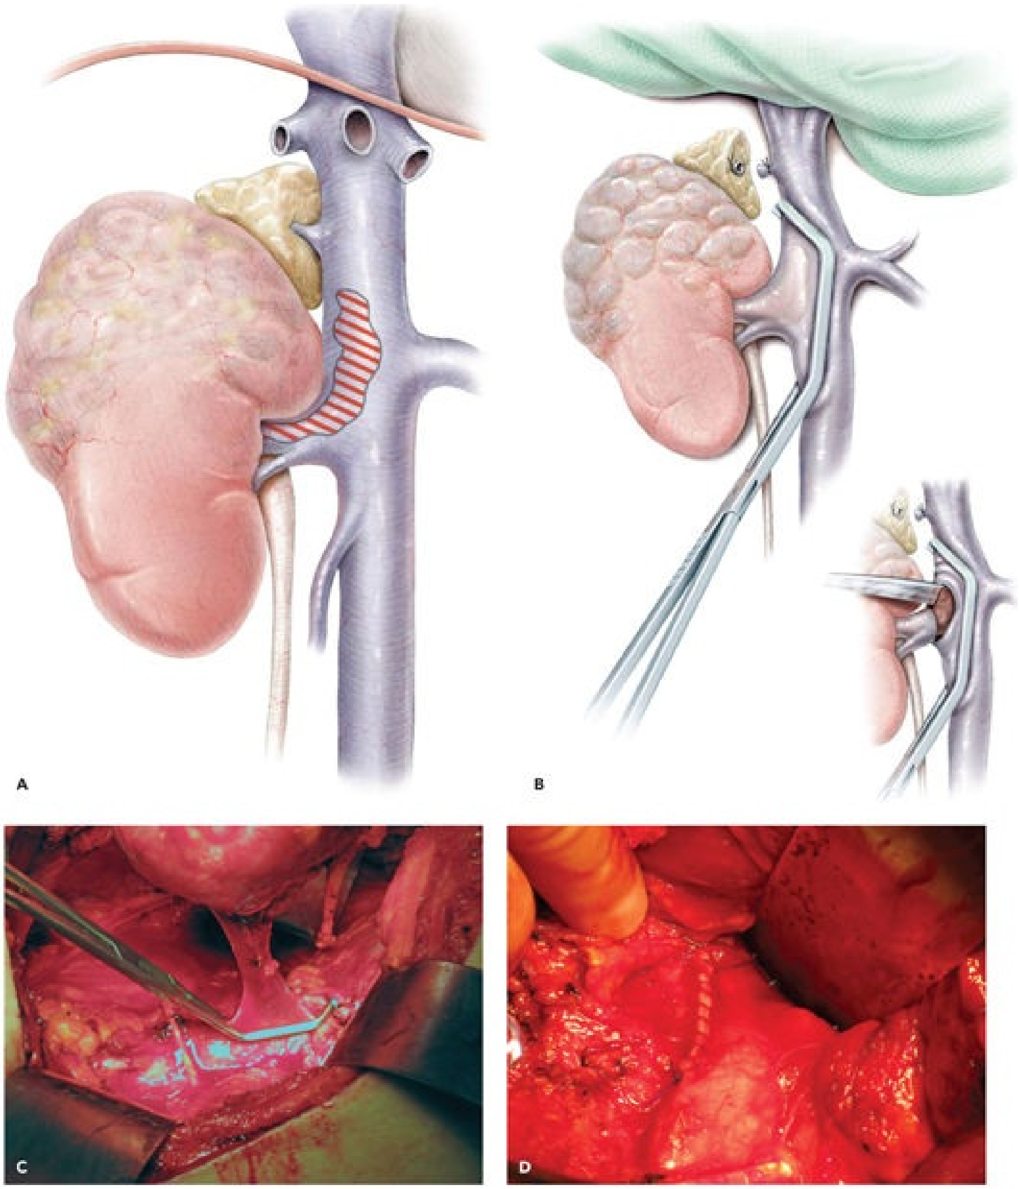

FIGURE 4.3 A and B: Removal of small intracaval tumor thrombus by side clamping of junction between renal vein and IVC. (Reprinted with permission from Bachmann A, Seitz M, Graser A, et al. Tumour nephrectomy with vena cava thrombus. *BJU Int* 2005;95:1373–1384. Copyright © 2005, John Wiley and Sons.) C and D: DeWeiss clamp applied to sidewall of cava for removal of renal vein thrombus with small intracaval extension.

Once adequately exposed, Rummel tourniquets are placed on the cephalad extent of the IVC, the contralateral renal vein, and caudal portion of the IVC (Fig. 4.4A–C). They are the occluded in rapid succession in the order of cephalad, vein, and caudal. An anterior longitudinal cavotomy is performed using curved scalpel followed by Potts scissors. This incision follows a curvilinear tract to incorporate the ipsilateral renal ostium, which will be removed en bloc with the complete specimen. The thrombus is then freed from the caval wall using Penfield neurosurgical spatulas. Any areas of caval wall invasion must be resected. If <50% of caval wall is involved, this may then be closed primarily. In cases where >50% of the wall is involved, then reconstruction using either synthetic polytetrafluoroethylene vascular patch or with a variety of bioprosthetic or autologous materials (pericardium, saphenous vein graft, bovine pericardium). The IVC is gently flushed with heparinized saline and evaluated for any residual fragments. The cavotomy is closed with continuous 4-0 polypropylene sutures. The inferiormost Rummel tourniquet is released first to flush the cava of blood and limit the risk of air embolus.

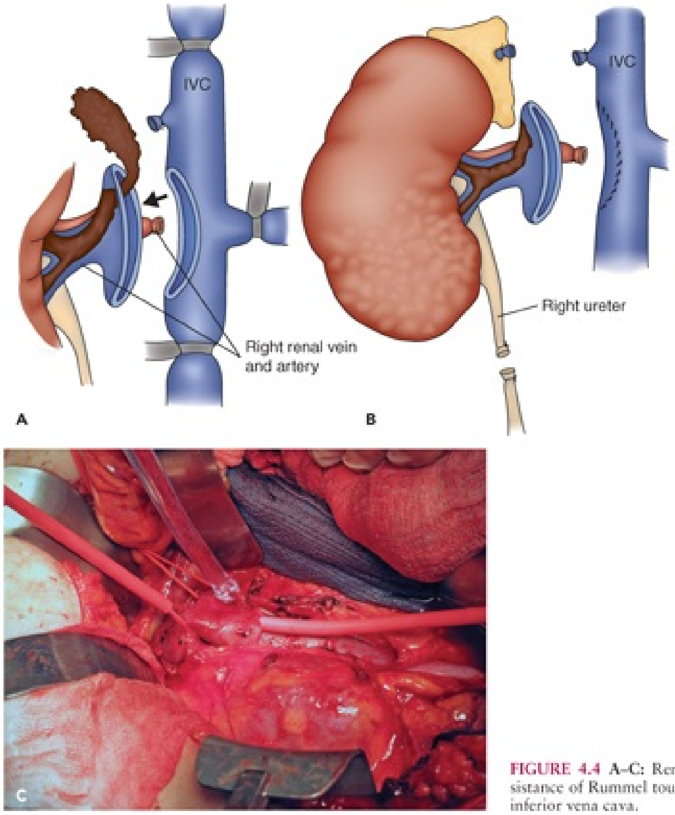

FIGURE 4.4 A–C: Removal of infrahepatic tumor thrombus with assistance of Rummel tourniquets avoiding cardiopulmonary bypass. *IVC*, inferior vena cava.

Once the tumor thrombus is removed from the vena cava, radical nephrectomy and lymphadenectomy (if indicated) can proceed. For tumors of the right kidney, exposure is unchanged. Now that the vein has been divided from the IVC, the right renal artery should be readily exposed. The artery is then divided distal to the angioembolization coils with two clips and silk suture ligature. The kidney is then mobilized within Gerota fascia posteriorly down to the psoas fascia taking as much pararenal fat as possible. Superiorly, the kidney and adrenal are mobilized from the hepatorenal ligamentous attachments. A large curve-shaped DeBakey clamp is passed along the superior portion of the adrenal gland to gain control of the phrenic vessels, which are divided and ligated using a 0 silk suture. Finally, the ureter is ligated with 2-0 Vicryl or silk suture and the specimen removed en bloc.

For left-sided tumors, once the left renal vein is disarticulated from the IVC and thrombus removed, the left renal pedicle must be controlled. To achieve this, the splenic flexure and the descending colon are mobilized, and the descending colon is reflected medially with care taken to avoid injury to the tail of the pancreas, or spleen. The left renal hilum is identified. Draining into the left renal vein, the adrenal vein and gonadal veins are identified and ligated with 0 silk suture. Once the vein is freed from its surrounding tributaries, the left renal vein is delivered from its insertion point on the IVC to the left side of the retroperitoneal space. To do this, a finger is placed along the left renal vein over the aorta. The surgeon can carefully palpate the anterior surface of the aorta and the inferior surface of the superior mesenteric artery (SMA) as the vein crosses beneath this latter structure. With gentle manual traction, the vein is delivered safely from between these vessels. The kidney is then mobilized within Gerota fascia. The adrenal gland is mobilized en bloc and superior attachments are divided using a large C-shaped clamp and silk suture ligature. The renal artery is next divided. We recommend approaching the left renal artery posteriorly to avoid inadvertent ligation of the SMA. To do this, the kidney is elevated medially on its vascular pedicle and the artery is identified posterior to the left renal vein and lateral to the left side of the aorta. The artery is divided with large Hem-O-Lok clips and 0 silk suture ligature. Occasionally, tumor-associated inflammatory changes might preclude precise vascular isolation, and a vascular stapler can be used. The ureter is then ligated and the kidney and adrenal gland, contained within Gerota fascia, are removed.

Retrohepatic Inferior Vena Cava Thrombus

Tumors that are reaching 2 cm below the hepatic veins may still be approached without circulatory bypass provided that proximal control of the IVC can be obtained (Fig. 4.5A). To access the retrohepatic IVC, the Langenbuch maneuver is performed by incising the peritoneal reflections attaching the liver to the diaphragm, namely, the coronary ligament and right or left triangular ligaments, the ligamentum teres, and the falciform ligament. This allows mobilization of the liver cephalad and medial exposing the retrohepatic cava (Fig. 4.5B). Minor hepatic veins may be divided using silk ties. Rummel tourniquets are applied, and the caval thrombus extracted (Fig. 4.5C). The porta hepatis is accessed via the foramen of Winslow and prior to cavotomy, the Pringle maneuver can be performed if necessary to prevent significant hepatic venous inflow and blood loss.

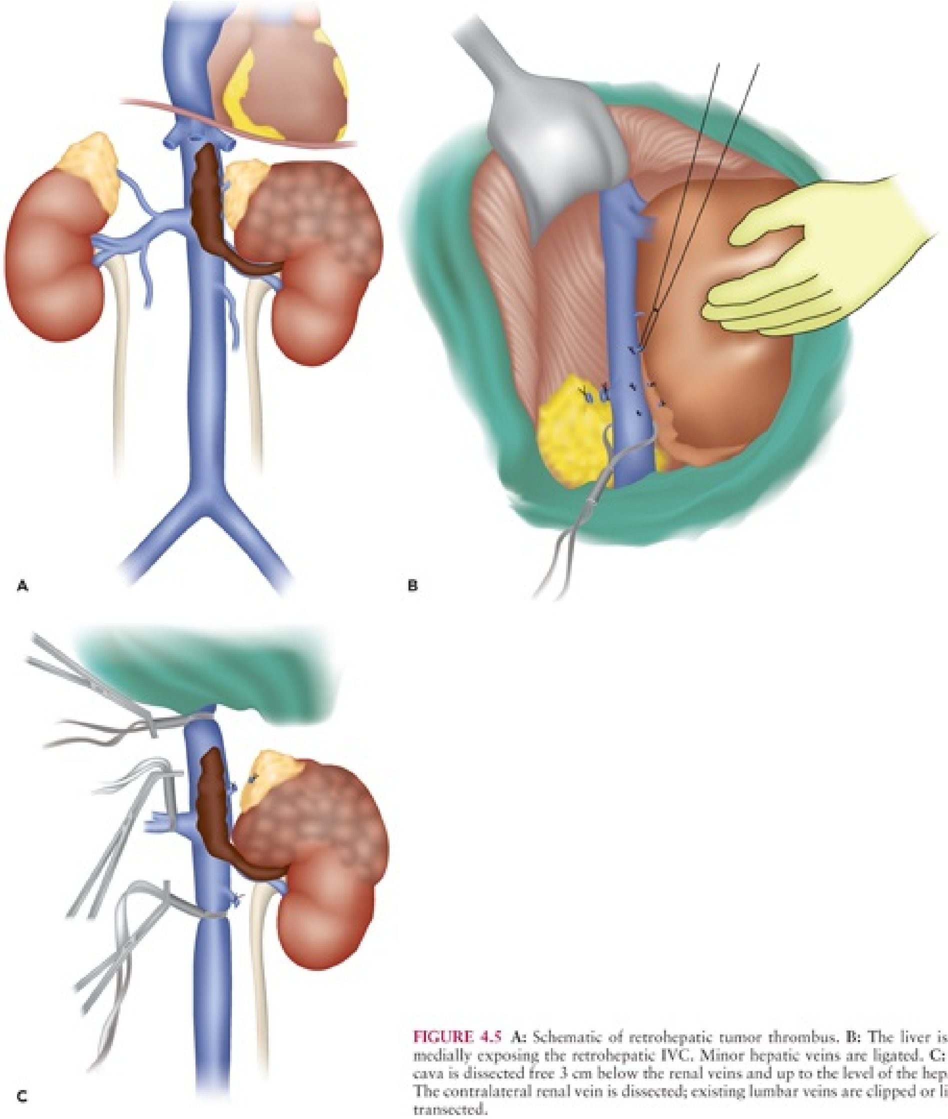

FIGURE 4.5 **A:** Schematic of retrohepatic tumor thrombus. **B:** The liver is retracted medially exposing the retrohepatic IVC. Minor hepatic veins are ligated. **C:** The vena cava is dissected free 3 cm below the renal veins and up to the level of the hepatic veins. The contralateral renal vein is dissected; existing lumbar veins are clipped or ligated and transected.

Supradiaphragmatic and Atrial Thrombus

When tumor thrombus reaches above the level of the diaphragm (Fig. 4.6A), then cardiopulmonary bypass with deep hypothermic circulatory arrest is used to provide maximal exposure to the supradiaphragmatic cava and right atrium and allow for tumor resection in a bloodless field. Two approaches have been developed to accomplish this maneuver, the traditional median sternotomy and the minimal access technique.

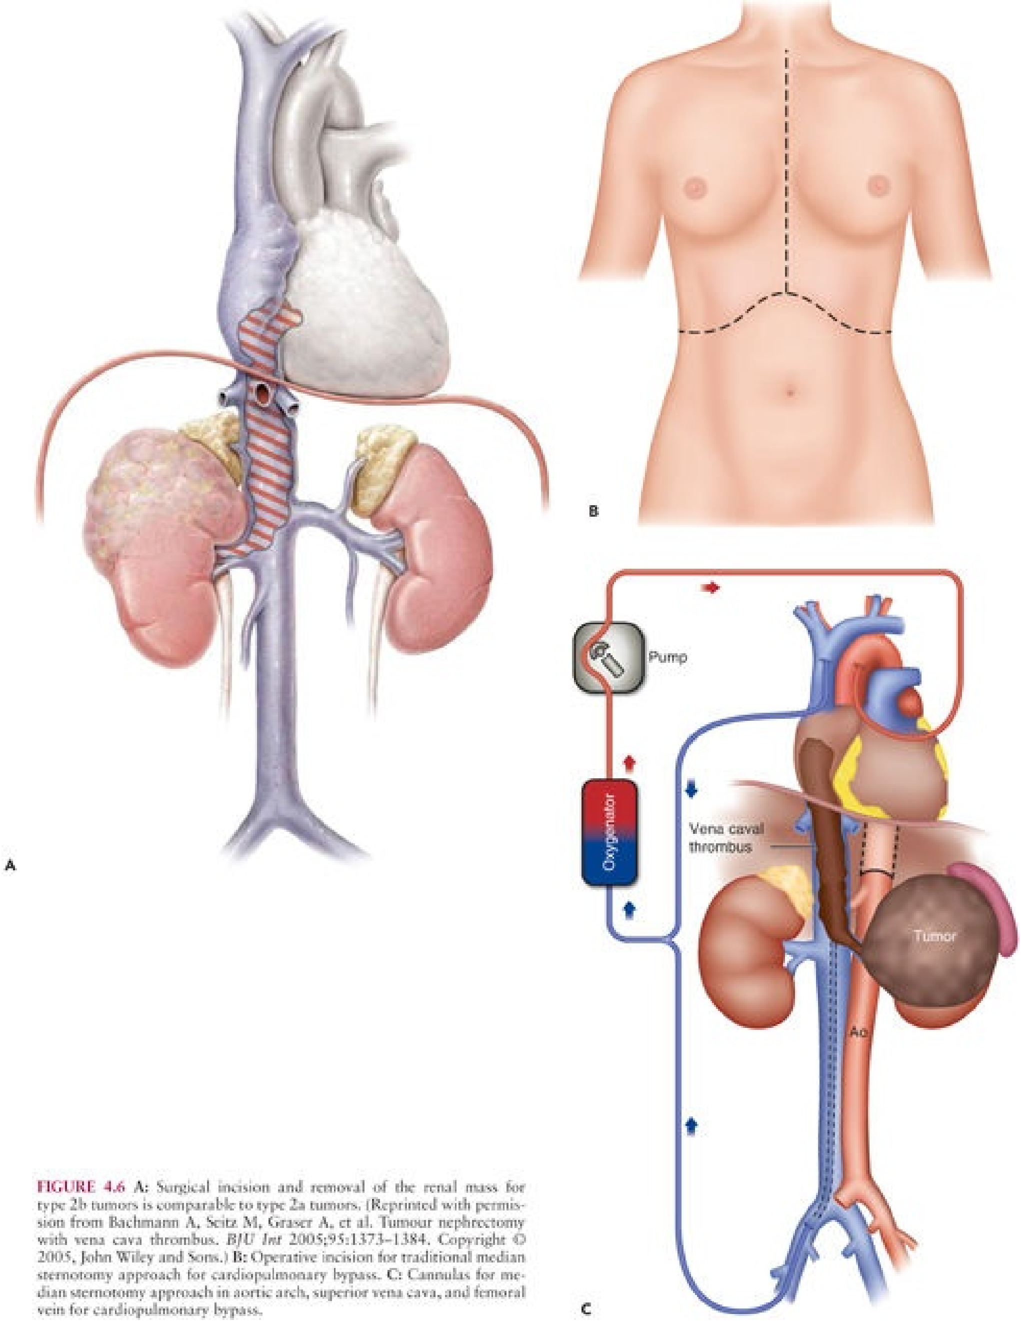

FIGURE 4.6 **A:** Surgical incision and removal of the renal mass for type 2b tumors is comparable to type 2a tumors. (Reprinted with permission from Bachmann A, Seitz M, Graser A, et al. Tumour nephrectomy with vena cava thrombus. *BJU Int* 2005;95:1373–1384. Copyright © 2005, John Wiley and Sons.) **B:** Operative incision for traditional median sternotomy approach for cardiopulmonary bypass. **C:** Cannulas for median sternotomy approach in aortic arch, superior vena cava, and femoral vein for cardiopulmonary bypass.

Traditional Median Sternotomy

As with infrahepatic IVC thrombus, the initial steps involve isolating and exposing the IVC. A chevron incision is made, the ascending colon is reflected medially, and the duodenum is kocherized. The liver is displaced cephalad exposing the retrohepatic portion of the IVC. The contralateral renal vein and caudal portion of the IVC are dissected free with again minimal traction on the IVC to prevent embolization. Meticulous hemostasis is obtained prior to systemic heparinization.

A midline sternal incision is made by the cardiothoracic team, and pericardial access is obtained. Systemic heparinization with low-molecular-weight heparin is administered, and the pericardium is suspended from the wound edges, and arterial and venous cannulas are placed in the ascending aorta and the right atrial appendage. Once vascular access is obtained, the patient is cooled and cardiopulmonary bypass is initiated.

Minimal Access

To limit the morbidity associated with a median sternotomy incision, a minimally invasive approach has been developed based on the approach originally described for aortic valve replacement by Cosgrove in 1996 (4,5). A right infraclavicular incision is made and carried down through subcutaneous tissues and pectoralis musculature. This right axillary artery is encountered and encircled with vessel loops proximally and distally. A right parasternal 2-inch incision is made over the fourth costal cartilage. This incision is carried down through the pectoralis musculature. The fourth costal cartilage is resected and the mammary artery and vein are ligated between ligatures and clips. The pericardium is opened and holding sutures of 0 silk are placed (Fig. 4.7). Systemic heparinization with low-molecular-weight IV heparin is administered. An 8-mm arteriotomy in the right subclavian artery is made and a Dacron tube graft is sutured in place using a running 5-0 Prolene suture. A purse-string suture of Ethibond is placed in the right atrium, and a two-stage venous cannula is introduced into the atrium and directed into the superior vena cava to avoid tumor thrombus in the IVC. Once vascular access is obtained, the patient is cooled to 17°C and formal circulatory arrest is commenced by administering cardioplegic solution. The patient is exsanguinated, and the head is protected and cooled in bags of ice.

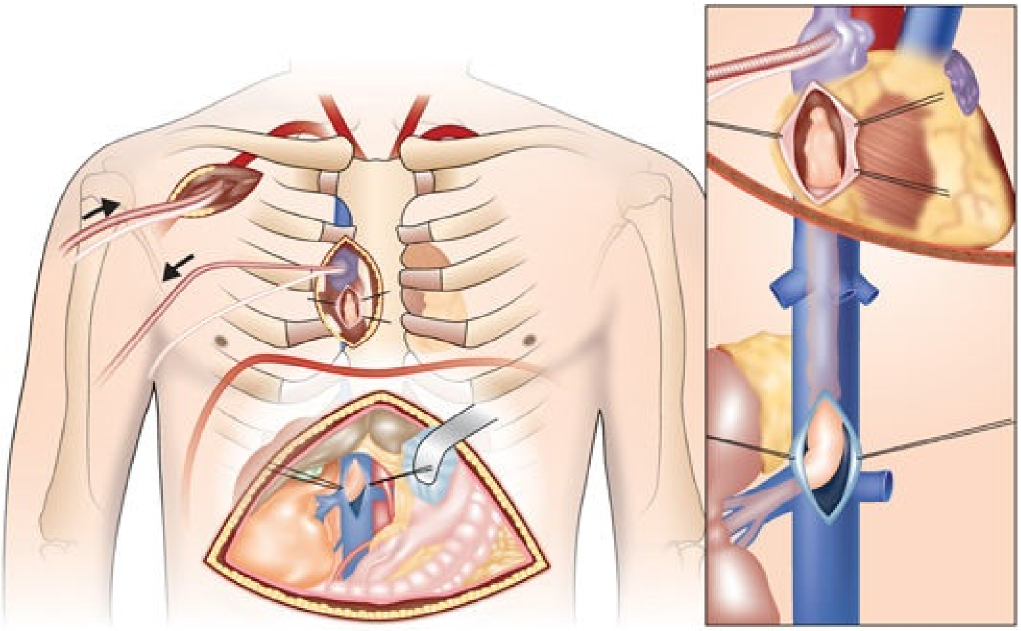

FIGURE 4.7 Schematic of minimal access technique for cardiopulmonary bypass.

A formal right atriotomy is made as well as an incision in the anterior vena cava from below. Tumor thrombus is removed from above and below by the cardiothoracic and urologic teams working in concert (Fig. 4.8). Once thrombus is removed, a gauze pad can be passed through the atriotomy from above down into the cavotomy below using a “shoe shine” maneuver to clear all tumor thrombus. Flexible cystoscopy and Fogarty balloons can be used to ensure complete thrombus removal. Once thrombectomy is complete, and the cavotomy and atriotomy is closed, the patient is rewarmed and the heart is cardioverted to regular rhythm. Protamine is used to reverse the heparin effects, and while rewarming takes place, the nephrectomy portion is completed as mentioned earlier. The right atrium is closed with prior purse-string suture and reinforced with pledgeted mattress sutures of Prolene. The arterial graft is amputated and the stump oversewn with a double layer of running 4-0 Prolene. A Blake drain is then placed in the pericardial space and a 28Fr chest tube is placed in the right pleural space. The fourth costal cartilage is reaffixed with a figure-of-eight Vicryl stitch, and the remainder of musculature, subcutaneous tissue, and skin are reapproximated with absorbable Vicryl sutures.

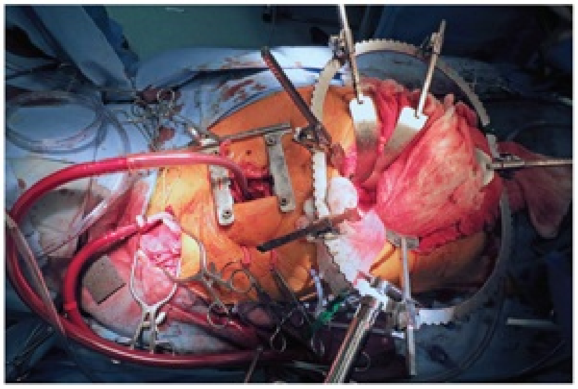

FIGURE 4.8 Minimal access incision for cardiopulmonary bypass using right parasternal and right supraclavicular incisions. Note the abdominal chevron incision below.

Venovenous Bypass

In patients with minimal supradiaphragmatic thrombus, venovenous bypass with a caval–atrial shunt is one alternative to cardiopulmonary bypass. Venovenous bypass can also be useful in patients who cannot tolerate IVC clamping or require significant IVC reconstruction. The vena cava is controlled at the infrarenal level and at the level of both renal veins as well as proximal tourniquet around the intrapericardial portion of the IVC. Cannulas can be placed in the right atrium or axillary vein and the femoral veins and bypass initiated prior to cavotomy. Bleeding from the hepatic venous system is managed with a Pringle maneuver or cross-clamping the hepatic veins. The Pringle maneuver can be used for up to 45 minutes before liver metabolism is significantly affected. Although this technique avoids cardiopulmonary bypass and circulatory arrest, the incidence of hepatic venous bleeding can occasionally be significant.

NEOADJUVANT TARGETED THERAPY

One interesting approach to managing intracaval tumors in RCC is to use neoadjuvant tyrosine kinase inhibitors to downstage the tumor and avoid the need for cardiopulmonary bypass. Horn et al. (6) have reported the use of neoadjuvant sunitinib in five patients with level III and level IV RCC. In their series, four patients had downstaging of their disease, and one case negating the need for cardiopulmonary bypass. Individual case reports of neoadjuvant sunitinib have also shown reduction in tumor size and stage (Fig. 4.9) (7). However, these results have yet to be validated in other larger series and conflicting reports of disease progression despite neoadjuvant targeted therapy puts these findings into perspective (8). However, the concept of neoadjuvant therapy to facilitate surgical removal remains intriguing.

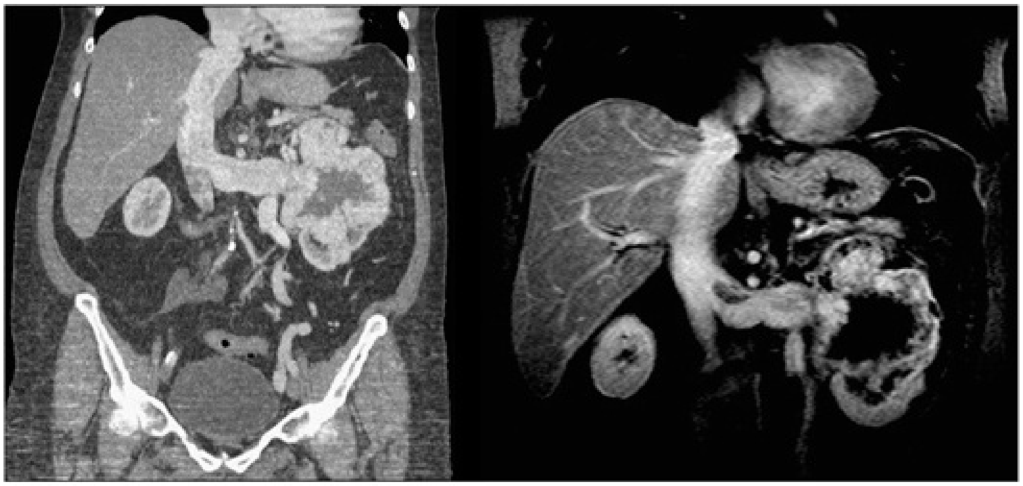

FIGURE 4.9 Preoperative downstaging of RCC with IVC tumor thrombus using neoadjuvant tyrosine kinase inhibitor. Prior to therapy, an atrial tumor thrombus (left) is reduced to an infrahepatic thrombus obviating the need for cardiopulmonary bypass and circulatory arrest.

COMPLICATIONS

Given the extensive nature of both the abdominal and thoracic portions of intracaval tumor thrombectomy and radical nephrectomy, even in experienced hands complications are not uncommon. The most common types of complications include bleeding complications, pulmonary complications, and abdominal complications.

Pulmonary complications include pneumonia, atelectasis, pulmonary embolus, and injury to lung parenchyma either using thoracoabdominal incisions or in accessing the right atrium and intrathoracic cava. Postoperative pulmonary toilet with incentive spirometry, bronchodilators, and chest physiotherapy can help prevent atelectasis and pneumonia. When cardiothoracic surgical involvement is employed, then standard 26Fr chest tubes are placed in the pleural space and removed on postoperative day 2. When a thoracoabdominal incision is used only, then smaller Dart chest tubes are employed. We have found that when compared to traditional median sternotomy, the minimal access technique is associated with significant decreases in postoperative complications for patients undergoing cardiopulmonary bypass and circulatory arrest, particularly pulmonary complications including prolonged mechanical ventilation (9).

Vascular complications are not uncommon given the nature of the vascular dissection. When cardiopulmonary bypass is not employed, lumbar venous back bleeding from uncontrolled lumbar vessels can be significant at times. If this occurs, an Allis clamp can grasp the open vessel intraluminally and a counterclockwise twist can be used to stop acute bleeding. A Fogarty balloon can also occlude the lumen of an open lumbar vessel. Avulsed lumbar vessels can be controlled using a pediatric hemostat and pediatric right angle to control the open vessel until it can be oversewn with 3-0 silk.

It is critical to emphasize the importance of understanding the proximity of the SMA to the left renal vein, particularly in left-sided tumors, as ligation of this vessel will carry dire consequences. For this reason, we advocate identifying the left renal artery from a posterior approach when ligating it so as not to misidentify the SMA.

Abdominal complications can include injury to any adjacent structures such as the liver, spleen, pancreas, and duodenum as well as colon or small bowel. These complications are occasionally unavoidable when large renal tumors abut or invade contiguous structures. Liver lacerations are best managed by using the argon beam coagulator to the injured site. The same may apply to small lacerations of the spleen; however, splenectomy may be required when larger injuries occur. Pancreatic injuries recognized at the time of surgery require that the capsule of the pancreas be closed with nonabsorbable suture and drained with a Jackson-Pratt device. Delayed recognition of a pancreatic leak is managed by a percutaneous drain, hyperalimentation, and somatostatin until the drainage subsides.

OUTCOMES

Given the complexity of these cases, it is not surprising that perioperative mortality does occur with perioperative mortality rates that range from 5% to 10% in contemporary series. When nodal metastases are involved, overall survival is severely impacted. Published series have seen survival rates ranging from 5% to 28%. When nodal or distant metastases are absent, however, then overall survival rates are reasonable, ranging from 40% to 60% of patients. In our series, we have found 5-year cancer-specific survival rates on average of 53% with 65% survival of patients with isolated renal vein involvement to 40% survival of patients with advanced stage intracaval tumor thrombi.

CHAPTER 5 ■ DONOR NEPHRECTOMY: LAPAROSCOPIC TECHNIQUES

JIM C. HU AND ERIC G. TREAT

According to the National Institute of Diabetes and Digestive and Kidney Diseases, more than 871,000 people were being treated for end-stage renal disease, with 398,861 having some form of dialysis and 172,553 having a working transplanted kidney at the end of 2009 (1). The Scientific Registry of Transplant Recipients (SRTR) reported 16,811 kidney transplants were performed in 2011; 5,768 were from living donors (2).

Laparoscopic donor nephrectomy was first performed in 1995 (3). The generally accepted benefit of decreased hospital stay and postoperative pain associated with laparoscopic versus open donor nephrectomy may facilitate the acceptance of a unique surgery that leaves the patient in worse health postoperatively.

DIAGNOSIS

Strict guidelines and international standards have established that all donors have complete medical and psychosocial evaluation as well as evaluation by an independent donor advocate (4,5,6). At our institution, patients routinely see a nephrologist, surgeon, psychiatrist, and social worker. Medical evaluation includes a complete history and physical: urine tests: urinalysis, urine culture, 24-hour urinary protein excretion, and glomerular filtration test estimates; blood tests: complete blood count, coagulation screen (partial thromboplastin time, prothrombin time), serum electrolytes, urea, creatinine, liver function tests, fasting serum glucose, glucose tolerance test, lipid panel, and alkaline phosphatase; serology testing: HIV, hepatitis B and C, tuberculosis, syphilis, Epstein-Barr virus, and cytomegalovirus; compatibility testing: blood group type, human leukocyte antigen typing, and cross-matching; cardiopulmonary workup: chest X-ray and electrocardiogram. Other testing is performed as indicated. Every screened donor eventually has a multidetector computerized tomographic angiography/urography with reconstructions for evaluation of the kidneys and vascular anatomy. Any questionable findings on medical, surgical, and psychosocial evaluation are discussed in a multidisciplinary committee prior to proceeding with donation.

INDICATIONS FOR SURGERY

Healthy patients aged older than 18 years are eligible for donation. Medical contraindications to kidney donation are summarized in Table 5.1 (7). The decision-making process may be quite complex and multifactorial.

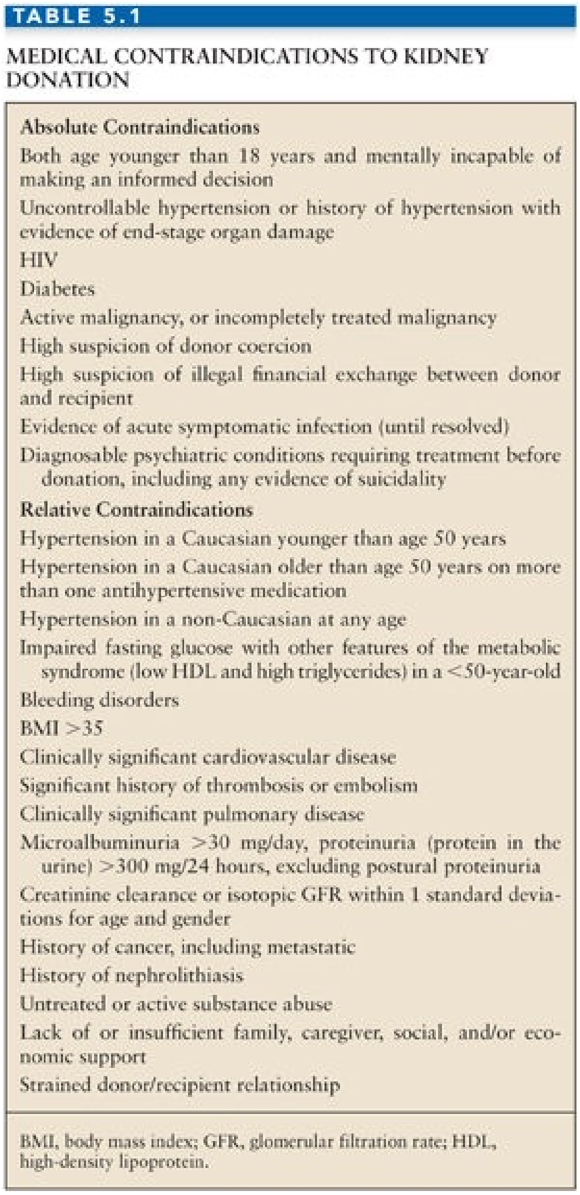

TABLE 5.1

MEDICAL CONTRAINDICATIONS TO KIDNEY DONATION

Absolute Contraindications

- Both age younger than 18 years and mentally incapable of making an informed decision
- Uncontrollable hypertension or history of hypertension with evidence of end-stage organ damage
- HIV
- Diabetes
- Active malignancy, or incompletely treated malignancy
- High suspicion of donor coercion
- High suspicion of illegal financial exchange between donor and recipient
- Evidence of acute symptomatic infection (until resolved)
- Diagnosable psychiatric conditions requiring treatment before donation, including any evidence of suicidality

Relative Contraindications

- Hypertension in a Caucasian younger than age 50 years
- Hypertension in a Caucasian older than age 50 years on more than one antihypertensive medication
- Hypertension in a non-Caucasian at any age
- Impaired fasting glucose with other features of the metabolic syndrome (low HDL and high triglycerides) in a <50-year-old
- Bleeding disorders
- BMI >35
- Clinically significant cardiovascular disease
- Significant history of thrombosis or embolism
- Clinically significant pulmonary disease
- Microalbuminuria >30 mg/day, proteinuria (protein in the urine) >300 mg/24 hours, excluding postural proteinuria
- Creatinine clearance or isotopic GFR within 1 standard deviations for age and gender
- History of cancer, including metastatic
- History of nephrolithiasis
- Untreated or active substance abuse
- Lack of or insufficient family, caregiver, social, and/or economic support
- Strained donor/recipient relationship

BMI, body mass index; GFR, glomerular filtration rate; HDL, high-density lipoprotein.

Relative surgical contraindications to transperitoneal laparoscopic donor nephrectomy include prior abdominal surgery (reoperative abdomen), intraperitoneal mesh, and other general contraindications to transperitoneal laparoscopy; however, most of these (e.g., peritonitis, cirrhosis, bowel obstruction) would have excluded the potential donor from donating based on medical evaluation alone.

Donor renal vascular and urologic anatomy is important in determining which kidney (left or right) to remove. Leaving the donor with the optimal kidney is the primary indication for choosing a particular side. For example, removing a kidney with a cyst, small cortical scar, or similar defect would be preferred. Typically, transplant surgeons prefer a left kidney due to longer renal vein length. The number of renal arteries and veins should also be considered. Having three or more arteries may lead to increased donor or recipient surgical complications or poorer graft outcomes; however, it is no longer considered an absolute contraindication (8,9). Duplicated ureteral anatomy is not contraindicated unless there is underlying renal deficiency of the associated kidney.

ALTERNATIVE THERAPY

Alternative procedures include hand-assisted laparoscopic, single-site laparoscopic, robotic-assisted laparoscopic, and “mini-incision” open and traditional open flank nephrectomy. Some centers have advocated extracting the kidney through a vaginal incision.

SURGICAL TECHNIQUE

Preparation

The patient undergoes a gentle bowel preparation the day before surgery with a clear liquid diet and a magnesium citrate suspension. All patients receive preoperative antibiotics and sequential compression devices (pulsatile stockings) for prophylaxis. After administration of general anesthesia with the patient in supine position, an orogastric tube to decompress the stomach (helpful for optimal splenic reflection during left laparoscopic donor nephrectomy [LDN]) is placed, abdominal hair is clipped, and Foley urethral catheter is inserted. Additionally, the Pfannenstiel incision is marked in the supine position (lower transverse incision approximately 8 cm in length, 3 cm above the symphysis pubis). Marking the incision site prior to positioning alleviates the distortion of gravity from the patient's pannus in keeping the incision midline and cosmetically even.

Positioning

The patient is positioned into a modified flank position (modified lateral decubitus). Starting with the patient supine with the contralateral arm abducted 90 degrees onto an arm board, the surgical team rotates the head, shoulders, torso, hips, and legs approximately 75 to 90 degrees perpendicular on the operating table. An axillary role placed just below the axilla relieves undue pressure on the shoulder and helps prevent brachial plexus injury. A back roll (rolled bedsheet) provides support for the lateral positioning. The inferior contralateral leg is flexed 90 degrees at the knee and the superior ipsilateral leg left straight and padded. We place the ipsilateral arm in a neutral position along the lateral torso in an adducted, anatomic position shown in Figure 5.1. To date, no positioning injury, neurapraxias, or complaints have been noted in patients positioned with the arm in this neutral position at our institution. Moreover, this positioning eliminates the need for an airplane, and if immediate open conversion is required, there is adequate space for a subcostal incision. Alternatively, the ipsilateral arm may be extended and abducted, supported by an airplane armrest over the contralateral arm. This position may limit laparoscopic motion range when panning into the pelvis. A moderate amount of table flexion allows for separation of the iliac crest from the lower rib cage. We minimize table flexion because overall it contributes only little benefit to the dissection and exaggerated flexion may lead to back pain postoperatively. Similarly, we do not elevate the kidney rest. Once positioned, 4-inch cloth tape secures the patient to avoid shifting. After prepping and draping, mannitol 12.5 g is administered intravenously.

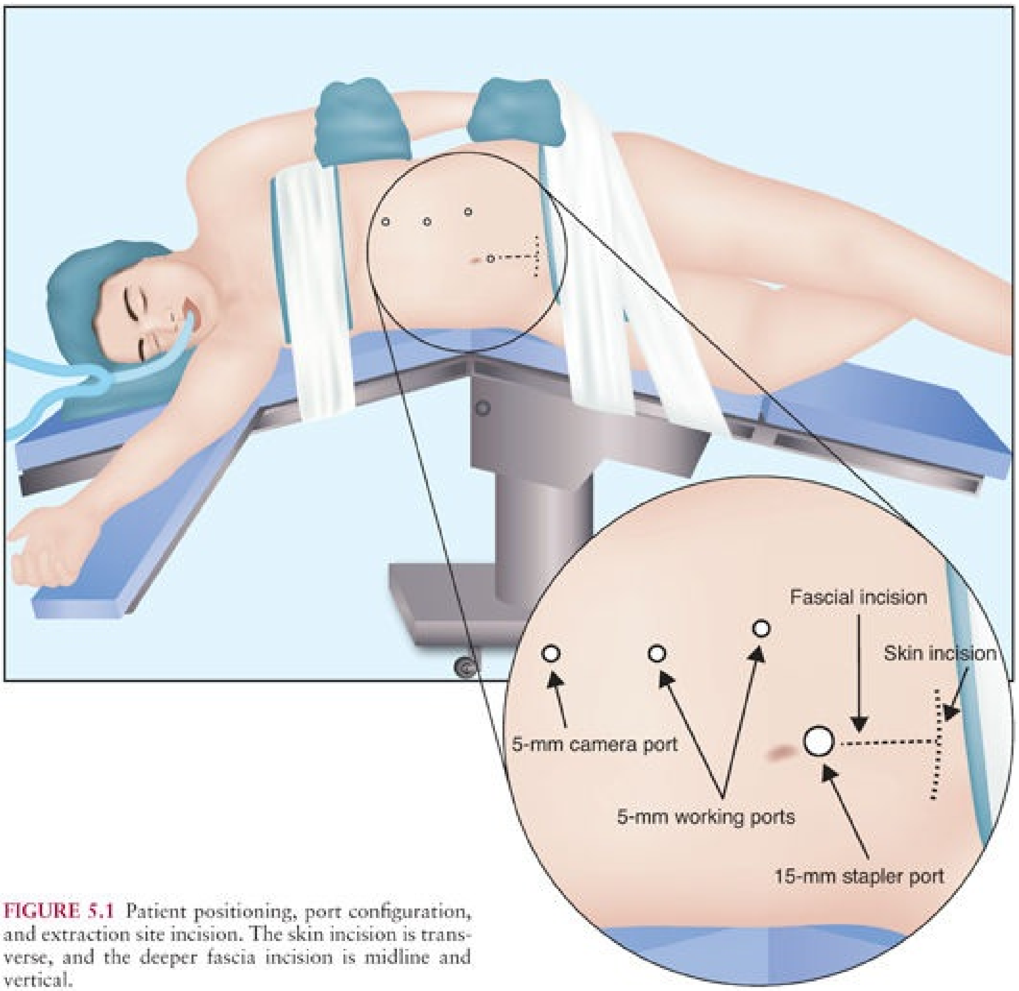

FIGURE 5.1 Patient positioning, port configuration, and extraction site incision. The skin incision is transverse, and the deeper fascia incision is midline and vertical.

Left-Sided Laparoscopic Donor Nephrectomy

Insufflation and Initial Trocar Placement

Pneumoperitoneum is obtained using a Veress needle placed midline and 0.5 cm superior to the umbilicus. Alternative sites, such as Palmer point, 3 cm below the middle of the left costal margin, or an open trocar placement technique may be used if there are concerns for significant adhesions from prior surgery.

After achieving 15 mm Hg of CO_2 insufflation pressure, the laparoscopic trocars are placed along the left rectus margin. We use 5-mm trocars, which obviate the need to close the fascia of the trocar sites with Endo Close devices that often snare the rectus muscle and may result donor discomfort. An optical obturator, 5-mm trocar with a 0-degree scope, is advanced under direct vision at the junction of the rectus border and costal margin (approximately 1 cm inferior to rib). This will serve as the camera port throughout the case. In the absence of satisfactory Veress needle placement and insufflation, we use the aforementioned approach for our initial trocar placement cautiously under direct laparoscopic vision, without pneumoperitoneum.

Once visual access to the peritoneal space is gained, we switch to the 30-degree, 5-mm scope and place the next two 5-mm trocars under direct vision. Figure 5.1 demonstrates the standard linear port configuration. The second 5-mm trocar is placed approximately 9 cm inferior to the initial trocar in the same line along the lateral boarder of the rectus muscle. The third 5-mm trocar is placed approximately 9 cm inferior to the second trocar however is slightly more lateral to the rectus margin by 1 to 2 cm to allow for better triangulation and reach to the kidney's upper pole. This trocar should be positioned in a horizontal plane lateral at approximately the same level as the umbilicus, and if it is too caudad, the range to dissect and reflect the spleen medially may be compromised.

Reflection of Colon and Retroperitoneal Exposure

The surgeon and assistant stand on the patient’s ventral side, the assistant controls the camera and laparoscope through the most cephalad trocar while the surgeon works through the two caudad trocars. Dissection begins with careful inspection of the surrounding anatomy. The stomach needs full decompression with the orogastric tube. A more distended stomach is at greater risk for injury during the lateral dissection of the spleen for medial reflection. The transverse and descending colon are identified, and commonly, the colon and/or omentum at the splenic flexure tend to be tented or have adhesions to the anterior abdominal wall. These are released using sharp dissection; however, care must be taken not to follow this dissection too laterally, which will result in premature release of the lateral attachments of the kidney and inadvertent incision of Gerota fascia, resulting in loss of countertraction during the medial upper pole and hilar dissection.

To gain retroperitoneal exposure, the white line of Toldt is incised approximately 1 cm lateral to the descending colon. In thinner individuals, this is demarcated by the lateral border of the mesenteric fat, which has a more yellowish hue compared to retroperitoneal adipose tissue (Fig. 5.2). The incision is carried caudally to the pelvic brim. Then, moving cephalad over the kidney, care is taken only to incise the peritoneal layer to preserve an anatomic approach and not enter the deeper attachments or Gerota fascia. Inadvertent entry into Gerota fascia over the kidney will obscure the hilar dissection because the fascia (and perinephric fat) will fall medially over the hilum. This incision is carried cranially, 1 cm lateral border of the spleen, well above the kidney. Often the peritoneal tissue overlying the kidney contains vascular supply so we switch to thermal ligation using a LigaSure (Covidien, Norwalk, Connecticut).

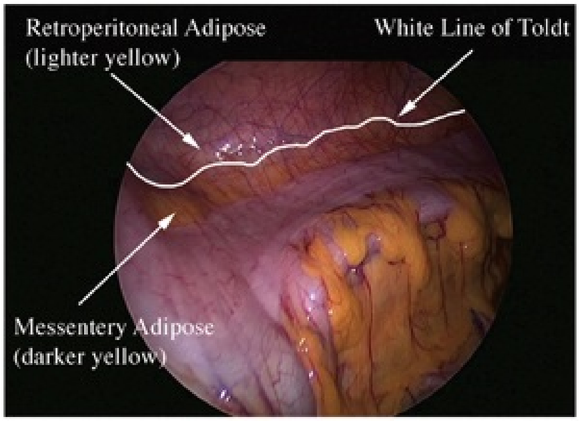

FIGURE 5.2 Descending colon. The incision to expose the left retroperitoneum is made 1 cm lateral to the colon. The mesenteric adipose tissue is typically a darker yellow hue and should be reflected with the colon.

Once the peritoneum is incised, a combination of sharp or blunt dissection is used to release the loose attachments and sweep the peritoneum and mesentery medially. Spinning a laparoscopic Kittner medially while maintaining lateral countertraction with a blunt-tip grasper is very effective to avoid an inadvertent peritoneal window. Additionally, arterial pulsations within the mesenteric fat often serve as a landmark to shift the dissection more laterally. During this maneuver, below the lower pole, the psoas muscle is one of the first structures to be identified lateral to the ureter and gonadal vein and cephalad to the common iliac artery. With more medial reflection of the peritoneum, the gonadal vein is identified coursing just under Gerota fascia. This plane between the peritoneum and Gerota fascia is carried cranially, lateral to the tail of the pancreas and approximately 1 cm lateral to the spleen. The prior incision of the peritoneum needs to be carried up superiorly well above the spleen to ensure the spleen is released medially to allow adequate exposure for the medial upper pole dissection. Care is taken not to release the attachments too far medial to the edge of the adrenal gland because the effects of gravity aid in medial traction via these attachments of the adrenal gland later in the procedure. The stomach may be encountered and must be avoided during this step, and a commonly present prominent diaphragmatic vein serves as the landmark for the upper extent of the dissection (Fig. 5.3).

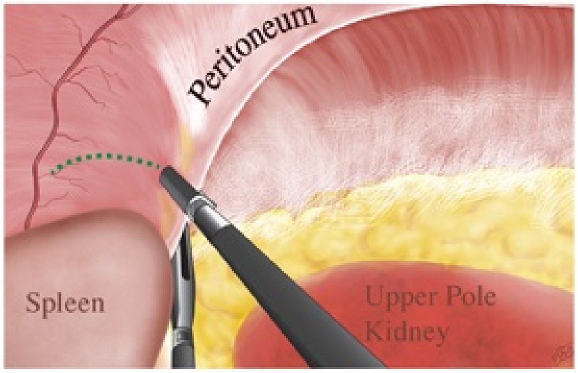

FIGURE 5.3 Reflecting the spleen. The peritoneum is incised well beyond the upper pole of the kidney toward the diaphragm to allow the spleen to reflect medially and expose the entire upper pole. The small inferior diaphragmatic vessels are typically seen and mark the upper extent of the peritoneal incision.

At this point, we approach LDN through a bottom-up approach with corresponding incremental risk. By performing the ureteral dissection early versus late, in case of open conversion, this obviates the need to gain exposure to the ureter toward the pelvis through a small mini-open conversion incision that may need to be enlarged in challenging situations.

Gonadal Vein, Ureter, and Posterior Dissection

After gaining exposure to the retroperitoneum through medial reflection of the peritoneal cavity, we dissect around the gonadal vein at just below the level of the lower pole where the ureter typically crosses underneath (Fig. 5.4). We divide Gerota fascia overlying the gonadal vein in a cephalad direction, directly anterior to the gonadal vein. Extending this dissection of Gerota fascia more cephalad across the renal vein often reveals the confluence of the adrenal and renal vein on the superior edge of the renal vein, more medial to the takeoff of the gonadal vein on the inferior edge of the renal vein. This serves as a key landmark for the later adrenal dissection. The LigaSure is then used to ligate and divide the gonadal vein at the level of the lower pole. We use the LigaSure device due to the consistent ability to ligate the gonadal, adrenal, and lumbar veins, thus avoiding clips near the hilum that may increase the subsequent risk of endovascular stapler misfire on the hilar vessels. Additionally, the LigaSure facilitates blunt dissection without concern of thermal injury.

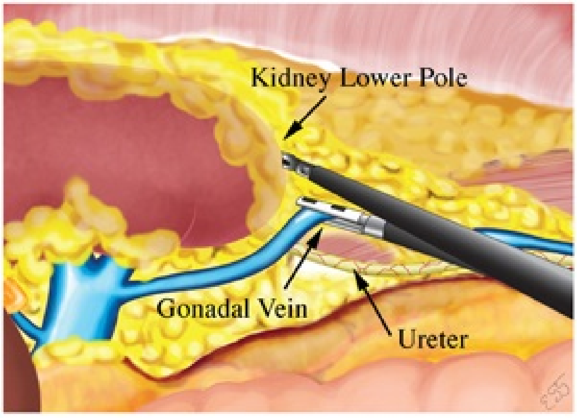

FIGURE 5.4 Division of the gonadal vein. The lower pole of the kidney is the landmark for where the gonadal vein is ligated. The ureter typically crosses underneath at this point as well making for easy identification.

At the point of gonadal vein division, we bluntly dissect onto the psoas muscle fascia, establishing the borders of the ureteral dissection. We routinely ligate the gonadal vein just below the level of the lower pole without a difference in recipient ureteroneocystostomy complications. Moreover, others have shown that this is associated with less postoperative ipsilateral varicocele discomfort in male donors. Carefully elevating the fatty tissue lateral to the ureter and sweeping the ureter down, we continue to divide the lateral attachments down to the level of the pelvic brim. Attention is given to dissect superficial to the psoas muscle fascia, as sensory nerves for the genitofemoral nerve may be damaged with dissection underneath this fascial layer, resulting in a deficit of ipsilateral anterior thigh sensation. Then, with gentle upward tension on the ureter, the plane between the ureter and gonadal is divided using the LigaSure and blunt downward sweeping motions. Care is taken not to strip the ureter of its blood supply. The ureteral dissection ceases at the common iliac artery, but the ureter is not divided until after hilar vessels are divided for two reasons. First, it provides a point of fixation during hilar division; and second, premature division leads to greater subsequent effort to keep track of the ureter and prevent it from flopping into areas of dissection.

Next, with careful elevation and release of the posterior attachments of the kidney bluntly, the LigaSure is used to dissect medial to the proximal gonadal vein stump toward the renal vein (lateral release results in the gonadal vein stump flopping and obstructing subsequent hilar dissection); however, this dissection ceases before potential lumbar veins are encountered typically arising from a similar point along the renal vein as the confluence of the gonadal and renal vein. The 30-degree scope is angled to visualize behind the kidney toward the upper pole while the kidney is then elevated off the psoas and quadratus muscle fascia with largely blunt dissection. This release enables maximal stretching of the hilar vessels to ensure maximal vessel length when subsequently stapled.

Upper Pole Dissection and Release of the Adrenal Gland

After reflecting the tail of the pancreas away from the medial edge of the upper pole (typically done when exposing the retroperitoneum), we enter Gerota fascia, dissecting into the perinephric fat slightly lateral to the edge of the adrenal. Often, the earlier made incision in Gerota fascia started at the lower pole to identify the adrenal vein at its confluence with the renal vein can simply be carried cranially along the adrenal edge. As the lateral edge of the adrenal gland is identified and dissected away from the kidney, the dissection plane is carried as medial as possible along the lateral edge of the kidney to prevent injury to hilar branches to the upper pole. Using a grasper in the surgeon’s left hand to create tension by holding the lateral edge of the adrenal medially and upward greatly facilitates this dissection (Fig. 5.5). Great care is taken to carefully ligate this tissue to avoid inadvertent upper pole renal artery injury. This dissection is carried down to the posterior body wall muscle (quadratus lumborum) and extended superolaterally, resulting in complete release of the upper pole of the kidney away from the spleen. The adrenal vein is dissected out to allow ligation and division. Then, the upper edge of the renal vein proximal to the adrenal vein stump is released with careful blunt dissection to prepare the exit site of the endovascular stapler jaw.

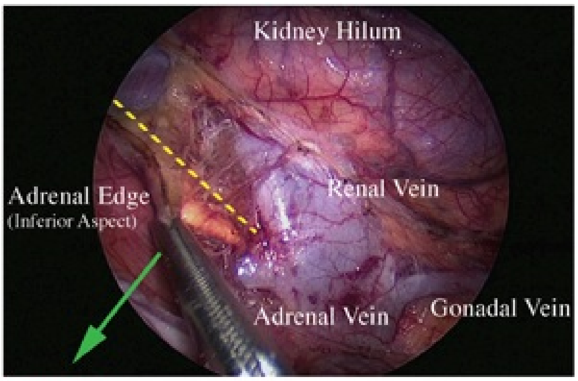

FIGURE 5.5 Adrenal dissection. Careful traction of the adrenal gland anterior, medial and inferior (*green arrow*) allows for exposure of the lateral border (*yellow dashed line*) of the adrenal gland for dissection and release of the kidney's upper pole.

Pfannenstiel Extraction Site, Ligation of Lumbar Veins, and Hilar Dissection

At this point, we coordinate with the recipient surgeon prior to creation of the extraction site to minimize cold ischemia time. The second mannitol of 12.5 g dose is given intravenously. The surgeon makes the horizontal skin incision, marked prior to positioning, continuing down to the anterior rectus sheath. The fascia is then cleared superiorly toward the umbilicus and inferiorly, undermining the skin and subcutaneous adipose tissue, to allow for a vertical midline incision through the fascia, splitting through the bellies of the rectus muscle (Fig. 5.6). The 30-degree scope view of the convergence of the medial umbilical ligaments facilitates identification of the midline, which is always higher than anticipated when landmarking with surface anatomy due to the effect of gravity on the pannus. A cephalad vertical fascial incision is made to accommodate the 15-mm trocar, and 1-cm bridge of fascia is left intact to hold the trocar circumferentially then extended caudal to total approximately 12 cm to allow for quick extraction of the donor kidney. The fascial bridge supports the 15-mm trocar and prevents loss of pneumoperitoneum.

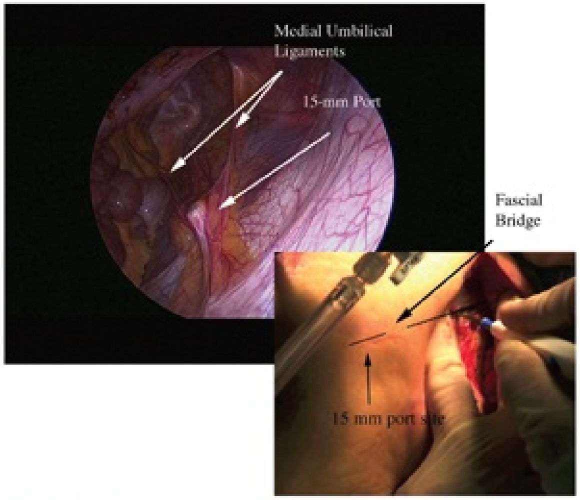

FIGURE 5.6 Low transverse incision. The patient's midline is easily found by viewing the medial umbilical ligaments. A small 1-cm fascial bridge is created when making the vertical fascial incision to prepare the extraction site. The bridge supports the 15-mm trocar and maintains pneumoperitoneum. When the kidney is in the retrieval bag and ready to remove, the bridge is easily transected with cautery, thereby minimizing warm ischemia time.

After completion of the extraction site, the kidney is gently elevated, placing the hilum on tension and the lumbar veins are dissected out, ligated, and divided with the LigaSure to maximize hilar vessel length. Next, the laparoscopic suction tip is passed through the 15-mm extraction site trocar (to simulate the angle of the endovascular stapler) and slid over the aorta behind the renal vein, entering and exiting proximal to the gonadal and adrenal vein stumps, respectively. Formerly, we meticulously dissected out the renal artery to its origin from the aorta; however, this was associated with an increased risk of lymphocele and potential bleeding. Currently, we thin out a pedicle comprising the renal artery as low as possible onto the aorta, using care to leave lymphatic and neurovascular tissue on the aorta. This made the dissection more efficient with less risk. Prior to division of the hilar vessels, the lateral attachments of the kidney are divided with the LigaSure, and the kidney is freed completely with the exception of the hilum and ureter.

Stapling the Hilum and Extraction of the Donor Kidney

Again, we coordinate with the recipient surgeon prior to extracting the kidney for exchanges within the hospital. The surgeon elevates the kidney by using two blunt-tip instruments in the two more caudad 5-mm trocars (Fig. 5.7). The assistant holds one of these blunt-tip instruments (along with the camera) while the surgeon holds the lower one and uses the laparoscopic articulating endovascular GIA stapler (Covidien, Norwalk, Connecticut) with vascular 60-mm loads to divide the renal artery followed by the vein, through the previously established channel. Alternatively, a liver retractor placed through a fourth 5-mm trocar in the anterior axillary line, will elevate the upper pole, however will require an additional trocar placement. Additionally, although some institutions prefer the TA laparoscopic stapler due to the theoretical advantage of gaining a millimeter from the absence of staple lines on the specimen side, the need to use the laparoscopic scissors to cut distal to the staple line is an extra step that may prolong ischemia time compared to the firing and cutting of an endo GIA stapler, and there is additional iatrogenic risk of using scissors and/or cutting a serrated edge of the vessel that must be subsequently trimmed. Next, the ureter is tented upward and a large Weck clip (Teleflex, Research Triangle Park, North Carolina) is applied on the ureter at the level of the common iliac artery before sharp division proximal to the clip. A 15-mm laparoscopic bag is then placed medial to the kidney, allowing gravity to aid it falling in along with a laparoscopic grasper handling the perinephric fat. Prior to cinching the laparoscopic specimen bag, care is taken to ensure that the entire kidney and ureter are completely contained. Electrocautery is used to divide the fascial bridge, preperitoneal fat and peritoneum. Once extracted, the kidney is removed from the bag and immediately submerged in ice. The staple lines are carefully cut off using tenotomy scissors and the renal artery is identified, gently dilated with a hemostat and flushed with 400 mL of heparinized Lactated Ringers (University of Wisconsin solution for export exchanges).

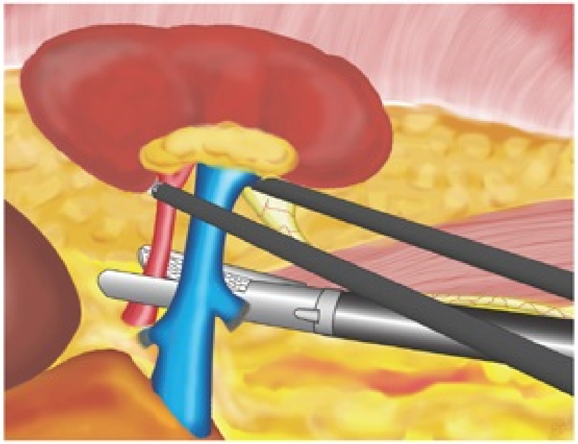

FIGURE 5.7 Elevating the kidney. Using blunt-tip instruments, the kidney is elevated, placing the hilar vessels on stretch to maximize length for transplantation. The assistant holds the camera and upper pole instrument while the surgeon holds the lower pole instrument and operates the stapler.

Closure

A 0-polydioxanone (PDS, Ethicon, Somerville, New Jersey) is used to close the anterior rectus sheath in a running fashion. Insufflation is resumed and inspection of the surgical field for hemostasis is performed, particularly at staple lines and clipped ureteral stump. Prominent pooling of blood after resumption of pneumoperitoneum is concerning. In the absence of any bleeding, the laparoscopic sucker is used to extract as much of the CO_2 as possible prior to trocar removal to lessen the likelihood of postoperative shoulder/chest discomfort due to CO_2 diaphragm irritation. The incisions are infiltrated with 0.5% Marcaine and the ports sites and extraction site incision are closed preferably with 4-0 absorbable monofilament subcuticular stitches.

Routine Postoperative Care

All patients follow a postoperative pathway. The orogastric tube is removed prior to extubation. A recovery room and early postoperative day 1 hematocrit is checked. The Foley catheter is removed and diet advanced to regular early on the first postoperative day and ambulation is encouraged. Intravenous ketorolac is given 0.5 mg/kg prior to extubation and continued around the clock as well as oral opioid pain medications.

Right-Sided Laparoscopic Donor Nephrectomy

Patient preparation, positioning, and acquiring pneumoperitoneum are performed as described earlier. The majority of the steps for a right-sided procedure remain the same as the left except a few notable changes. The orientation of trocars is the same; however, an extra 15-mm trocar is occasionally swapped for the standard 5-mm trocar most caudad later in the procedure for improved staple angle and ultimately renal vein length. The liver sometimes extends caudal and requires a fourth 3-mm trocar placed near the subxiphoid and a locking grasper clamping the abdominal wall below the diaphragm laterally to retract the liver throughout the case. We tend to place this after the colon has been mobilized. The ascending colon tends to travel more medial and the duodenum presents after mobilization rather than the pancreas. The gonadal vein rarely needs to be ligated. The adrenal vein directly enters the vena cava and rarely seen or needed to be ligated. Few, if any, lumbar branches extend from the right renal vein.

Exposure of the retroperitoneum is created by incising the white line of Toldt generally 2 to 3 cm lateral to the ascending colon. This is extended caudal to the pelvic brim and cranial over the kidney, up between the lateral edge of the liver. The liver can be released from lateral attachments and at this point we place the grasping forceps to retract the liver if needed. As the mesentery and colon are swept medial off Gerota fascia using similar techniques described earlier, the duodenum often presents and is gently swept (“kocherized”) medial away from the vena cava and hilum.

The lower pole of the kidney serves as a landmark for locating and identifying the ureter and gonadal vein. The gonadal vein rarely enters the renal vein, and care is taken to trace the anterior surface, incising the Gerota fascia up to the insertion, into the vena cava. Carrying this more cranially often reveals the right renal vein. The ureter typically rests slightly lateral to the gonadal vein at the lower pole. Once identified, it is lifted anteriorly and the lateral and medial attachments released in a manner similar described previously down to the level of the iliac vessels.

The adrenal gland is released from the upper pole of the kidney using LigaSure ligation. A plane is developed between the upper pole and inferior edge of the adrenal gland. This plane is developed down to the posterior quadratus and psoas muscles. Once the upper pole is released, the posterior attachments are released using blunt dissection. The hilar vessels are carefully identified and isolated.

At this point, after coordination with the transplanting surgeon, the extraction site incision is made (as described before) and the most inferior working port switched to a 15-mm trocar to accommodate the endovascular stapler. Often due to the angle of vena cava insertion, using this port site aligns the stapler to maximize renal vein length. The lateral attachments are then divided. Carefully, using a similar “chopsticks” technique as for the left donor nephrectomy, the kidney is elevated placing the hilum on stretch. The renal artery and then vein are stapled and the ureter clipped and cut. The kidney is extracted, and closure is the same as the left side.

OUTCOMES

Results

The initial early technical issues leading to renal allograft dysfunction, failure, and loss in the recipients have largely been overcome. The Cochrane database published a review and meta-analysis of open versus laparoscopic donor nephrectomies in 2011 (10). In summary, laparoscopic approaches were associated with less pain and blood loss but longer warm ischemia times than open procedures; however, no difference in short-term graft consequences. Complication rates were the same. Table 5.2 summarizes the outcome measures in the Cochrane review, none of which had significant differences between the two different surgical approaches.

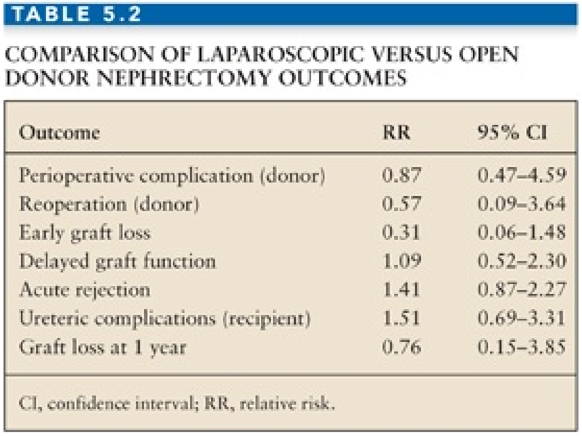

TABLE 5.2

COMPARISON OF LAPAROSCOPIC VERSUS OPEN DONOR NEPHRECTOMY OUTCOMES

Outcome	RR	95% CI
Perioperative complication (donor)	0.87	0.47–4.59
Reoperation (donor)	0.57	0.09–3.64
Early graft loss	0.31	0.06–1.48
Delayed graft function	1.09	0.52–2.30
Acute rejection	1.41	0.87–2.27
Ureteric complications (recipient)	1.51	0.69–3.31
Graft loss at 1 year	0.76	0.15–3.85

CI, confidence interval; RR, relative risk.

Complications

Several studies have published complications rates for donor nephrectomy. Schold et al. (11) reported an overall donor nephrectomy complication rate of 7.9% in the National Inpatient Sample (NIS), analyzing 69,117 cases representing 89% of all donor nephrectomies performed in the United States registered in the SRTR database. However, another NIS study of 6,000 cases demonstrated an 18% complication rate during 1999 to 2005 period (12). Population-based studies are unable to distinguish surgical approaches such as open, hand-assisted laparoscopic, or pure laparoscopic donor nephrectomy. Similarly, there is variation in single-center approaches, methodology, and reporting, with overall complications ranging from 7% to 15% (13–15). Our overall surgical complication rate with more than 1,300 laparoscopic donor nephrectomies is 7.9%. Complications organized by modified Clavien classification are shown in Table 5.3 for our experience (16). Perioperative mortality from donor nephrectomy is very low and reported to be 3.1 per 10,000 donors and considered to be in the range of 0.03% to 0.06% (17).

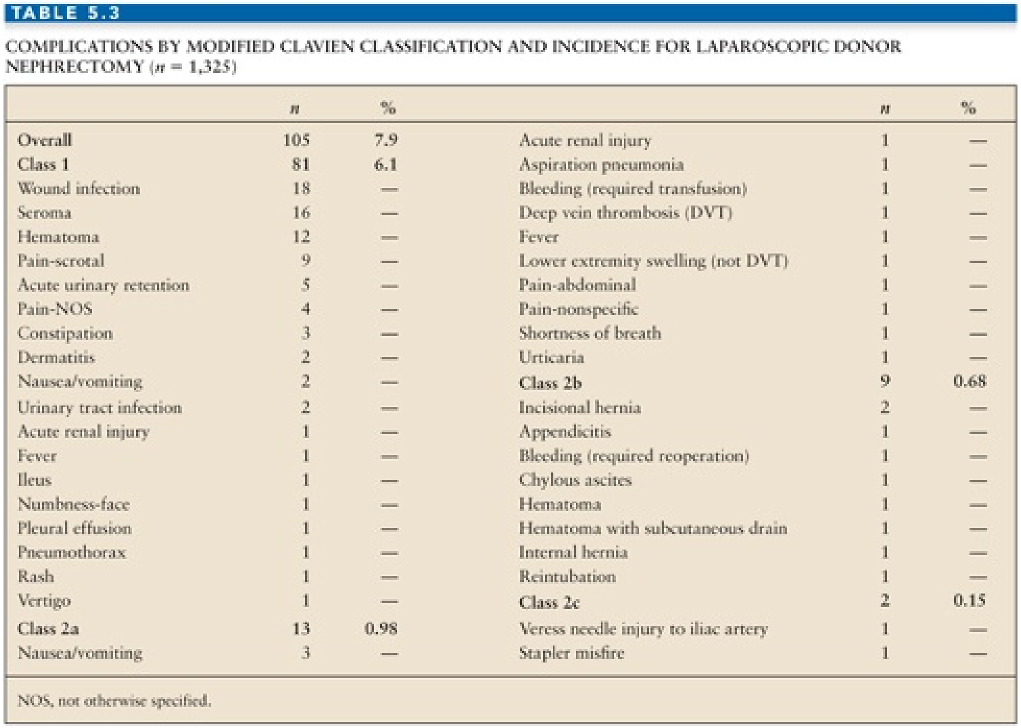

TABLE 5.3

COMPLICATIONS BY MODIFIED CLAVIEN CLASSIFICATION AND INCIDENCE FOR LAPAROSCOPIC DONOR NEPHRECTOMY (n = 1,325)

	n	%		n	%
Overall	105	7.9	Acute renal injury	1	—
Class 1	81	6.1	Aspiration pneumonia	1	—
Wound infection	18	—	Bleeding (required transfusion)	1	—
Seroma	16	—	Deep vein thrombosis (DVT)	1	—
Hematoma	12	—	Fever	1	—
Pain-scrotal	9	—	Lower extremity swelling (not DVT)	1	—
Acute urinary retention	5	—	Pain-abdominal	1	—
Pain-NOS	4	—	Pain-nonspecific	1	—
Constipation	3	—	Shortness of breath	1	—
Dermatitis	2	—	Urticaria	1	—
Nausea/vomiting	2	—	**Class 2b**	9	0.68
Urinary tract infection	2	—	Incisional hernia	2	—
Acute renal injury	1	—	Appendicitis	1	—
Fever	1	—	Bleeding (required reoperation)	1	—
Ileus	1	—	Chylous ascites	1	—
Numbness-face	1	—	Hematoma	1	—
Pleural effusion	1	—	Hematoma with subcutaneous drain	1	—
Pneumothorax	1	—	Internal hernia	1	—
Rash	1	—	Reintubation	1	—
Vertigo	1	—	**Class 2c**	2	0.15
Class 2a	13	0.98	Veress needle injury to iliac artery	1	—
Nausea/vomiting	3	—	Stapler misfire	1	—

NOS, not otherwise specified.

Open conversion rates are generally low and usually around 1%. As with any laparoscopic procedure, there is always the possibility of open conversion. The decision to convert most often reflects good judgment and is not a complication. The surgeon should have all instruments necessary for open surgery. Typically, a subcostal incision connecting two or more ports if possible. In most cases, conversion is due to ongoing hemorrhage or failure to progress secondary to adhesions.

CHAPTER 6 ■ LAPAROSCOPIC/ROBOTIC NEPHRECTOMY AND PARTIAL NEPHRECTOMY

JEAN-CHRISTOPHE BERNHARD, CHARLES METCALFE, AND INDERBIR S. GILL

Standard transperitoneal and retroperitoneal laparoscopic nephrectomy (LN) were first performed in 1990, and their partial nephrectomy (PN) counterparts followed in 1993 and 1994 (1).

Equivalent 5-year cancer cure rates combined with decreased morbidity and recovery time have made LN the current standard of care for surgically treating renal malignancies in industrialized countries. Laparoscopy is also the standard today for performing nephrectomy for benign disease. Although open partial nephrectomy (OPN) remains the standard of care, pure laparoscopic partial nephrectomy (LPN) has been performed at high-volume medical centers of laparoscopic surgical excellence. However, concerns regarding not only both warm ischemia time and difficulties in technique training but also the large propagation of robotic assistance technology made it progressively replaced by robot-assisted LPN.

DIAGNOSIS

Nowadays, renal masses are most often identified incidentally during radiologic imaging. Only 30% of diagnosed patients present with hematuria or abdominal or flank discomfort. Additionally, patients are increasingly identified incidentally. Tumors are typically characterized and staged using abdominopelvic computerized tomography (CT) or magnetic resonance imaging (MRI) scan and chest radiography. Preoperative blood work includes metabolic panels including serum creatinine, liver function studies, alkaline phosphatase, and calcium. If the latter two studies are elevated or if the patient has bone pain or other evidence of metastases, a bone scan will be performed. Brain imaging is selectively obtained in patients with cerebral symptoms or evidence for metastasis. Nuclear renography is utilized in patients with renal insufficiency or if there is concern regarding the function of the contralateral kidney.

INDICATIONS FOR SURGERY

Simple nephrectomy is indicated for benign conditions such as chronic pyelonephritis, nephrosclerosis, multicystic dysplastic kidney, postrenal transplantation or renovascular hypertension, reflux or obstructive nephropathy, and symptomatic acquired renal cystic or autosomal dominant polycystic kidney disease (ADPKD). Radical nephrectomy is indicated for tumors worrisome for malignancy.

Renal oncologic surgery has evolved concomitantly with stage migration, with a significant shift toward techniques that maximize renal function outcomes in addition to cancer cure. This shift is the result of level II evidence correlating impaired renal function with cardiovascular morbidity and overall mortality (2). Studies have demonstrated superior renal function outcomes and overall survival for patients who undergo PN (or nephron-sparing surgery) rather than radical nephrectomy (3,4). As a result, nephron-sparing surgery is now accepted as standard of care for all stage T1a and most stage T1b renal masses (5). With the ongoing adoption of minimally invasive techniques and robotic assistance spread, surgeons are increasingly performing LPN, which eliminates the morbidity of an open incision. Given the enhanced dexterity and three-dimensional (3D) vision afforded by the robotic platform, a rapidly growing number of PN procedures are being performed robotically (at least in the United States), even for complex and technically “difficult” tumors.

ALTERNATIVE THERAPY

Open radical nephrectomy (ORN) and OPN may be performed. Active surveillance and ablative therapies (such as cryotherapy and radiofrequency ablations) are also therapeutic alternatives, particularly for patients with small renal masses who are elderly or who have significant medical comorbidities, hereditary forms of renal cancer, or multiple tumors. Ablative procedures can be performed percutaneously with CT or MRI guidance and laparoscopically.

PATIENT PREPARATION

A formal bowel preparation is not routinely performed, but a clear liquid diet the day before surgery augmented by a Dulcolax suppository or an oral saline cathartic (e.g., magnesium citrate or Fleet Phospho-Soda) is often employed. One gram of cefazolin is administered preoperatively. Deep venous thrombosis prevention with subcutaneous heparin (5,000 U 2 hours prior to procedure and continued every 12 hours postoperatively until the patient is ambulatory or up to 1 month postoperative in case of neoplastic disease) and/or pneumatic compressive stockings are used.

PATIENT POSITIONING

Under general anesthesia, intravenous access and endotracheal intubation are obtained with the patient supine. Orogastric and Foley catheters are inserted to decompress the stomach and bladder. The patient is then placed in a modified (30- to 70-degree) lateral decubitus position, with the umbilicus over the break in the table. For retroperitoneoscopic procedures, the patient is placed in or closer to the true lateral decubitus position. An axillary roll is placed, the table is flexed as necessary (usually minimally compared with open flank surgery), and a beanbag or padding is positioned to support the buttocks and flank. Pillows are placed between the flexed lower and straight upper leg. The upper arm rests on a well-padded arm board (or pillows) without tension on the brachial plexus. Three-inch tape is used to secure the patient around the hips, shoulders, and thighs to ensure stability when rolling the table to facilitate bowel retraction (Fig. 6.1).

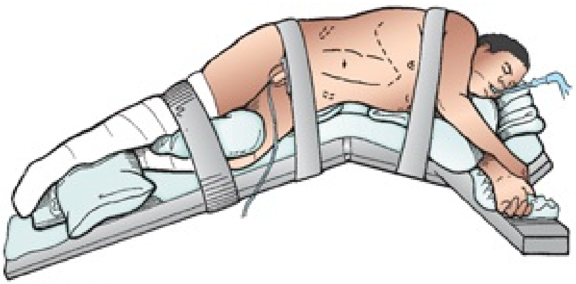

FIGURE 6.1 The patient is placed in a modified (70-degree) lateral decubitus position, with the umbilicus over the break in the table. SURGICAL TECHNIQUE

Transperitoneal Radical or Total Nephrectomy

Access

Although the insufflation technique with the Veress needle can be used, we recommend an open access for the camera port placement. It is commonly inserted at the level of the umbilicus lateral to the ipsilateral rectus muscle. The abdomen is insufflated to 13 to 15 mm Hg. Some surgeons prefer a pressure of 20 mm Hg during the trocar placement. Typically, a 10- or 12-mm trocar is placed lateral to the rectus at the level of the umbilicus using a visual obturator trocar (e.g., Visiport, AutoSuture or Optiview, Ethicon Endo-Surgery). Once the peritoneum has been entered, the intraperitoneal contents are inspected for injury or adhesions. Trocar site placement varies significantly based on surgeon preference and patient body habitus. Most surgeons prefer the laparoscope (“camera”) port positioned between the working ports, which is the authors’ preference. Some place it caudad to the working ports. Many surgeons use a 30-degree laparoscope placed through an umbilical port, with working ports widely spaced in the subxiphoid midline and the far lateral abdomen (anterior axillary line, umbilical level), creating a 90-degree angle in relation to the umbilical trocar. Other surgeons place the working ports closer to the umbilical trocar, keeping them at least 10 cm apart. Others reduce the angle of the working ports in relation to the umbilicus to approximately 60 to 70 degrees, creating a trocar “diamond” configuration. Alternatively, one can use a 0-degree laparoscope placed through a trocar lateral to the rectus muscle and just cephalad to the umbilicus, with the working ports shifted slightly cephalad and laterally, respectively, to maintain at least 10-cm or five-fingerbreadths distance between trocars. A 5-mm trocar is often placed in the far lateral (anterior to posterior axillary line) position for retraction, and another 5-mm trocar is often placed below the xiphoid process for right-sided procedures to elevate the liver using a locking grasper attached to the lateral abdominal wall. Obese patients or patients with protuberant abdomens will need to have the trocars shifted laterally to maintain effective working angles into the retroperitoneum. Although technically more challenging, single-portal access nephrectomy can be performed for small hypotrophic kidney.

Reflection of the Colon

The ipsilateral ascending or descending colon must be mobilized to gain access to the kidney and renal hilum. The parietal peritoneum is first incised medial to the line of Toldt, approximately 1 cm lateral to the mesenteric fat lying lateral to the colon. This incision is carried from the iliac vessels to the level of the spleen (left) or liver (right). Atraumatic graspers are used in the nondominant hand to provide counter tension, and a hook electrode, Endoshears (scissors), or harmonic scalpel is used in the dominant hand to perform the dissection. Endoshears are particularly useful when dissecting in close proximity to bowel and when tissue planes are relatively avascular. Selective use of monopolar cautery through the instrument or use of a bipolar grasper in the nondominant hand allows for an efficient and elegant dissection by an experienced surgeon. Conversely, the harmonic scalpel excels at maintaining hemostasis when tissue planes are more vascular, and it is an excellent blunt-tipped dissection tool. Less experienced surgeons and surgeons in training may find the harmonic scalpel an easier tool to master. For left-sided procedures, many surgeons advocate carrying the peritoneal incision above the spleen laterally, allowing the spleen to fall medially with the pancreas and colon. Others prefer to carry the peritoneal incision through the phrenicocolic ligament to the spleen but then carry the dissection medially, leaving the spleen suspended on a “hammock of peritoneum caudad to the spleen and extending to the left abdominal sidewall” (Fig. 6.2). The splenophrenic attachments are left intact while the splenocolic and then renocolic fascial attachments are divided in layers until the descending colon is fully mobilized medially and the left gonadal vein is visible.

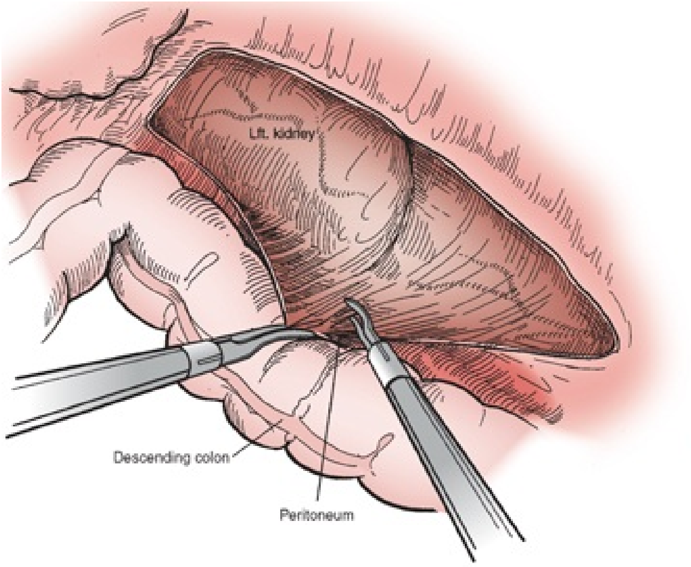

FIGURE 6.2 Mobilization of the colon using medial traction to demonstrate and divide attachments. (Reprinted with permission from Bishoff JT, Kavoussi LR, eds. *Atlas of Laparoscopic Retroperitoneal Surgery*. Philadelphia: WB Saunders, 2000. Copyright © 2000 Elsevier Inc. All rights reserved.)

For right-sided procedures, the peritoneum just lateral to the ascending colon is divided and carried to the level of the liver. This peritoneal incision is also carried medially, staying approximately 1 cm away from the lateral border of the colonic hepatic flexure. This incision then proceeds cephalad to approximately 1 cm below the liver and back laterally along the inferior surface of the liver to the sidewall. This approach will leave a wedge-shaped area of peritoneum covering the anterior aspect of the right kidney (Fig. 6.3). Once the ascending colon is mobilized medially, the duodenum is subsequently identified and a fascial incision is made approximately 1 cm lateral to its second stage. A Kocher maneuver is performed to move the duodenum medially. Third, the inferior vena cava (IVC) is exposed by incising the fascia and dissecting along its lateral border. For both left- and right-sided procedures, care is taken to preserve the lateral attachments of the kidney to prevent it from falling medially, inhibiting dissection of the renal hilum and the medial aspect of the Gerota fascia.

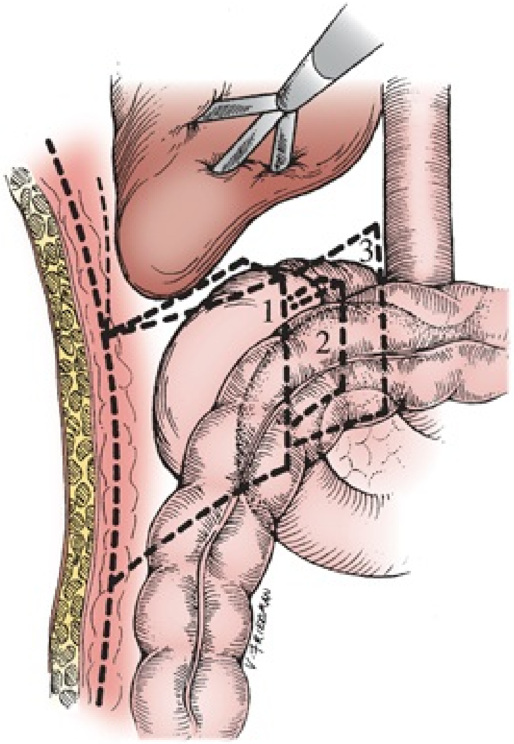

FIGURE 6.3 Diagram of the right-sided nephrectomy demonstrating the wedge-shaped configuration. The numbers refer to the three distinct levels of dissection along the medial aspect of the kidney: colon, duodenum, and inferior vena cava.

Gonadal Vein Dissection

Once the colon is fully mobilized, the gonadal vein is identified. Many urologists find the gonadal vein to be the “gateway” for initiating the nephrectomy portion of the procedure and carrying the dissection to the renal hilum. For left-sided nephrectomies, the fascia overlying the gonadal vein is divided and this dissection is carried cephalad to the renal vein. Care must be taken to dissect anterior to the gonadal vein to prevent injuring small gonadal venous tributaries or hilar vessels. The harmonic scalpel is useful for dividing these fascial attachments and maintaining hemostasis. This will allow for exposure of the anterior aspect of the left renal vein and subsequently the adrenal vein. The adrenal vein may be dissected using the harmonic scalpel or a gently curved dissector (e.g., Maryland). It is subsequently cauterized (e.g., with a paddle bipolar instrument), clipped (e.g., with Hem-O-Lok clips), and divided. The gonadal vein is then divided 1 to 2 cm below the renal vein in a similar fashion. It is included with the radical nephrectomy specimen, particularly for large and lower pole tumors. For right-sided procedures, the fascia over the gonadal vein may similarly be divided along the course of the vein up to its junction with the IVC. The right gonadal vein may, particularly for large tumors, be divided and removed with the specimen. Conversely, the dissection can be made just lateral to the right gonadal vein for smaller mid and upper pole tumors. The plane of dissection between the gonadal vein and the tail of the Gerota fascia (containing the ureter) is developed, and the latter is elevated anterolaterally by the assistant (using a laparoscopic Kittner, atraumatic grasper, or suction device) to allow dissection to the renal hilum via an inferoanterior approach (Fig. 6.4A and B).

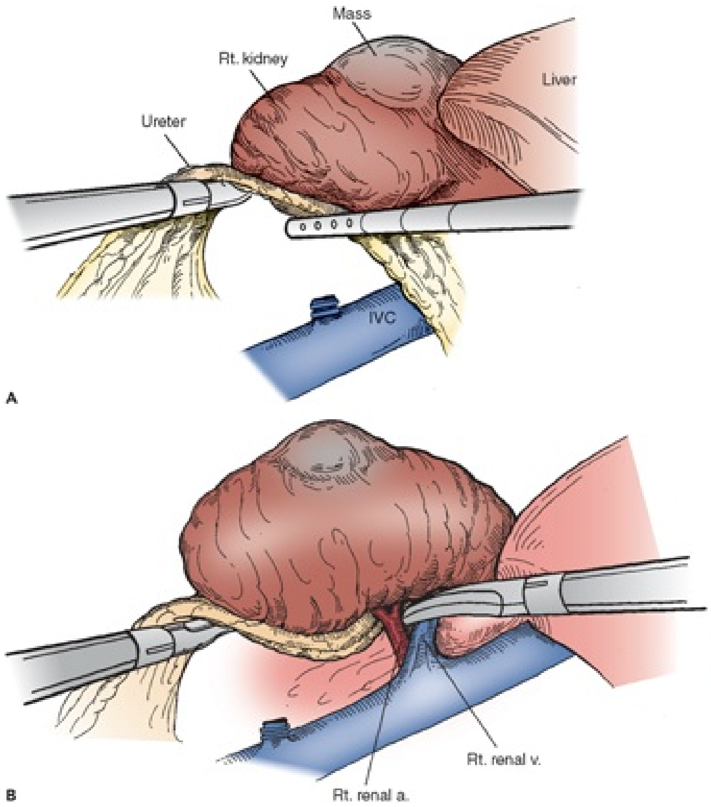

FIGURE 6.4 Elevation of ureter and tail of the Gerota fascia (**A**) to allow dissection to and exposure of renal vessels (**B**). *IVC*, inferior vena cava. Dissection of Ureter and Tail of the Gerota Fascia

For right-sided procedures, the ureter and tail of the Gerota fascia are elevated anterolaterally and the dissection carried along the gonadal vein to the IVC cephalad and to the iliac vessels caudad. For left nephrectomies, the dissection of the ureter and medial tail of the Gerota fascia is often performed after dividing the left adrenal and gonadal veins, if a true radical nephrectomy is to be performed. The adrenal gland and gonadal vein are spared when performing a simple nephrectomy or in select cancer patients without evidence of invasion on preoperative imaging. The tail of the Gerota fascia is mobilized medial to the gonadal vein from the renal hilum to the iliac vessels.

Securing the Renal Blood Vessels

Firm anterolateral elevation of the lower pole is critical in order to facilitate dissection of the hilum. This is accomplished by placing a laparoscopic Kittner or atraumatic grasping instrument under the tail of the Gerota fascia, the ureter, and the lower pole and lifting to the abdominal sidewall. With the hilum on tension, a harmonic scalpel, suction instrument, hook electrode, dissector (e.g., Maryland), or Endoshears can be used to dissect out the renal artery and vein and any necessary tributaries (e.g., lumbar or accessory vessels). Lymphatic vessels and fascial attachments inferior to and occasionally encasing the renal artery must be divided bluntly or sharply. Once adequate vessel exposure (at least a 2-cm space) is created, an endovascular gastrointestinal anastomosis (GIA) stapler is used to divide first the renal artery and then the vein. Alternatively, a series of at least three Hem-O-Lok clips may be applied to the vessels, dividing them approximately 1 cm lateral to the clips. Hilar side branches (gonadal, adrenal, lumbar, and accessory) may be ligated and divided in a variety of ways. Cauterization with either the LigaSure device or three overlapping deployments of a standard paddle bipolar cautery is effective. Standard titanium or locking polymer Hem-O-Lok clips may be used. The authors favor sequential paddle bipolar cauterization of the vessel and placement of a Hem-O-Lok clip on the stay side of the vessel if it will not be in the path of the endovascular GIA stapler when dividing the renal vessels.

Upper Pole Isolation

Once all hilar vessels have been divided, the dissection is carried superiorly. For right radical nephrectomies (RNs), the adrenal vein must be identified, ligated, and divided. Hem-O-Lok clips, preferably two on the stay side, may be used. The remaining suprarenal attachments and middle suprarenal arteries are divided with the harmonic scalpel or stapler (Fig. 6.5). A similar dissection can be performed for left RNs, separating the adrenal from the aorta and diaphragm. Alternatively, for simple nephrectomies and selectively for small, non–upper pole renal tumors with a normal ipsilateral adrenal gland on preoperative abdominal CT or MRI and intraoperative exam, the adrenal gland can be spared by placing the kidney on caudad traction and dividing the attachments between the adrenal gland and upper pole, staying adjacent to the adrenal. At this point, if it has not been performed previously, the ureter is clipped and divided and any remaining posterior or lateral attachments are divided by rotating the kidney as necessary.

Organ Entrapment

Benign kidneys may be morcellated in a durable entrapment sac, but malignant kidneys should be removed intact. The risk for tumor spillage and the loss of histologic staging information virtually always outweigh the morbidity benefits of minimizing the extraction incision. The kidney is placed into a deployable entrapment sack (e.g., Endo Catch II, U.S. Surgical, Norwalk, Connecticut). Hemostasis is checked, and then the sack is brought out through an incision extended from a 12-mm trocar site. Alternatively, the specimen may be removed through a Pfannenstiel incision. Trocar sites larger than 5 mm should have a fascial closure suture (e.g., interrupted 0 Vicryl) placed prior to specimen extraction.

Retroperitoneal Nephrectomy

Access

A 2-cm incision is made just below the tip of the 12th rib in the midaxillary line. A Kelly clamp is used to separate the subcutaneous fat and expose the flank musculature. The muscle is bluntly divided, and the underlying thoracolumbar fascia is pierced to enter the pararenal fat of the retroperitoneum. “S” type or Army-Navy retractors are used for exposure, and a fingertip is inserted and rotated 360 degrees in order to palpate the psoas muscle and confirm an appropriate retroperitoneal location. A balloon dilator is introduced and filled to 800 mL with room air. During insufflation, a 10-mm laparoscope may be introduced to view the dissection. A 10-mm blunt-tipped cannula is introduced with 30 mL of air in the balloon (U.S. Surgical). After tightening the outer ring sponge to compress the balloon against the inner abdominal wall, the retroperitoneum is insufflated to 15 to 20 mm Hg. Of note, some surgeons alternatively make the incision midway between the iliac crest and the tip of the 12th rib in the posterior axillary line. Additionally, a visual obturator trocar with a 10-mm 0-degree laparoscope may be used instead to enter the retroperitoneal space. Entry must be at a 10-degree anterior angle. Angling too far posteriorly will injure the quadratus or psoas musculature, whereas too anterior of a trajectory may allow entry into the peritoneum or cause colon injury.

Procedure

After obtaining retroperitoneal entry, blunt dissection is performed using only the scope. Anteriorly, the peritoneum is swept medially, exposing the transversalis fascia. Once peritoneal dissection off the abdominal wall is complete, accessory ports are placed in the upper and lower midaxillary line and a 5-mm trocar is placed in the anterior axillary line (Fig. 6.6). Some surgeons eliminate the lower midaxillary line port (three-port approach), while others maintain this trocar and add another anterior to it (five-port approach).

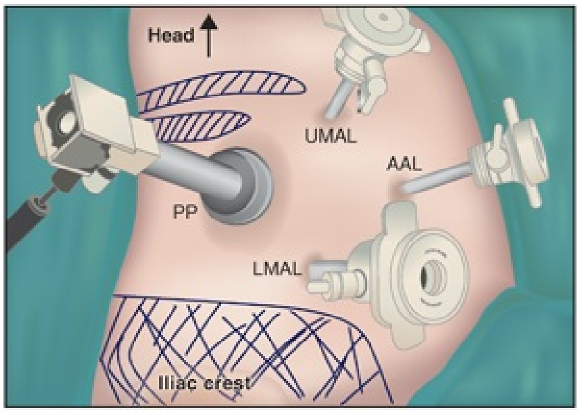

FIGURE 6.6 Port placement during retroperitoneal right retroperitoneoscopic renal surgery. The primary port (*PP*) is inserted by the open technique caudad to the tip of the 12th rib. The 12-mm lower midaxillary line (*LMAL*) port is placed 2 to 3 cm cephalad to the iliac crest. The 5-mm anterior axillary line (*AAL*) port is placed at the level of the PP. The 5-mm upper midaxillary line (*UMAL*) is placed near the tip of the 11th rib. Care must be taken to avoid transpleural placement of this trocar.

If balloon dilation was effective, the kidney should be displaced anteriorly. The psoas muscle is cleaned of fat and the dissection is carried cephalad and medially until the pulsating renal artery is visualized. The Gerota fascia is incised and the renal hilum is dissected, clipping the artery and the vein. For left-sided nephrectomy, the posterior ascending lumbar vein may be encountered prior to viewing the artery. It should be dissected, clipped with Hem-O-Lok clips, or cauterized and divided. Circumferential dissection of the Gerota fascia is performed. On the right side, cephalad dissection will lead to the adrenal vein, which will be clipped or cauterized and divided. The adrenal vein will also typically be divided during left nephrectomy. The ureter is doubly clipped and divided, followed by division of the remaining retroperitoneal attachments. The specimen is entrapped in a deployable sack and removed through the initial port site by extending the incision horizontally anterior to the tip of the 12th rib. Morcellation of benign kidneys can be performed in an impermeable sack (e.g., LapSac, Cook Urologic, Spencer, Indiana).

The peritoneal cavity may be entered during anterior dissection of the Gerota fascia, but it does not necessitate conversion to a transperitoneal technique. Conversion to a transperitoneal laparoscopic or open flank nephrectomy approach can be performed in difficult cases. Similar to the transperitoneal technique, the retroperitoneum is inspected for hemostasis with CO_2 pressure at 3 to 4 mm Hg prior at end of the case. The port sites will not require fascial closure but are irrigated, and the skin is closed with 4-0 subcuticular suture.

Transperitoneal Partial Nephrectomy

Access and renal exposure are similar to transperitoneal LN (Fig. 6.7A and B). The renal hilum is identified (Fig. 6.8). At this point, the operation will vary somewhat, depending on the PN technique that is employed. In most instances, the renal artery and vein are carefully dissected, and elastic loops are placed for safe recognition of the arteries (Fig. 6.9A and B). A complete hilum dissection can be performed if superselective clamping/zero-ischemia PN is planned, and direct tumor feeding arteries can be divided (Fig. 6.10A–D). The Gerota fascia is then opened horizontally across the anterior midpole, and the perirenal fat is reflected off the capsule. Fat is reflected until the tumor is visualized and then exposed, leaving it covered with fat. Endoshears or the harmonic scalpel is used to separate the fat from the capsule, with care taken not to get subcapsular (Fig. 6.11). Intraoperative ultrasound is performed in case of totally endophytic tumor or to assess the depth of the tumor (Fig. 6.12). Complete liberation of the kidney is important to ensure to get the best tumor exposure and visualization of all its faces (Fig. 6.13A and B).

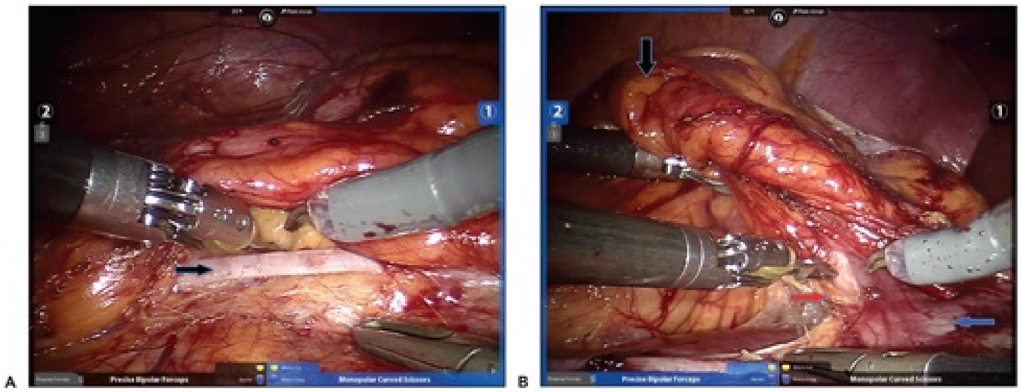

FIGURE 6.7 A: Dissection along the gonadal vein (*arrow*) during a right robotic PN carried cephalad to the lateral side of the vena cava. B: The lower pole of the kidney along with its fat (*black arrow*) is then elevated anterolaterally by the third robotic arm (using a ProGrasp forceps) to allow dissection to the renal pedicle (*red arrow*) via an inferoanterior approach. The IVC is displayed at the tip of the *blue arrow*.

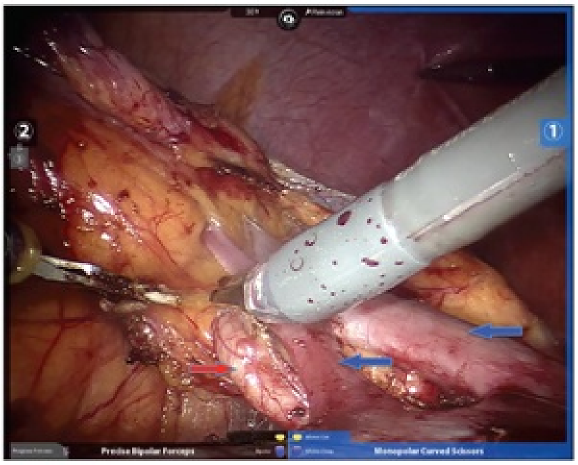

FIGURE 6.8 Pedicle dissection (in this case, two renal veins [*blue arrows*] and an early retrocaval division of the artery [*red arrow*]).

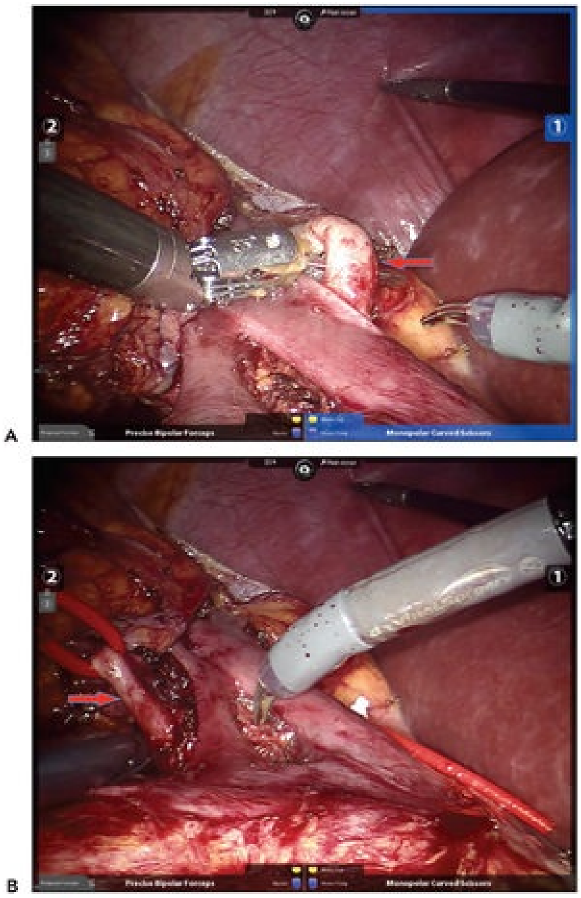

FIGURE 6.9 **A:** The secondary superior artery (*red arrow*) is first isolated and an elastic loop will be placed. **B:** The secondary lower artery (*red arrow*) is also isolated and spotted with an elastic loop.

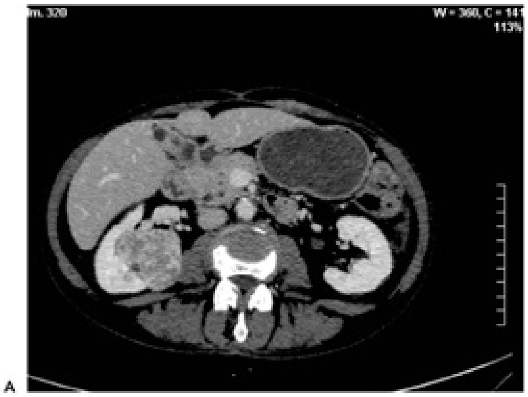

FIGURE 6.10 Due to the characteristics of the tumor (5.4 cm, right upper pole, hilar tumor) shown on the axial CT scan slice (**A**), *(continued)*

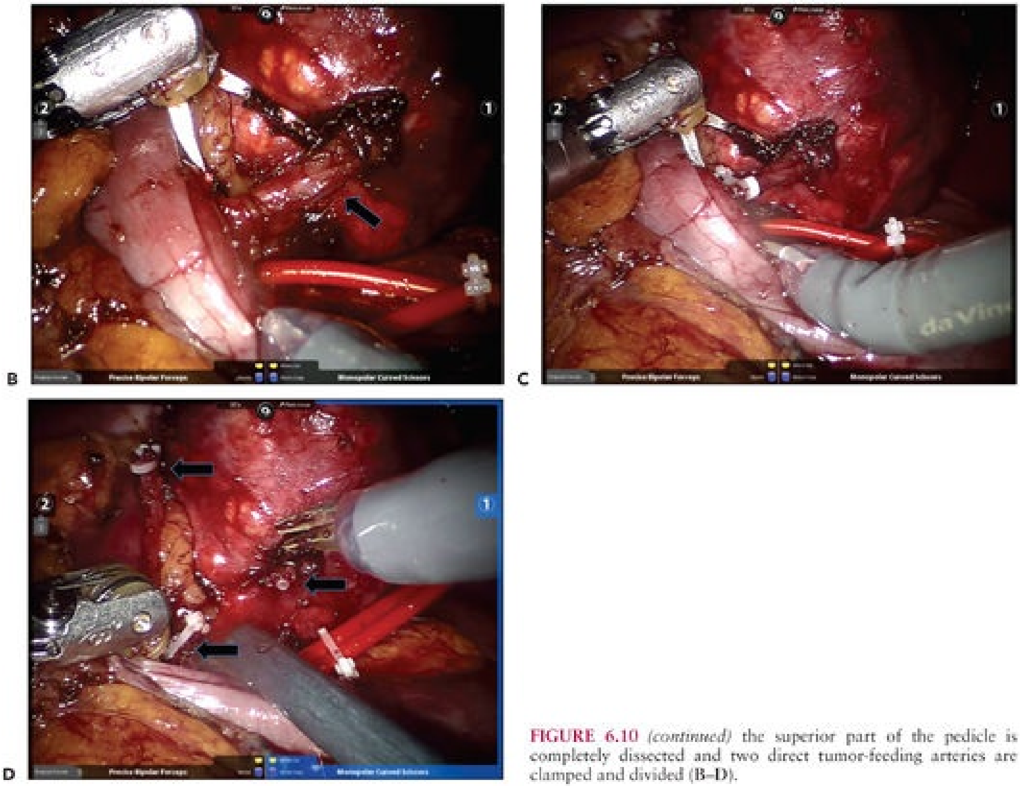

FIGURE 6.10 *(continued)* the superior part of the pedicle is completely dissected and two direct tumor-feeding arteries are clamped and divided (**B–D**).

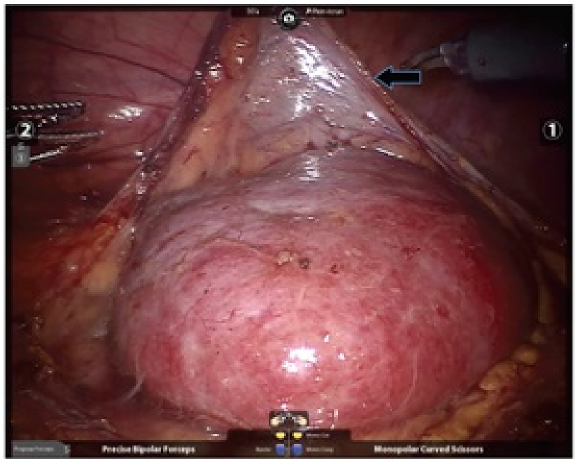

FIGURE 6.11 The Gerota fascia (*arrow*) is elevated anterolaterally by the assistant or by the third robotic arm (ProGrasp forceps). The anterior face of the kidney (view of the lower pole) is progressively freed of fat.

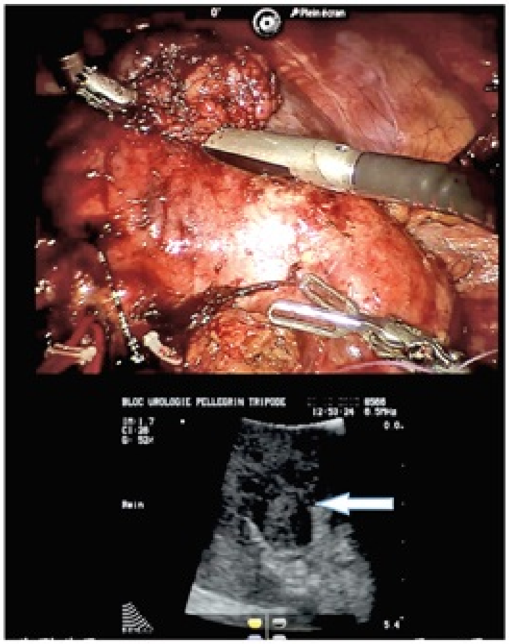

FIGURE 6.12 Intraoperative ultrasound with TilePro display for a hypoechoic, totally endophytic renal mass (*arrow*).

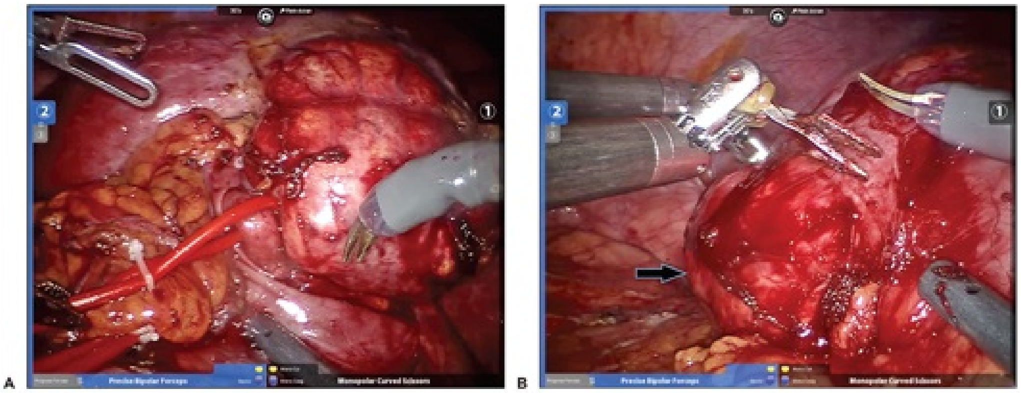

FIGURE 6.13 **A:** Anterior view of the upper pole hilar tumor. **B:** The kidney is then completely rotated on its pedicle to display the posterior face of the tumor (*arrow*).

The major challenges of laparoscopic nephron-sparing surgery are difficulty performing regional hypothermia (cold ischemia), difficulty maintaining hemostasis if hilar clamping is avoided, and difficulty completing the procedure within a 20-minute warm ischemic period. Previously, numerous techniques were used in an effort to perform simultaneous tumor resection and hemostasis but are not recommended, and LPN technique may closely mimic the OPN technique. Before vessel clamping and incision, tumor circumference is marked by scoring the renal capsule with electrocautery using monopolar scissors. Intraoperative ultrasound is used to delineate tumor margins, if necessary. Both the renal artery and vein can be clamped with laparoscopic bulldog clamps, but usually arterial clamping only is enough (Fig. 6.14). Small polar or very exophytic tumors can be removed without clamping (zero-ischemia). Based on tumor location and preoperative careful CT scan analysis (potentially with vascular 3D imaging reconstructions), a superselective arterial clamping can be decided in order to avoid ischemic injury to safe parenchyma regions. The excision is initiated by dissecting perpendicularly into the kidney with monopolar curved laparoscopic scissors (Fig. 6.15). This approach causes less tissue distortion than the use of the harmonic scalpel, bipolar cautery, or “hot scissors” (which are ineffective at preventing bleeding or urine leakage) and allows for a more accurate inspection for a positive surgical margin or an opening into the collecting system. A meticulous effort is made to avoid dissecting too superficially into the pseudocapsule or the tumor itself. The tumor is removed with the thinnest margin of normal parenchyma because tumor enucleation is as safe as real tumorectomy. Visual assessment of negative margin is performed during tumor excision as well as collecting system opening (Fig. 6.16A and B). Absorbable suture (4-0 Monocryl or V-Loc barbed suture) is used in a running fashion to close the collecting system if entered and perform parenchymal hemostasis at the same time, of which can be anchored by Hem-O-Lok or tied (Fig. 6.17). An interrupted sutured closure of the capsule or running crossing sutures with Hem-O-Lok, often bolstered, is then performed over a Surgicel or Gelfoam sponge (Fig. 6.18). The closure is often augmented by hemostatic agents (e.g., Tisseel or FloSeal) placed directly into the defect or impregnated in the Gelfoam. A roll of Surgicel may also be placed into the defect prior to reapproximating the capsule.

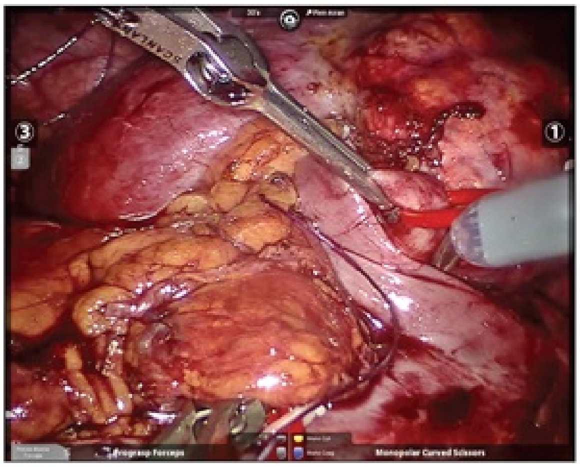

FIGURE 6.14 The superior secondary artery is clamped with a laparoscopic bulldog.

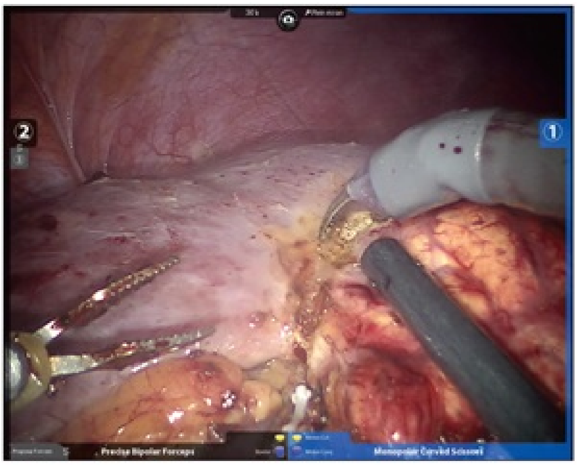

FIGURE 6.15 The excision of the tumor is initiated by dissecting perpendicularly into the kidney with the monopolar curved scissors.

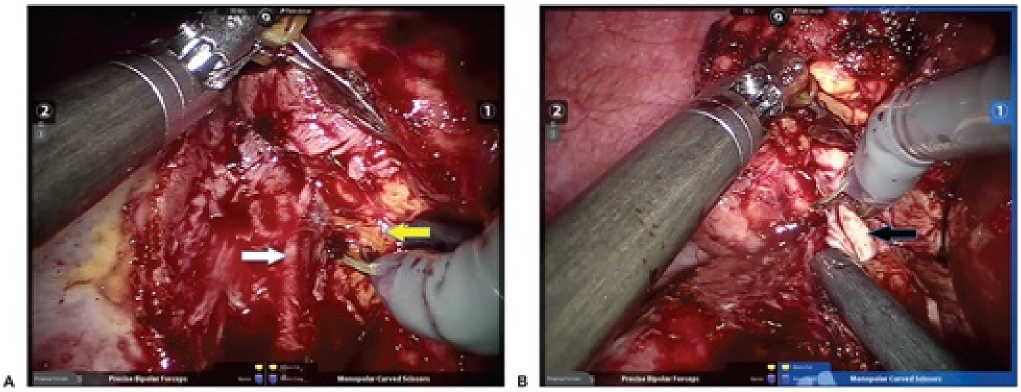

FIGURE 6.16 **A:** The tumor excision is carried on with cold scissors along an arterial branch (*white arrow*) and entering the sinusal fat (*yellow arrow*). **B:** Large opening of the collecting system (*black arrow*).

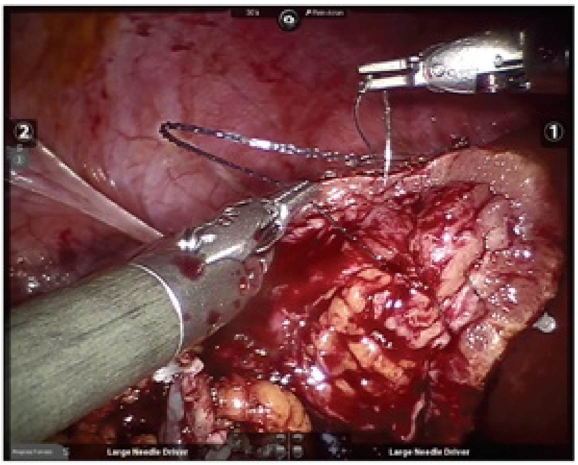

FIGURE 6.17 V-Loc barbed running suture for collecting system closure and parenchymal hemostasis.

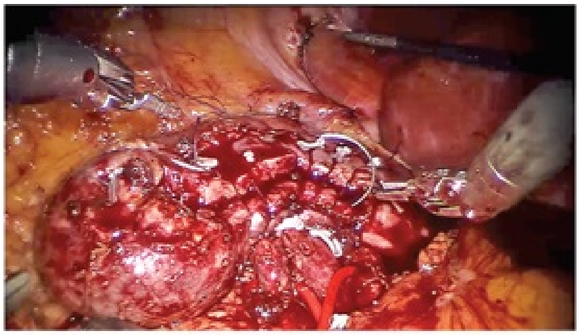

FIGURE 6.18 Capsular renorrhaphy: running crossing suture with Hem-O-Lok reapproximating the edges of the parenchymal wound.

The bulldog clamps are released and hemostasis assessed. In order to decrease warm ischemia time, unclamping can be performed just before superficial renorrhaphy (6). The retroperitoneum is irrigated and aspirated. If hemostasis is adequate at an insufflation pressure of <5 mm Hg, then the perinephric fat is reapproximated. It may be sutured or held in position with clips (Fig. 6.19). A closed system drain (e.g., Jackson-Pratt) is placed inside of the Gerota fascia and away from the renal parenchymal closure. The specimen is placed in a deployable entrapment sack if not done previously and extracted. The specimen inspection allows confirming the macroscopic negative margin status (Fig. 6.20). The incisions are closed.

Transperitoneal Robotic Partial Nephrectomy

Patient positioning is similar to laparoscopic. Peritoneal access is gained. The 12-mm port (camera port) is placed in line with the tip of the 12th rib and along the lateral rectus line. The peritoneum is inspected for further port placement. The 8-mm robotic ports are then placed. A bariatric robotic port is placed at the costal margin one handbreadth lateral and cephalad to the camera port. A second 8-mm bariatric port is placed along the same line as the camera but just cephalad to the pubic bone. In order to use the robotic technology to its fullest potential, a third regular 8-mm robotic port is placed laterally directly above the lower pole of the kidney (used to help retract). An equilateral triangle configuration is formed between the camera port, the lateral robotic port, and the lower robotic port to minimize instrument clashing. Assistant ports are placed between the camera port and the lower robotic port as well as one between the camera port and the upper robotic port. As in regular laparoscopic surgery, a liver retractor port is placed for right-sided tumors (Fig. 6.21).

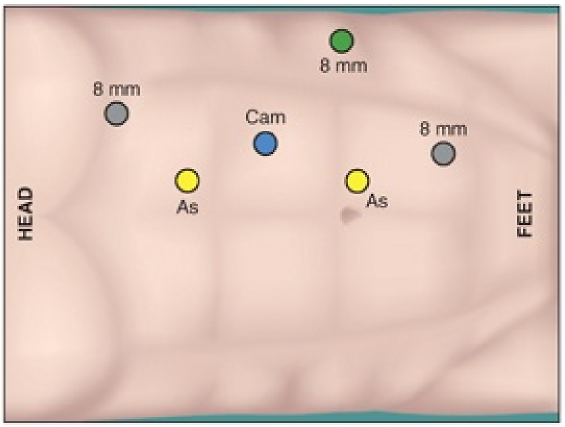

FIGURE 6.21 Port placement for a left robotic transperitoneal PN. The 12-mm endoscope port is *blue*, and 8-mm ports are used for left, right, and fourth arms. *As* are the assistant ports.

The robot is docked posteriorly to the patient with the camera arm coming in to the patient on a 15-degree angle in line with the camera port (Fig. 6.22).

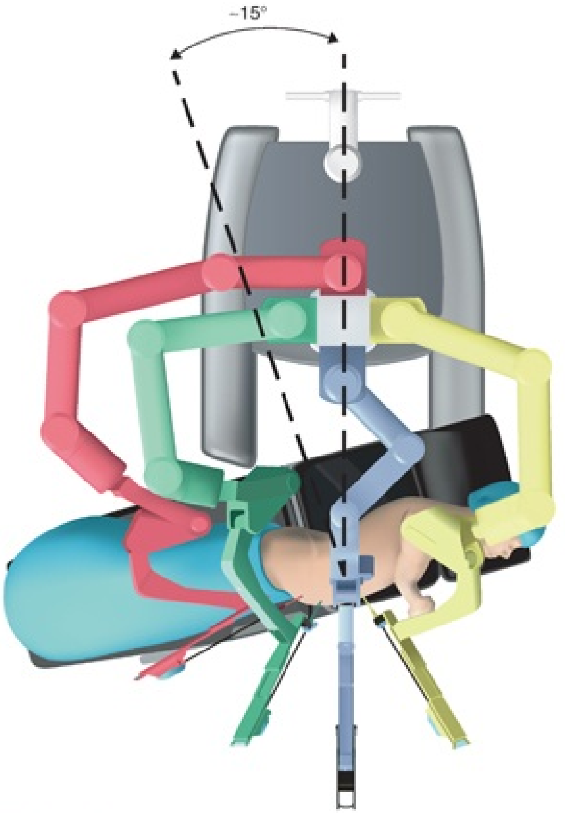

FIGURE 6.22 Top view of robot docking position for a right robotic transperitoneal PN.

Tumor resection and renorrhaphy principles are similar to laparoscopic methods. The advantages to the robotic technology are the 7 degrees of freedom and 90 degrees of articulation made possible by the EndoWrist. This allows for more intricate pedicle and tumor dissection as well as renorrhaphy. Robotic assistance greatly facilitates the complete hilum dissection required for superselective clamping/zero-ischemia techniques.

Retroperitoneoscopic Partial Nephrectomy

Access and renal exposure are as described in the description of retroperitoneoscopic nephrectomy. This technique is typically performed only by true LPN experts when treating small posterior renal tumors. Hilar dissection and clamping are performed selectively. Excision of the tumor is performed as described for transperitoneal LPN with negative margins confirmed and the defect covered with a fibrin glue bandage if shallow (cortex) or closed with interrupted capsular/parenchymal sutures if deeper (e.g., into the renal medulla). Of note, the limited space within the retroperitoneum makes suturing difficult, and most laparoscopic surgeons prefer to perform LPN transperitoneally. The specimen is entrapped in a deployable sack and removed, followed by hemostasis confirmation, drain placement, and closure.

Retroperitoneal Robotic Partial Nephrectomy

The patient is placed in the full flank position. Full flex is performed in order to try to achieve the maximal distance between the iliac crest and the 12th rib. The camera port is placed in the midaxillary line two fingerbreadths cephalad of the iliac crest. Access into the retroperitoneum is the same as with laparoscopic. The 8-mm robotic ports are placed under direct vision with a 30-degree up camera. The first two robotic ports are placed in the posterior and anterior axillary line. The peritoneum is then swept medially, and the fourth robotic port is placed as medial and inferiorly as possible under direct vision. An assistant port is placed between the camera port and the medial dissecting port (Fig. 6.23).

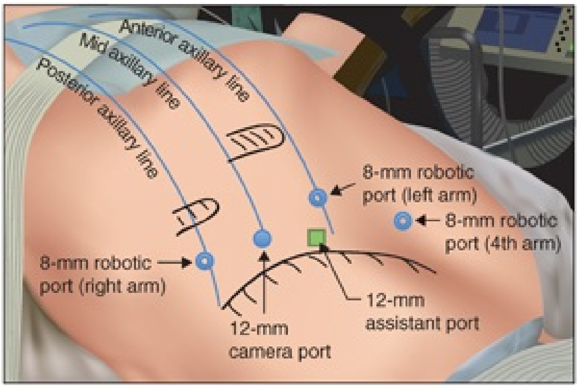

FIGURE 6.23 Port placement for a right robotic retroperitoneal PN.

The robot is docked at the head of the patient. The steps of the retroperitoneal portion of the case are similar to the laparoscopic description.

POSTOPERATIVE CARE

Postoperative care is similar regardless of the laparoscopic approach, and it is similar for nephrectomy and PN patients. Ketorolac (Toradol) 15 mg every 6 hours as requested is typically prescribed for 36 hours. Oral narcotics are made available if necessary. A clear liquid diet is resumed immediately and advanced as tolerated. The patient ambulates on postoperative day 1 and is typically discharged in the evening or the following morning. Parenteral antibiotics are discontinued on postoperative day 1. Oral analgesics are prescribed on discharge. Dulcolax suppositories are given as necessary for postoperative constipation, and patients can be discharged taking a stool softener (e.g., Colace). The drain is usually removed at postoperative day 2 when the volume has decreased to <50 mL per day. For PN, if a question exists regarding a urinary leak, a drain fluid creatinine level is obtained.

OUTCOMES

Laparoscopic Nephrectomy

In order for laparoscopic radical nephrectomy (LRN) to replace ORN as the standard of care, it has to provide equal cancer control with improved patient morbidity and convalescence at comparable operative efficiency. All three issues have been well demonstrated, and it has been confirmed that the oncologic efficacy of LRN for the treatment of localized renal cell carcinoma is equivalent to that of ORN (7–12).

In 2007 already, Colombo et al. (11) reported a 5-year 81% overall and a 90% cancer-specific survival for their LRN cohort compared to a 6-year 79% overall and 92% cancer-specific survival for their ORN cohort. The mean tumor size was 6 cm (5.8 and 6.2 cm, $P = .44$). Blood loss and operative times were lower in the LRN cohort (7). Other recent studies have continued to demonstrate that perioperative outcomes, including operative time, blood loss, postoperative analgesia requirements, length of hospital stay, and duration of convalescence, largely favor LRN.

Laparoscopic Partial Nephrectomy

Oncologic outcomes are comparable between LPN and OPN for T1a and T1b lesions. A multicenter study evaluated 1,800 consecutive patients undergoing either laparoscopic or open PN for tumors ≤7 cm in diameter. Positive surgical margins were found in 1.6% of laparoscopic PN specimens and in 1.0% of specimens from patients who underwent the open procedure (13). Lane and Gill (14) reported long-term oncologic outcomes of laparoscopic and open PN for T1 tumors. At 7 years, cancer-specific survival for T1a tumors was 95% in both cohorts; likewise, 7-year cancer-specific survival for T1b tumors was similar for both procedures (14).

Robotic Partial Nephrectomy

Contemporary robotic PN series indicate low positive margin rates between 0% and 5.9%, which are comparable with those of OPN (1.0%) and LPN (1.6%). The excellent stereoscopic vision and the dexterity of the robotic wrist probably contribute to the low positive margin rates observed in these series. Specific long-term oncologic outcome data for robotic assisted PN are not yet available (15–22).

COMPLICATIONS

Laparoscopic Nephrectomy

Laparoscopy is the current surgical standard for routine simple and radical nephrectomy due to equivalent cancer control and complication rates with decreased patient morbidity and convalescence. Even when LN has been expanded to treat complex situations, equivalent or nearly equivalent low complication rates have been observed. It is now not only feasible but increasingly reasonable for an experienced laparoscopic surgeon to selectively use LN to treat patients with large stage T2 tumors, hilar lymphadenopathy, kidneys needing autotransplantation, bilateral renal tumors, horseshoe kidneys, ADPKD, xanthogranulomatous pyelonephritis, and profound obesity. Although da Vinci (Intuitive, Sunnyvale, California) robotic-assisted laparoscopic surgery has little role in routine LN, it may have a future role in certain complex procedures, such as caval thrombectomy.

Of importance, complications do occur at an increased rate during a surgeon’s initial learning curve. Improvements in training and skills distribution throughout the urologic community are therefore needed. Although LN has made great inroads into the academic centers, its adoption into private, community practice has lagged behind (23). Laparoscopic-naïve open renal surgeons currently in practice need to remember that a significant time investment in retraining is required to work through an approximately 20-case learning curve. It is also critical that new technology does not inappropriately supersede a more appropriate operative procedure, as is highlighted by concerns that LRN may be inappropriately replacing PN in the treatment of small renal tumors (24). Future expansion of indications for nephron-sparing surgery and robotic assistance equipment spread will progressively diminish the role of LRN.

Laparoscopic Partial Nephrectomy

Compared to OPN, LPN reduced entry trauma, demonstrating improvements in hospital stay, operative time, and recovery time compared to open surgery (13). However, early series of LPN also revealed a higher rate of complications, both urologic (such as urinary leak and hemorrhage) and nonurologic (including deep vein thrombosis and pulmonary embolism), reflecting the learning curve (25). With experience and contemporary technical refinements to the procedure (e.g., the use of hemostatic agents or bolsters), Simmons and Gill (26) reported equivalent complication rates between open and LPN in 2007. In the same study, comparison of historical versus contemporary LPN outcomes demonstrated that overall complications had decreased from 33% to 19%, occurrence of postoperative hemorrhage decreased from 9.5% to 4.5%, urine leaks reduced in prevalence from 4.5% to 2%, and nonurologic complication rates dropped from 15% to 11% (26).

Despite improvements, there remain four principal concerns with LPN: controlling hemostasis; obtaining negative margins (particularly during the learning curve); avoiding lengthy (>30 minutes) warm ischemic times and renal injury; and treating large, complex, or centrally located tumors. Robotic assistance significantly improved PN technique and at least the issues regarding ischemia time and treatment of large tumors.

Robotic Partial Nephrectomy

Complication rates in contemporary robotic PN series, even those including large, complex tumors, remain low (8.6% to 24.5%). With adequate minimally invasive expertise, robotic PN demonstrated at least equal and sometimes even better perioperative outcomes and complication rates (27–30).

In a single-institution series of 102 patients who underwent LPN or robotic PN, Wang et al. (28) reported decreased warm ischemia time (19 minutes versus 25 minutes) and shorter hospital stay (2.5 days versus 2.9 days) for the robotic PN cohort, but no difference in complication rates between the two groups. A recent study comparing 118 patients who underwent LPN with 129 patients who underwent robotic nephron-sparing surgery also found similar rates of postoperative complications between study arms (10.2% versus 8.6%) (27). In a multi-institutional study of 450 patients who underwent robotic PN, complications were stratified using the Clavien-Dindo classification system (27,32). Overall, 71 patients experienced a complication (16%); 8 complications were intraoperative and 65 were postoperative. A total of 54 complications were classified as Clavien grade I or II (12%), which required conservative management only, whereas 17 complications were Clavien grade III or IV (4%), necessitating subsequent intervention.

The rates of postoperative hemorrhage after minimally invasive PN are relatively low at <5% and are similar between laparoscopic and robotic series, with rare need for angioembolization (0.4%) (22,26). The majority of delayed postoperative hemorrhages arise from arterial pseudoaneurysm or arteriovenous fistula formation (32). As expected, with increasing tumor centrality and involvement of major vascular structures during resection, the risk of vascular anomalies also rises. Angioembolization can readily control the source of postoperative PN hemorrhage if recognized quickly and can obviate the need for operative reintervention, which carries a significant risk of radical nephrectomy. A high index of suspicion is necessary with a low threshold for angiointervention in any patient who presents with postoperative anemia or hemodynamic instability after PN.

In conclusion, LN is the current standard of care for noncancer disease and for big tumors not amenable to nephron-sparing surgery. LPN outcomes now closely approach those of OPN at elite centers but remains a challenging procedure with long learning curve. These are the reasons why it is getting supplanted by robotic PN offering the advantages of the minimally invasive approach that are desirable to patients as well as stereoscopic 3D vision and articulated instruments, which make it an ideal platform for the surgeon to treat even the most complex tumors. Novel techniques are emerging that aim to further maximize postoperative renal function by reducing, and even eliminating, surgical ischemia. The published series of robotic PN have demonstrated that it is safe and feasible, with comparable perioperative outcomes to LPN and open surgery. With the increasing incidence of small renal masses, experience with robotic PN is likely to grow and further refinements will be aimed at maximizing the trifecta of postoperative renal function, oncologic control, and perioperative outcomes.

CHAPTER 7 ■ MINIMALLY INVASIVE NEPHROURETERECTOMY

ALON Z. WEIZER AND JEFFREY S. MONTGOMERY

EPIDEMIOLOGY

Upper tract urothelial carcinoma (UTUC) is a rare entity representing approximately 5% of all urothelial carcinomas (1). Based on Surveillance, Epidemiology, and End Results (SEER) data from 1973 to 2005, the incidence of UTUC has increased from 1.88 to 2.06 cases per 100,000 person-years. This includes an increase in ureteral tumors from 0.69 to 0.91 cases per 100,000 person-years and a slight decrease in renal pelvic tumors from 1.19 to 1.15 cases per 100,000 person-years over this time period. The increased incidence is associated with an increase in the median age at diagnosis (from 68 to 73 years old) and an increase detection of in situ disease without dramatic increases in regional or distant disease (2). Despite this, the literature suggests that approximately 60% of UTUC are invasive at the time of diagnosis (3). Roughly 2% to 5% of patients have bilateral UTUC on presentation, and up to 4% of patients will develop a contralateral UTUC at some point in their course. Although the incidence of UTUC has increased, other studies have suggested that survival has not improved. Eylert et al. (4) combined multiple data sets in England from 1985 to 2010 and found that an increased number of patients were diagnosed at more advanced stages with a decrease in 5-year overall survival from 60% to 48% over the study period.

Explanations for the increased incidence of UTUC include increased survival among patients with bladder cancer who are at risk of developing metachronous UTUC (incidence in bladder cancer patients is 0.75% to 6.4% after cystectomy) (5), the increased use of intravesical therapy especially in the setting of carcinoma in situ, and improved detection with current cross-sectional imaging and endoscopic technology. However, because there has been little change in the management of UTUC (nephroureterectomy remains the mainstay of treatment with limited data on the use of perioperative chemotherapy), the increased incidence has not been associated with a decline in mortality.

RISK FACTORS

Patients who develop UTUC share many of the same characteristics as those who develop bladder cancer. These include exposure to tobacco (6) and environmental/occupational exposures including aromatic amines (7). Several specific risk factors include chronic inflammation caused by nephrolithiasis or recurrent ascending urinary tract infections. Congenital or acquired obstruction (as seen in patients with chronic nephrolithiasis and ureteral stricture) may increase the risk of developing UTUC. Due to the rarity of the disease, it is unclear whether congenital abnormalities of the upper urinary tract such as ureteral duplication or ectopic kidneys predispose to UTUC. An increased incidence of UTUC in parts of Taiwan has been associated with blackfoot disease and exposure to arsenic in drinking water (7). *Aristolochia fangchi* and *Aristolochia clematis* contain aristolochic acid, which is found in certain Chinese herbal preparations (8) and is also endemic to the Balkans. This has been associated with UTUC and may play a role in the development of Balkan nephropathy (9). Finally, patients with hereditary nonpolyposis colon cancer (HNPCC) have an increased risk of UTUC and bladder cancer; this population requires screening for urothelial carcinoma (10).

DIAGNOSIS

The diagnosis of UTUC can be challenging. In patients without a prior history of bladder cancer, signs and symptoms typical of UTUC, including hematuria, flank pain, fever/infection, and hydronephrosis, can mimic nephrolithiasis. This becomes more confusing when patients present with a stone due to urine stasis caused by an obstructing tumor. Because the standard imaging for stone disease is a noncontrast computerized tomography (CT) scan, an UTUC may not be apparent unless it is causing a contour deformity of the kidney or the ureter. In addition, a calcified tumor may be interpreted as a stone, and if treated with shock wave lithotripsy as opposed to endoscopic management, a delay in diagnosis occurs.

In the absence of symptoms, hematuria should be evaluated according to the current American Urological Association hematuria guidelines with a CT urogram, cystoscopy, and urine cytology (11). Even in the setting of symptoms suggestive of nephrolithiasis, consideration should be made for obtaining a urine cytology, especially if the patient has risk factors for bladder cancer (although nephrolithiasis can cause cytologic atypia). Pursuit of cross-sectional imaging with a contrast-enhanced excretory phase or endoscopic visualization should be considered if symptoms persist. Finally, recalcitrant irritative voiding symptoms presumed to be caused by a urinary tract infection treated with a course of culture-directed antibiotics warrant further evaluation for urothelial carcinoma with cystoscopy, upper tract imaging, and cytology. For patients who cannot undergo CT with contrast due to compromised renal function, magnetic resonance (MR) urogram can be considered if their estimated glomerular filtration rate (eGFR) is ≥30 mL per minute. For those with eGFR <30 mL per minute, magnetic resonance imaging (MRI) of the abdomen/pelvis without gadolinium, noncontrast CT scan, or renal ultrasound can be informative but should be coupled with retrograde pyelograms and possible ureteroscopy to complete a full evaluation of the urinary tract.

Several options for diagnosis exist if a patient has a filling defect in the upper urinary tract or positive urine cytology without visible signs of disease in the bladder on cystoscopy. We believe that a filling defect on imaging studies with a positive selective cytology from that upper urinary tract is adequate to make the diagnosis of UTUC. Ureteroscopy with biopsy can still be performed but may not be necessary in the setting of a large filling defect and positive selective cytology. Alternatively, image-guided percutaneous biopsy can be considered for bulky upper tract masses. Although some contend that tumor seeding of the biopsy tract is a possibility, there may be a risk of lymphatic dissemination of tumor due to use of pressurized irrigation with ureteroscopy (12). We have not seen tumor tract seeding when employing a biopsy sheath during percutaneous biopsy. For patients with a positive cytology but without visible signs of disease, random bladder and prostatic urethral biopsies should be obtained in addition to ureteroscopy with ureteral barbotage cytology to rule out the possibility of occult disease in these locations. Use of ureteral brushes or other biopsy tools are helpful in obtaining an adequate cytologic or tissue diagnosis in the upper urinary tract.

Patients with UTUC should undergo additional staging to assess for metastatic disease. This includes a chest X-ray or chest CT, complete blood count, and comprehensive metabolic panel (including liver function tests and an alkaline phosphatase). These can help guide the need for additional imaging including nuclear medicine bone scan to assess for bony metastasis and chest CT if the chest X-ray is concerning. Symptoms of bone pain may also guide the use of a bone scan, regional plain films, or selective MRI or CT depending on location.

Patients with a prior history of bladder cancer warrant special consideration. Microscopic or gross hematuria, persistent urinary symptoms, or abnormalities on urinalysis despite treatment for urinary tract infection warrant additional evaluation. Urine cytology should be part of standard surveillance for patients with a history of bladder cancer. For patients with an intact bladder and prior endoscopic and/or intravesical bladder therapy, upper tract imaging should be performed prior to any biopsy. In situations with no obvious bladder recurrence, endoscopic evaluation should include bladder and prostatic urethral biopsies as well as retrograde pyelograms, selective upper tract cytology, and ureteroscopy. Cystectomy patients, especially with a history of carcinoma in situ, should undergo a CT or an MR urogram if possible. If this is not possible due to poor renal function, MRI of the abdomen and pelvis, loopogram (for ileal conduit), or cystogram (for neobladder) may help identify an upper tract lesion. Upper urinary tracts not accessible by retrograde ureteroscopy may warrant a percutaneous antegrade approach to identify disease.

ALTERNATIVE THERAPY

Nephroureterectomy is considered the standard treatment for UTUC. However, there are several patient and disease factors that obligate alternative or interim approaches. There is a large percentage of UTUC patients with compromised renal function (13), and nephroureterectomy may necessitate dialysis. Renal function may be compromised by medical renal disease related to smoking, hypertension, diabetes, or cardiovascular disease or may be due to prior surgical intervention for upper tract disease. In addition, the disease itself may influence initial treatment strategies. Because of the difficulty in accurately assessing the stage (i.e., depth of invasion) of UTUC, grade is used to assess the potential aggressiveness of the disease. Patients with low-grade focal tumors of the renal pelvis or ureter may be managed with endoscopic approaches. Ureteroscopy is often the most straightforward option. There are various tools that can be used for both resection and ablation of these lesions. In order to get adequate tissue for diagnosis, we tend to use an access sheath and backload the BIGopsy device (Cook, Bloomington, Indiana). This is especially useful for proximal ureteral and renal pelvis tumors. For more distal tumors, a semirigid ureteroscope is used with a biopsy forceps. We often combine biopsy with ureteral wash cytology, and for flat lesions, ureteral brushings. Both a holmium laser as well as ureteroscopic Bugbee electrode (2Fr) can be used for lesion ablation. For larger low-grade collecting system tumors, percutaneous resection can be considered because the risk of tumor seeding is low with these tumors. Access is achieved in the identical fashion to percutaneous nephrolithotomy. For lower and interpolar lesions, direct access to the tumor with the use of a resectoscope can allow for complete endoscopic removal and hemostasis.

However, occasionally due to angulation and narrow calyceal diameter, the tumor cannot be accessed with a resectoscope and a flexible nephroscope with biopsy forceps, laser, or Bugbee are needed to manage the lesion. In patients with previous urinary diversion, antegrade percutaneous renal access may be necessary if retrograde access is not possible.

Patients with focal but high-grade tumors may benefit from endoscopic therapy in addition to adjuvant intraurinary chemo/immunotherapy to reduce the risk of recurrence and progression. Although several approaches have been described, we believe that placement of a nephrostomy tube and antegrade instillation is the most reliable approach. Other options include placement of an indwelling ureteral stent with intravesical instillation (relying that the medication will reflux into the upper tract) or retrograde placement of an externalized ureteral catheter prior to each treatment with instillation of the medication via this catheter. This strategy is both cumbersome and time-consuming for the urologist and the patient. Similar to high-grade, non–muscle-invasive bladder cancer, the preferred intraurinary treatment for high-grade papillary tumors and carcinoma in situ upper tract disease is bacille Calmette-Guérin (BCG). Approximately, 30% of patients recur following upper tract instillation with a median follow-up of >20 months in a review by Carmignani et al. (14). Options for second-line therapy for those who fail an initial induction course of BCG include a second induction course of BCG (+/− interferon) or instilled chemotherapy (e.g., mitomycin, gemcitabine, docetaxel). Managing high-grade disease conservatively, however, carries risk of incomplete treatment and disease progression and therefore should be driven by patient life expectancy, extent of disease, renal function, and potential additional morbidity of nephroureterectomy. The risk of recurrence is high (as much as 80%) making nephroureterectomy the preferred treatment option for patients with high-grade disease (14).

When endoscopic management is performed for UTUC, a strategy of surveillance with endoscopy is necessary to evaluate for recurrence and metastases. Patients should undergo three-dimensional cross-sectional imaging at least yearly to evaluate for possible metastases. Patients managed conservatively at first do not appear to have worse outcomes when compared to patients managed with nephroureterectomy initially (15).

Patients with bilateral high-grade upper tract disease present a unique challenge and often require bilateral nephroureterectomy. Although recent data suggests that patients requiring dialysis for postsurgical indications have better outcomes than those requiring dialysis for medical renal disease, the substantial effect that dialysis has on patient quality of life needs to be considered (16). Also, with a history of UTUC, patients must be free of disease recurrence for at least 2 years prior to being listed for renal transplant.

Lesions of the distal or midureter may be managed by segmental resection with data suggesting similar cancer control to nephroureterectomy (17). Details of this approach are discussed elsewhere in this book. However, we have found that robotic-assisted approaches are effective with good outcomes for patients undergoing distal ureterectomy, psoas hitch, and/or Boari flap reconstruction with the ability to remove as much as two-thirds of the ureter. In addition, lymphadenectomy can be performed at the time of the procedure. In patients with bulky or locally advanced disease, neoadjuvant chemotherapy should be considered as the presence of both kidneys and preserved renal function allows for optimal chemotherapy dosing (18). However, there is currently no prospective, randomized evidence to support this approach. The same cisplatin-based regimens that are used for invasive bladder cancer are typically employed in this setting.

Finally, in those patients who have unresectable disease or are poor surgical candidates, palliative management should be driven by patient goals and symptoms. Early referral to specialists in palliative care is important to avoid unnecessary interventions. The most common symptoms seen in patients with locally advanced disease are pain and hematuria, with or without clot retention and the need for blood transfusion. Palliative radiation can effectively manage pain and gross hematuria caused by unresectable UTUC in select patients. Given the extensive vascular network supplying the renal pelvis and ureter, renal angioembolization often fails to control hematuria arising from UTUC.

INDICATIONS FOR SURGERY

After considering the treatment alternatives presented earlier, patients with localized high-grade Ta-T4 urothelial carcinoma are suitable candidates for nephroureterectomy. The decision on how best to approach nephroureterectomy depends on the extent of the disease and the skillset of the surgeon. There are no absolute indications for open versus a minimally invasive (i.e., laparoscopic, hand-assisted, or robotic) approach. However, there are several clinical circumstances that can help guide this decision. Most of the published literature indicates that the oncologic outcomes for open and minimally invasive nephroureterectomy are similar. An open approach has traditionally been advocated for patients with significant pulmonary disease due to the concern for absorption of carbon dioxide during laparoscopy that would result in patient hypercarbia. There are two issues with this teaching. First, the open incisions used for nephroureterectomy can result in significant abdominal pain that can compromises the depth of patient inspiration during recovery. Second, a hand-assisted approach in this patient population can hasten the procedure and allow the insufflation pressure to be reduced (10 mm Hg), limiting carbon dioxide absorption while still providing patients the recovery benefits of laparoscopy. Patients who cannot tolerate a hand-assisted nephroureterectomy are likely not appropriate surgical candidates. Other relative indications for open surgery include bulky disease, presence of lymphadenopathy, as well as prior extensive endoscopic management that could result in significant perinephric inflammation. Although these procedures are more challenging, we believe they are still amenable to minimally invasive approaches at the discretion of the surgeon.

Selecting a hand-assisted, conventional laparoscopic, or robotic approach also depends on the surgeon’s experience, but patient and disease characteristics influence this decision. In general, we employ a hand-assisted approach when patient comorbidities dictate an expeditious procedure or when tactile perception would be advantageous (e.g., bulky specimens or perirenal inflammation). For patients with renal pelvis tumors, we often combine an endoscopic approach for the management of the bladder cuff with a hand-assisted approach. An endoscopic bladder cuff can also be used with a conventional laparoscopic approach. We do not recommend performing an endoscopic bladder cuff for distal ureteral tumors because of risk of tumor spillage. In the case of large distal tumors, combining a conventional laparoscopic approach for the nephrectomy portion with a lower midline or Gibson incision to perform an open distal ureteral dissection and bladder cuff avoids a single large incision or two separate incisions. This is especially useful when managing upper tract recurrences in patients with a urinary diversion where the distal ureteral anatomy is often distorted and prior surgery creates scarring around structures such as the iliac vessels or bowel.

For most patients, robotic-assisted nephroureterectomy is our preferred approach. The advantages of this approach include (a) techniques have been described that obviate patient repositioning during the case (although we do reposition the robot but not the patient), (b) the location of the extraction incision can be tailored to the patient, (c) a robust lymphadenectomy can be performed, and (d) a watertight bladder closure can be achieved once the distal ureter and bladder cuff are excised. In our experience, the primary disadvantage of the robotic approach is longer average operative times compared to laparoscopic approaches. The appropriate nephroureterectomy approach is the one that best allows the individual surgeon to adhere to oncologic principles.

SURGICAL TECHNIQUE

Patient Preparation

Although there are some differences in patient positioning and surgical technique by approach selected, patient preparation is similar for all patients undergoing minimally invasive nephroureterectomy. Staging is performed for all patients as described earlier including cross-sectional imaging combined with upper tract opacification (Fig. 7.1). This allows for the accurate anatomic evaluation of any upper tract disease, definition of the renal hilar vascular anatomy as well as the presence of lymphadenopathy or solid organ metastases. In addition, patients undergo preoperative lab evaluation with a comprehensive metabolic panel including liver function tests, complete blood count, coagulation panel, electrocardiogram, and blood type and screen. We do not cross-match for blood products given the low incidence of blood transfusion associated with this procedure. In addition, patients undergo preoperative evaluation by anesthesiology with directed evaluation by cardiology, pulmonology, or other medical services as indicated. Mechanical bowel preparation is not necessary; a clear liquid diet beginning 24 hours prior to surgery with nothing by mouth 4 hours prior to surgery is recommended.

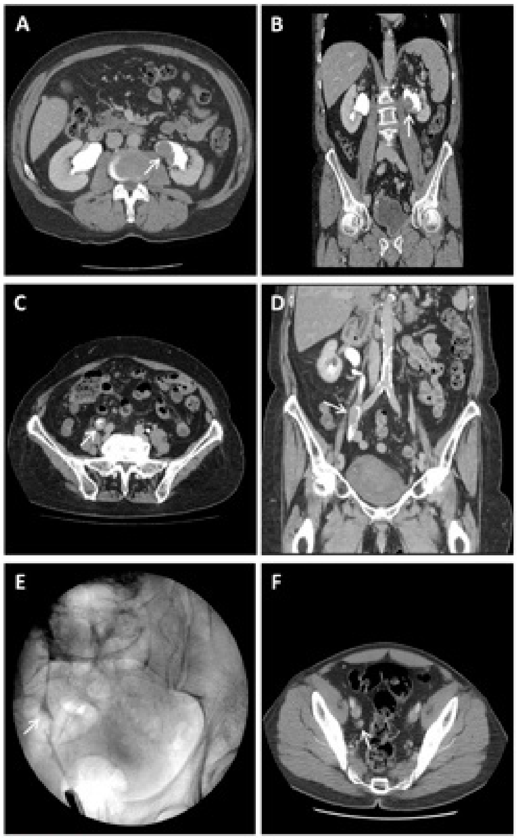

FIGURE 7.1 Upper tract urothelial carcinoma. Tumor location indicated with *arrows* in each image. Transverse (A) and coronal (B) views of a large renal pelvis tumor on CT urogram excretory phase. Transverse (C) and coronal (D) CT urogram view of a tumor occupying most of the midureter. A classic "goblet sign" on retrograde pyelogram (E) of a right-sided distal ureteral tumor. This same tumor on a transverse section of a contrast-enhanced CT (F).

Obtaining informed consent from the patient, including a description of the procedure along with a discussion of the surgical risks is a crucial step. The general risks of this procedure include bleeding requiring blood transfusion, infection (e.g., abscess, urinary tract infection, wound infection), damage to surrounding structures (e.g., bowel, blood vessels, nerves, bladder, pancreas and depending on the side of the procedure, liver or spleen), bladder urine leak requiring prolonged drainage, disease recurrence, and need for additional treatments.

Although we prefer that all other antiplatelet medications be discontinued 5 to 7 days prior to surgery, there is good data to support continuation of at least 81 mg of aspirin throughout the perioperative period in patients with prior cardiac stenting. In fact, discontinuation of aspirin likely increases the risk of a cardiac or thromboembolic events in surgical patients (19).

It is critical to ensure that any urothelial disease within the bladder is controlled prior to nephroureterectomy. Although cystoscopy can be performed at the time of the nephroureterectomy to evaluate the bladder, if disease is found, there is limited ability to determine whether the bladder pathology would influence surgical decision making. As such, we recommend office cystoscopy at least 2 weeks prior to surgery so that bladder tumors can be resected and staged. In addition, some groups have reported on the use of perioperative intravesical mitomycin at the time of nephroureterectomy to reduce the risk of bladder recurrence, which has been reported to be as high as 30% (20).

Patient Positioning

A surgical beanbag is placed on the operating table with a drawsheet above and below the beanbag to facilitate proper positioning. The patient is initially in the supine position on the table. Intravenous antibiotics to cover skin flora are administered within 1 hour of surgical incision. We routinely use 5,000 units of subcutaneous heparin in addition to lower extremity sequential compression devices for venous thromboembolic prophylaxis. After induction of general anesthesia, a Foley catheter is placed as well as an orogastric tube to minimize the risk of injury to the viscera when accessing the abdominal cavity. We ensure that the circulating nurse has access to the catheter in the event that the bladder needs to be filled during the procedure. In cases where an endoscopic bladder cuff approach is used, the Foley catheter is placed following this portion of the procedure.

Prior to positioning, it is important to assure that there are sufficient members of the operative team available to lift and secure the patient. The patient is brought to a modified lateral decubitus position with the operative side elevated at a 45- to 60-degree angle from the horizontal plane. The downside knee is flexed at the knee and hip, the upside leg is straight and parallel to the floor, and pillows are placed between the legs and also on the table to support the upside ankle. Some surgeons choose to position the patient’s iliac crest over the table break and mildly flex (15 to 30 degrees) the table to lengthen the space between the costal margin and iliac crest. An axillary roll is generally not necessary, but it should be assured that the downside axilla is not compacted against the operating table to avoid a brachial plexus injury. The upside arm is secured on an elevated arm board in an anatomic position, assuring that it will not obstruct the movement of the surgical instruments during the case. The downside arm is supported with a table-level, detachable arm board. Assure that there are no tubes or cords under the patient or under any securing tape or straps because these can cause pressure necrosis during the case. The beanbag is then formed along the patient’s sides to support this position, and air is evacuated from the beanbag to secure it in place. All pressure points are padded and 3-inch padded cloth tape is brought over the hips and across the chest just below the axilla to firmly secure the patient to the table but avoiding compression (Fig. 7.2). The surgical, anesthesia, and nursing teams should evaluate the patient to assure proper positioning and support. The abdomen, flank, and lower chest are sterilely prepped and draped so that the boundaries of the operative field include the midchest, superiorly; posterior axillary line, laterally; beyond the umbilicus, medially exposing the midline; and the pubic symphysis, inferiorly. Prior to the initial incision, a surgical verification is performed to confirm the correct patient, surgical site (marked in the preoperative holding area), antibiotics given, appropriate equipment, surgical team introductions, fire safety assessment as well as risk-based venous thromboembolism prophylaxis.

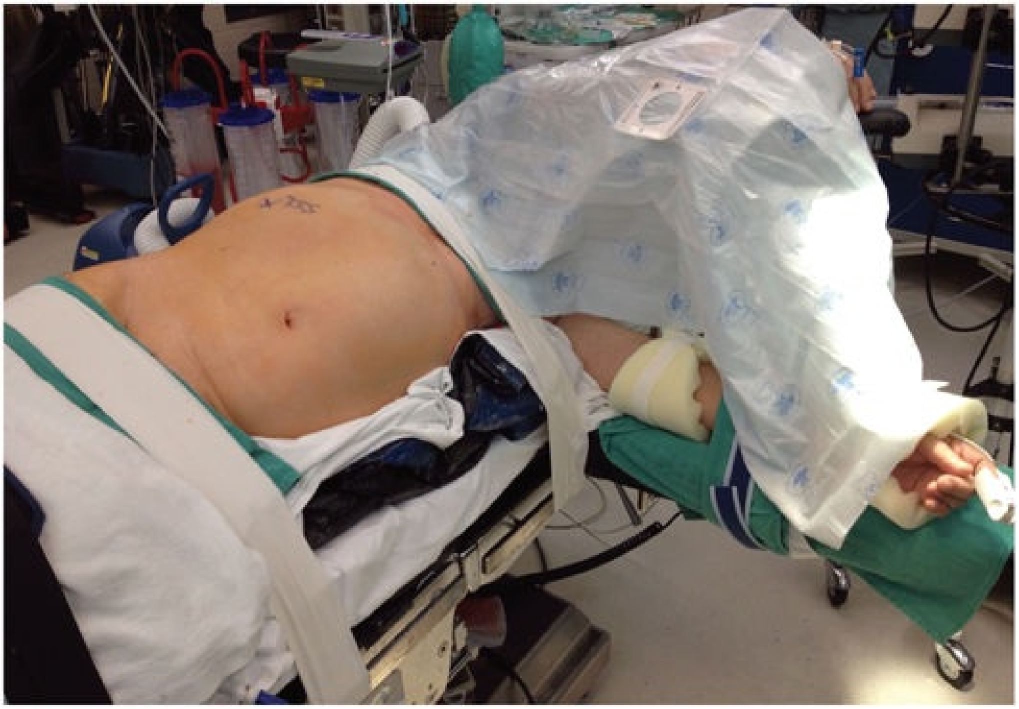

FIGURE 7.2 Our standard patient positioning for all of our minimally invasive nephroureterectomy approaches. The patient is at a 60-degree angle to the operating table, supported with a beanbag and padded tape. The ipsilateral arm is supported on an elevated arm board and the contralateral arm on a bed-level arm board. Both arms are padded at pressure point, secured in place, and draped an upper body warming apparatus.

Transperitoneal Laparoscopic Radical Nephroureterectomy

Although minimally invasive retroperitoneal nephroureterectomy has been reported in small series (21), the majority of minimally invasive nephroureterectomies are performed via a transperitoneal approach. The transperitoneal approach offers a larger working space as compared with the retroperitoneoscopic approach. Transperitoneal options include conventional laparoscopic, hand-assisted, and robotic techniques. All of these approaches offer the patient the benefits of a minimally invasive procedure; the approach selected is most influenced by the surgeon's experience and comfort level with a specific technique.

For all approaches, the abdominal and pelvic cross-sectional staging imaging should be reviewed, preferably available in the operating room at the time of surgery, to note the patient's anatomy. Special attention should be paid to the renal hilum, identifying any complexity of the renal vasculature to aid in surgical planning. The surgeon should once again assure that there are no signs of metastatic disease or lymphadenopathy which may indicate that the patient should receive neoadjuvant chemotherapy.

Conventional Laparoscopic Nephroureterectomy

Initial abdominal access is gained either via a Veress needle technique, open Hasson technique, or with a direct optical trocar technique (http://www.auanet.org/common/pdf/education/BLUS-Handbook.pdf). There are multiple effective port configurations, and this is left to individual surgeon preference and experience. Figure 7.3 shows the suggested port placement for a conventional laparoscopic approach. An incision is made approximately 1 cm to the ipsilateral side of the umbilicus, and the abdomen is accessed with a Veress needle. If the patient has had previous abdominal surgery, access is gained at a site away from incision lines to avoid bowel adhesions. A 5-

mm or 10/12-mm camera port (depending on camera lens size available) is placed at this site. Under laparoscopic vision, a 10/12-mm working port is placed at the level of the umbilicus just lateral to the rectus muscle, a 5-mm working port is placed 2 cm below the medial aspect of the ipsilateral costal margin, and a 5-mm assistant port is placed in the ipsilateral axillary line 2 to 3 cm superior to the anterior superior iliac spine. This port configuration is similar to that for a laparoscopic nephrectomy with the notable addition of a 5-mm or 10/12-mm port in the midline between the umbilicus and pubic symphysis to allow for the dissection of the distal ureter.

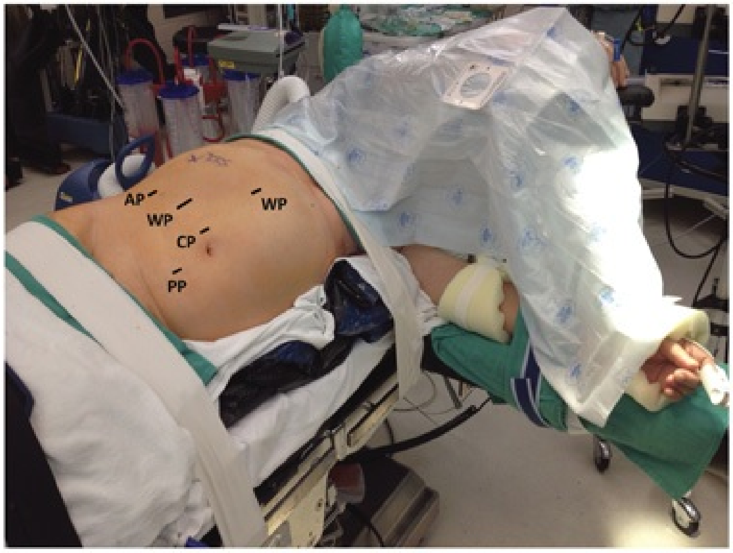

FIGURE 7.3 The suggested port configuration for a conventional laparoscopic nephroureterectomy. *AP*, assistant port; *CP*, camera port; *PP*, pelvic port; *WP*, working port.

There are some important general principles when deciding on port placement for a conventional laparoscopic nephroureterectomy and individual port locations may vary according to each patient's body habitus:

1. An ergonomic configuration for the surgeon and assistant is of utmost importance to assure comfort and avoid surgeon injury.
2. For obese patients, the port configuration should be displaced laterally to assure optimal access for dissection.
3. For patients with compact abdominal surface areas, it may be prudent to flex the patient to expand the operative space.
4. It may be necessary to alter the port locations to assure adequate spacing between the ports (i.e., approximately 5 cm or 1 fist-breadth apart).
5. It may also be necessary to move the lateral assistant port toward the midclavicular line or down into the pelvis to achieve proper spacing.

The dissection begins by sharply (with judicious use of cautery to maintain hemostasis) incising along the white line of Toldt and reflecting the colon medially to expose the surface of Gerota fascia, taking care not to enter the colon mesentery. On the left side, this portion of the dissection is generally more extensive and involves releasing the lateral colonic attachments down into the pelvis and along the spleen. On the right side, care should be used when kocherizing the duodenum off of the medial aspect of the Gerota, renal hilum, and vena cava. Focusing on the lower pole of the kidney, the space is developed posteriorly, lateral to the great vessels, to expose the psoas muscle. The lower pole Gerota containing the ureter can then be elevated by the assistant surgeon with a laparoscopic sucker or grasper. Within this elevated tissue, the gonadal vein and ureter can be exposed. For renal and proximal ureteral UTUC, the ureter can be clipped at this time. For more distal tumors, the ureteral dissection can be carried inferiorly until the surgeon is beyond the site of the tumor to clip the ureter to avoid migration of tumor cells into the bladder.

On the right side, the gonadal vein should be reflected medially from the specimen. The para-aortic lymphadenectomy for left renal and proximal ureteral tumors can be facilitated by including the gonadal vein with the specimen. For distal left-sided tumors, the gonadal vein can be reflected medially from the specimen. The inferomedial and posterior dissection is carried superiorly to the renal hilum. On the left side, beware of lumbar veins that variably course to the renal and/or gonadal vein. Elevating the lower pole of the kidney to put the renal hilum on stretch, space is made superior and posterior to the renal hilum to allow adequate access for a laparoscopic stapling device. We generally staple the renal artery and vein en bloc, although these vessels can be separately isolated and stapled at the surgeon's discretion. It is important to avoid the use of clips around the renal hilum prior to stapling to avoid entrapping clips in the staple load, causing staple malfunction and possible vascular catastrophe. It is also important to assure that additional staple loads are available in the room prior to stapling the hilum.

With the hilum controlled the dissection proceeds along the superomedial boarder. If there is no concern for adrenal involvement with disease, the adrenal gland can be dissected free of the specimen by incising into the Gerota fascia at the medial edge of the adrenal. To maintain hemostasis, cautery or another energy source should be freely employed during this portion of the case. Once the adrenal is released, the plane of dissection should once again continue outside of the Gerota fascia to free the upper pole of the specimen. The lateral side wall attachments are then released to free the renal portion of the specimen. The ureteral dissection is then carried as inferiorly as possible. The management of the intramural ureter and bladder cuff as well as lymphadenectomy will be described later in this chapter. The specimen should be entrapped in a laparoscopic sack to avoid specimen fracture and tumor spillage during extraction. A round drain is brought into the abdomen via the 5-mm lower quadrant port and draped in the pelvis. The end of the entrapment sack suture is brought through the 12-mm working port. If an additional 12-mm port is used, the fascia at this site is closed with 0-polyglactin suture using a Carter-Thomason device. The remaining ports are removed under direct vision. The camera port incision is extended to allow the removal of the specimen in the entrapment sack. The extraction site fascia is closed with two individual, running no. 1 looped polydioxanone sutures beginning at the apices of the incision. The subcutaneous tissue along all incisions is infiltrated with 0.5% Marcaine. The incisions are irrigated and the skin is closed with 4-0 Monocryl suture and overlying Indermil (Henkel, Dusseldorf, Germany) glue. A drain sponge is placed, and the drain is secured to the skin with a nylon suture.

Hand-Assisted Nephroureterectomy

Because an incision is necessary for specimen extraction with laparoscopic nephroureterectomy, making this incision at the beginning of the case to allow for the use of the surgeon's hand during the case makes the dissection more expeditious. In addition, having a hand in the abdomen may make more surgeons comfortable with offering patients a minimally invasive approach. Additional advantages of the hand-assisted over the conventional laparoscopic approach include the following:

1. The surgeon's hand can be used to gain vascular control in the event that bleeding occurs during the procedure.
2. The hand facilitates dissection through retraction and blunt dissection.
3. Ports can be placed under direct vision with the hand supporting the abdominal wall to avoid injury to the viscera.
4. A laparotomy sponge can be placed through the hand port to assist with hemostasis and visualization.
5. Additional ports can be placed through the hand port as needed to facilitate the course of the

dissection.

There is evidence that the rate of wound complications is higher with the hand-assisted approach as compared with the conventional laparoscopic approach with incision and intact specimen extraction at the conclusion of the procedure, presumably due to prolonged local wound trauma at the hand-port site (22). Hand-port complications (e.g., infection, hernia, and dehiscence) are associated with patient obesity, history of smoking, prolonged operative time, and omission of perioperative antibiotics.

With the patient supine prior to positioning, it is helpful to mark the patient's midline with a permanent marker to assist with midline hand-port placement. The patient is positioned and secured as described earlier. After the patient is prepped and draped, the patient is rotated approximately to a horizontal position with the surgeon and assistant standing on opposite sides of the patient. The hand port should be placed in a location that allows the surgeon to reach above the upper pole of the kidney and down into the pelvis for the ureteral dissection. Most commonly, the optimal placement is in a periumbilical location, with an equal amount of the hand port above and below the umbilicus (Fig. 7.4), but this can be adjusted superiorly or inferiorly as needed. In obese patients, the hand port may need to be placed in a paramedian location. The length of the hand-port incision corresponds to the diameter of the surgeon's hand and forearm—on average 8 cm. The camera port (5 mm or 10/12 mm, depending on lens size available) is placed inferior and slightly lateral to the hand port to allow visualization of the upper retroperitoneum for the nephrectomy portion of the case and the pelvis for the ureterectomy portion of the case. A surgeon working port is placed approximately 4 cm above the midline of the hand port and an assistant port is placed approximately 2 to 3 cm superior and medial to the anterior superior iliac spine (ASIS). At least one of these should be a 10/12-mm port depending on the angle at which the surgeon elects to control the renal hilum—parallel to the great vessels from the ASIS port or more perpendicular to the great vessels from the superior port. For right-sided procedures, a 5-mm port may be placed inferior to the xiphoid for use of a liver retractor as needed. Finally, a midline pelvic port is placed to facilitate the dissection of the distal ureter (see Fig. 7.4).

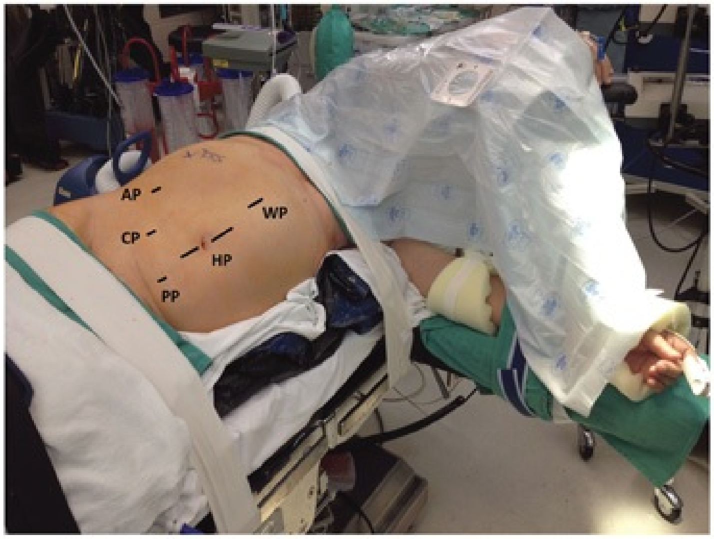

FIGURE 7.4 Hand-assisted laparoscopic nephroureterectomy port placement. *AP*, assistant port; *CP*, camera port; *HP*, hand port; *PP*, pelvic port; *WP*, working port.

The nephrectomy portion of the case proceeds as described earlier, with early clipping of the ureter below the level of the tumor and control of the renal hilum. Inserting the surgeon's hand that corresponds to the side of the procedure for the nephrectomy portion (e.g., left hand for left-sided tumor) has been described. We feel that it is more ergonomic to insert the hand opposite the side of the specimen for the nephrectomy and swapping hands for the ureteral dissection. Once the specimen is freed, it is placed in a laparoscopic sack for extraction. A round drain is brought into the abdomen via the ASIS port and draped in the pelvis. The hand port is removed and the specimen is retrieved via the hand-port site. The closure proceeds as described previously.

Robotic-Assisted Laparoscopic Nephroureterectomy

Robotic-assisted laparoscopic nephroureterectomy was first reported in 2006 (23,24). The advantages of the robotic approach include the following:

1. Three-dimensional, 10× magnified vision
2. Wristed instrumentation with 7 degrees of freedom
3. Intracorporeal bladder cuff with watertight closure, avoiding the need for additional procedures or incisions to complete the dissection
4. Improved surgeon ergonomics with a seated operating position

There are several reported techniques for robotic nephroureterectomy with various recommendations for patient positioning, port placement, and need for robot redocking to perform the nephrectomy and distal ureteral/bladder cuff dissection. The techniques include putting the patient in a partial flank position, docking the robot over the patient's ipsilateral shoulder to perform the nephrectomy portion and repositioning the patient in low lithotomy and Trendelenburg and redocking the robot between the legs for the distal ureteral dissection and bladder cuff (25); having the patient in partial flank and low lithotomy for the entire case, rotating the patient to approximate a supine position along with Trendelenburg and redocking the robot between the legs for the distal ureteral dissection without repositioning the patient (26); and placing the patient in full or partial flank position, docking the robot from the ipsilateral side of the patient, without repositioning of the patient or robot cart (27,28). Herein, we describe our technique for robotic nephroureterectomy but acknowledge that the earlier approaches are appropriate options. Ultimately, patient positioning and port placement are subject to surgeon experience and preference. With an experienced robotics team, the time needed to reposition the robot cart and redock the robotic arms is negligible if a technique that requires redocking is used.

The patient is positioned and secured in the lateral decubitus position as described earlier. To avoid clashing of the camera with the ipsilateral arm during the distal ureteral resection and bladder closure, we tuck this arm to the patients' side in an anatomic position, pad it with foam, and secure it with tape. The operating table is rotated 45 degrees around the vertical access (clockwise for a left-sided procedure and counterclockwise for a right-sided procedure). The abdomen is accessed with a Veress needle medial to the lateral rectus line at the level of the umbilicus and insufflated to 15 mm Hg. A 12-mm camera port is placed at this site. Under laparoscopic vision, a second 12-mm assistant port is placed 4 cm above the umbilicus. Four 8-mm robotic ports are placed: robotic port #1 approximately 8 cm above the camera port in the lateral rectus line; robotic port #2 approximately 8 cm inferior and lateral to the camera port in line with the ASIS in the midclavicular line; robotic port #3 is placed approximately 4 cm superior and medial to the ASIS; and robotic port #4 approximately 4 cm to the contralateral side and below the umbilicus (Fig. 7.5).

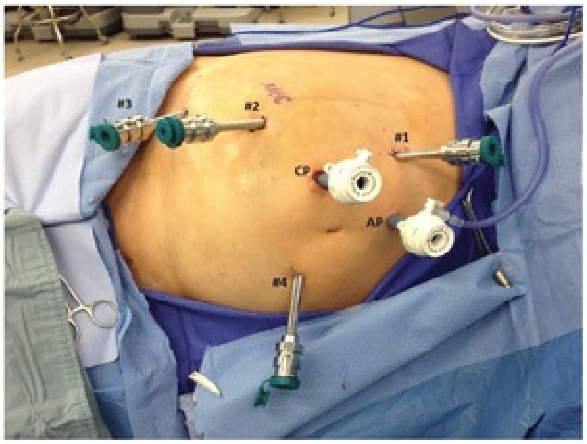

FIGURE 7.5 Port configuration for a robotic-assisted laparoscopic nephroureterectomy. *AP*, assistant port; *CP*, camera port. The 8-mm robotic ports are numbered as indicated in the text.

The robot is docked at a 45-degree angle from the head of the bed over the ipsilateral shoulder for the nephrectomy and proximal ureteral dissection. The monopolar curved scissors are placed in robotic port #1; the fenestrated bipolar grasper is placed in robotic port #2, and the ProGrasp forceps in robotic port #3. Robotic port #4 is used as a supplemental assistant port. The course of the nephrectomy portion of the procedure proceeds as described earlier. After freeing the nephrectomy specimen, the ureter is dissected as distally as possible from this position, usually to the level of the common iliac vessels. If the tumor is in the collecting system or proximal ureter, a retroperitoneal lymph node dissection can be complete in this position.

The robot is undocked, and the patient is rotated on the operating table toward the side of disease to approximate a supine position. The patient is placed in 30 degrees of Trendelenburg prior to redocking for the distal dissection to bring the bowel out of the pelvis. The fourth robotic arm is swung around to the opposite side of the robot, and the robot is redocked over the ipsilateral hip at the 45-degree angle from the foot of the bed. The monopolar, curved scissors is placed via port #2, the bipolar grasper via port #4, and the ProGrasp via port #3. Port #1 acts as a supplemental assistant port during ureterectomy portion of the procedure (see Fig. 7.5). The ureter is dissected down to the level of the bladder, leaving as much periureteral tissue on the specimen as possible. For distal ureteral tumors, a clip is placed distal to the site of the ureteral tumor to prevent tumor migration to the bladder and spillage. With the superior vesicle artery lateral, the intramural ureter is freed from the bladder until the ureteral orifice is at the apex of a cone of bladder mucosa indicating that the entire length of the ureter has been dissected free. The cone of bladder mucosa is the bladder cuff. Above the bladder cuff in the detrusor muscle, a 2-0 polyglactin suture is placed as a stay stitch. The bladder cuff is resected, and the kidney and ureter are placed in a laparoscopic extraction sack to be removed at the conclusion of the case. The bladder is then closed in two layers with running 2-0 polyglactin suture, with the stay suture closing the internal layer. The bladder is then irrigated with at least 200 mL of fluid to assure a watertight closure. For distal ureteral tumors, a pelvic lymph node dissection can be completed.

The robotic arm is released from port #3, and a round drain is placed in the pelvis through this robotic port. The robot is then undocked, and the procedure is converted to laparoscopy. The end of the entrapment sack stitch is brought through the supraumbilical 12-mm port. The incision is enlarged to extract the specimen, and the incisions are closed as described earlier.

Approaches to the Distal Ureter

Several approaches to the distal ureter and bladder cuff dissection have been described. The approach used depends mostly on the surgeon’s experience and preference, but tumor location should also be considered. There are several retrospective case series that report outcomes comparing various approaches to the distal ureter, but there is no level 1 data advocating one approach over another regarding oncologic efficacy. The approach used likely has negligible influence on patient outcomes, but the entire length of ureter, including the ureteral orifice and the surrounding bladder cuff, needs to be included in the nephroureterectomy specimen. There is a “field effect” associated with urothelial carcinogenesis (29), so the *entire extent* of the urothelium, including the distal ureter, is at risk for developing metachronous disease. In cases in which tumor subsequently develops in a retained distal ureter, management is quite difficult and may even require cystectomy.

The classic (intravesical) approach to the distal ureter includes an open incision, generally a suprapubic midline approach, bivalving the bladder, and circumferentially dissecting the bladder cuff and intramural ureter free from the bladder (30). The bladder cuff cystotomy is closed in at least two layers from inside the bladder using polyglactin suture, closing the detrusor muscle and then the overlying bladder mucosa. Polyglactin suture is also used to close the bivalved bladder and the posterior extravesical ureteral hiatus to further reinforce the cystotomy closure. The bladder is then irrigated with at least 200 mL of fluid via an indwelling catheter to assure the bladder is watertight.

To avoid bivalving the bladder, the open extravesical approach is an option as well. As the distal ureteric dissection proceeds, the ipsilateral obliterated umbilical ligament and superior vesicle pedicle are ligated and divided. The posterior bladder is rotated anteriorly and medially, dissecting the intramural ureter free from the bladder until a cone of bladder mucosa is seen surrounding the ureteral orifice situated at the apex of the cone. The bladder mucosa at the base of the cone is clamped with a right angle, excised, and the cystotomy is closed in at least two layers and confirmed to be watertight.

A transurethral approach to the distal ureter is commonly used, especially for hand-assisted and conventional laparoscopic nephroureterectomy cases. Generally, this is performed at the beginning of the procedure with the patient in the modified dorsal lithotomy position, placing a bladder catheter at the conclusion and repositioning the patient for the kidney and proximal ureteral dissection. The intramural ureter can be excised using a resectoscope with electrocautery loop back to perivesical fat (31) or cored out by incising the periureteral tissue using a 45-degree Collins knife (Fig. 7.6) (32). For both of these approaches, once converted to laparoscopy and after the nephrectomy is performed, the ureter is dissected down to the level of the bladder and the previously dissected intramural ureter is “plucked” from the bladder.

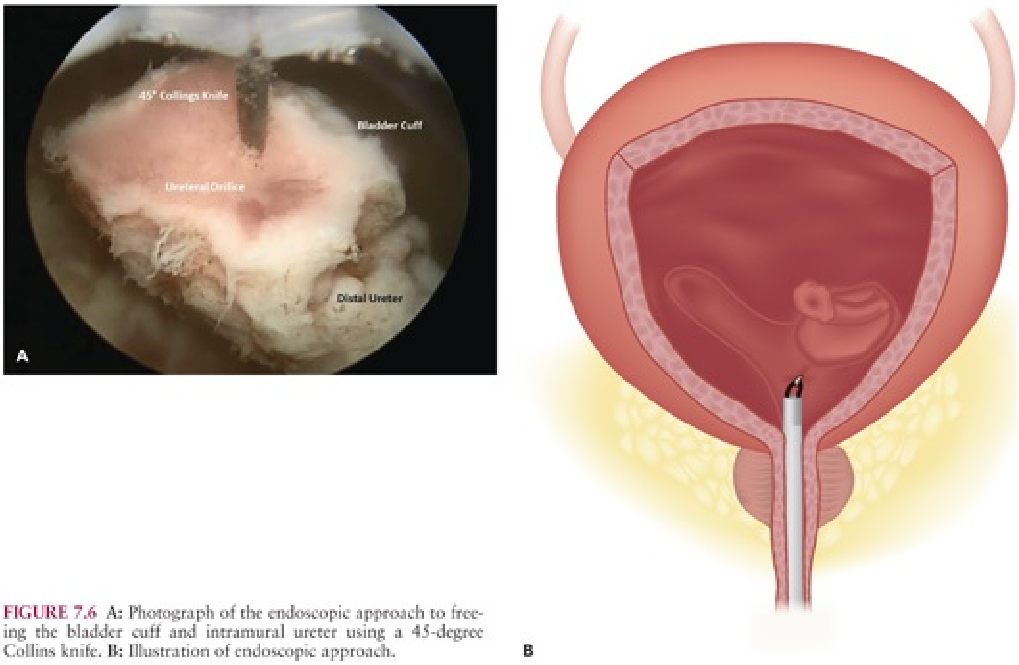

FIGURE 7.6 A: Photograph of the endoscopic approach to freeing the bladder cuff and intramural ureter using a 45-degree Collins knife. B: Illustration of endoscopic approach.

Other approaches to the distal ureter during laparoscopic nephroureterectomy include ureteral stripping and stapling. For the ureteral stripping (intussusception) technique, a ureteral catheter is placed endoscopically at the beginning of the case (33). The ureter is transected distally during the intracorporeal portion of the case, and the ureteral catheter is secured in place in the remaining distal ureter. At the conclusion of the case, the patient is repositioned in dorsal lithotomy, and a resectoscope is placed in the bladder. The ureteral catheter is pulled until the ureter is intussuscepted into the bladder and an endoscopic bladder cuff is obtained by circumferentially incising around the everted ureteral orifice. The stapled technique of managing the distal ureter involves the dissection of the ureter distally to the point that, under vision, the cone of bladder mucosa around the ureteral orifice is seen and then stapled using a laparoscopic stapler, similar to the extravesical open approach. Alternatively, the ureter is stapled as distally as possible laparoscopically. The intramural ureter is resected endoscopically either at the beginning or end of the procedure. From an oncologic sense, any stapling technique should be avoided in situations involving distal or intramural ureteral tumors because having a retained portion of distal ureter can result in dire consequences.

The robotic approach to the distal ureter is discussed earlier. It recapitulates the extravesical open approach without the need to ligate the ipsilateral bladder pedicle. The entire ureterectomy and bladder cuff procedure is performed intracorporeally without the need for an added endoscopic procedure to resect the intramural ureter. A watertight closure of the bladder can be achieved limiting the need for prolonged pelvic drainage and obviating the need for a cystogram to evaluate for bladder extravasation prior to removing the bladder catheter.

Lymphadenectomy

The use of lymphadenectomy at the time of nephroureterectomy has not yet become standard practice despite data that indicates that this procedure may improve recurrence-free and overall survival (34). Currently, there is no prospective, randomized data available comparing nephroureterectomy with and without lymph node dissection. Formal node dissection templates according to tumor location (i.e., renal collecting system/proximal ureter, midureter, or distal ureter) have not been established. The motivation to perform a dedicated node dissection as a component of nephroureterectomy is to more accurately stage patients who may benefit from adjuvant therapy for node positive status and to remove micrometastatic disease to the benefit of patient oncologic outcomes. The arguments against lymphadenectomy include longer operative time required, added complication and morbidity, and unproven benefit of the procedure.

There are several studies that show the feasibility of lymphadenectomy during laparoscopic and robotic nephroureterectomy (26,35). Busby et al. (36) compared the outcomes of lymph node dissection at the time of open or laparoscopic nephroureterectomy and showed that the median node count was greater in the laparoscopic cohort (3 versus 6 nodes). In a matched comparison of robotic and laparoscopic nephroureterectomy, Ambani et al. (26) found that lymphadenectomy was more frequently performed (59% versus 27%) and the median node count in those patients in whom a node dissection was performed was greater (5.5 versus 1.0) during the robotic nephroureterectomy, indicating that the robotic approach may facilitate lymphadenectomy during this procedure (26). The findings from these studies are important because a greater number of nodes obtained may result in superior patient survival (37).

We advocate for a regional node dissection during minimally invasive nephroureterectomy. The region of dissection is dictated by the location of the tumor and the lymphatic drainage of that site. In the pelvis, the ureters drain to the internal, external, and common iliac lymph nodes. The mid-left ureter drains to the para-aortic nodes, whereas the mid-right ureter drains to the paracaval and interaortocaval lymph nodes. The renal pelvis and proximal ureter drain to the hilar and para-aortic (left) or paracaval (right) lymph nodes. Every effort should be made to remove the corresponding lymph nodes packets in their entirety instead of simply obtaining a node sample. Clips and monopolar and bipolar cautery used during the dissection preserve hemo- and lymphostasis.

PERIOPERATIVE CARE AND SURVEILLANCE

Regardless of minimally invasive approach, postoperative care is similar. We leave both a Foley catheter as well as a Jackson-Pratt drain in the pelvis following the surgery. In addition, local anesthesia with 50% lidocaine/50% Marcaine is injected subcutaneously into the extraction site incision to aid with postoperative pain. There is no gastric suction tube left in place. Patients are maintained on subcutaneous heparin and sequential compression devices in the perioperative period to avoid thromboembolic events, and gastrointestinal prophylaxis is administered while hospitalized. In addition, antibiotics covering skin flora are continued for 24 hours after surgery. Although we do use intravenous narcotics the night of surgery, patients are transitioned to oral narcotics once tolerating a clear liquid diet. Ketorolac is used for 24 to 48 hours in patients with sufficient glomerular filtration rate (GFR) (>60 mL per minute) after surgery. Oral acetaminophen is also used around the clock to reduce narcotic use.

Early ambulation is encouraged. Additionally, patients are placed on a clear liquid diet the night of their surgery, and the diet is advanced as tolerated on postoperative day 1. As long as patients are ambulating, tolerating a regular diet, and have adequate pain control, we typically discharge patients home on postoperative day 2 or 3. As long as there is no concern for urine leak, the drain is removed prior to discharge from the hospital.

Patients return to clinic 7 to 10 days after surgery for removal of the catheter and voiding trial. We do not typically obtain a cystogram prior to catheter removal, especially following robotic-assisted surgery where a precise two-layered closure can be achieved. Patients are given oral gram-negative antibiotic coverage immediately proceeding and for 2 days following catheter removal. In addition, male patients are initiated on tamsulosin or another alpha blocker 3 days prior to removal of the Foley catheter and for at least 1 week following removal. Patients who are unable to void are taught intermittent self-catheterization following surgery.

The surveillance schedule is dictated by the disease stage and grade. All patients with pathologic stage T3 or higher and/or positive lymph nodes are referred for consultation with medical oncology within 6 weeks of surgery for consideration of adjuvant chemotherapy. Most patient undergo a CT urogram (or MR urogram or noncontrasted CT) depending on GFR, chest X-ray, complete blood count, comprehensive metabolic panel, urine cytology, and cystoscopy every 6 months for the first 2 years and then annually up to 5 years with decreased use of imaging and cystoscopy at that point depending on the stage and grade of the disease. For low-grade tumors or high-grade noninvasive tumors, imaging and labs are performed at 6 months, 18 months, 36 months, 60 months, and then as needed; cystoscopy is performed every 6 months for the first year and then annually thereafter with a urine cytology at each cystoscopy visit. Cystoscopies for patients with carcinoma in situ on pathology follow the schedule for invasive disease but imaging and labs for noninvasive disease. The goal of surveillance is to identify disease recurrence in a timely fashion while reducing the morbidity of imaging and surveillance cystoscopy.

OUTCOMES

Nephroureterectomy remains the standard therapy for management of UTUC. There is a great deal of literature describing both the surgical and cancer control outcomes of patients undergoing minimally invasive nephroureterectomy. Several studies have shown comparable outcomes for minimally invasive approaches compared to open surgical management (38). In terms of minimally invasive approaches, the most robust data on outcomes is available for hand-assisted or conventional laparoscopic approaches with less data available for robotic-assisted outcomes. The few studies that have compared robotic approaches with other minimally invasive approaches have demonstrated comparable perioperative and short-term outcomes.

PERIOPERATIVE OUTCOMES

Several studies have compared perioperative outcomes for the various approaches to nephroureterectomy. Using the U.S. Nationwide Inpatient Sample, Hanna et al. (39) identified 7,401 and 754 patients undergoing open and laparoscopic nephroureterectomy, respectively, from 1998 to 2009. To adjust for potential differences, they used propensity score–based matching to compare perioperative results between the two approaches. There were no significant differences in patient age, race, gender, Charlson comorbidity index, hospital type, location, or procedure volume. Patients undergoing a laparoscopic approach were less likely to receive a blood transfusion (odds ratio [OR] 0.61; 95% confidence interval [CI] 0.47 to 0.79, P <.001), have an intraoperative complication (OR 0.43; 95% CI 0.26 to 0.73, P = .002), have a pulmonary complication (OR 0.44; 95% CI 0.24 to 0.80, P = .007), or have length of stay longer than 5 days (OR 0.43, 95% CI 0.36 to 0.51, P <.001). There were no statistical differences in other complications or in-hospital mortality (39).

In the only randomized study of the two approaches, 80 patients with localized UTUC were randomized to either open (flank and separate lower abdominal incision) or laparoscopic nephroureterectomy. The study was powered (90%) to detect a difference in mean time to discharge between the two groups (alpha of 0.05). However, it was not powered to detect a difference in other perioperative or oncologic outcomes. Patients were stratified by stage and age. There were no statistical differences in operative times between the two groups, but blood loss was significantly less with the laparoscopic approach (104 mL versus 430 mL, P <.001—no blood transfusions were necessary in either group) as was length of stay (2.3 versus 3.7 days, P <.001) (40).

In one of the few studies comparing laparoscopic versus robotic nephroureterectomy, Ambani and colleagues (26) identified 22 matched pairs from a single institutional cohort. They observed both had a significantly increased operative time (298 versus 251 minutes) and blood loss (380 mL versus 233 mL) for the robotic versus the laparoscopic approach with an associated higher rate for blood transfusion (9% versus 0%) with a similar rate of complication but increased use of lymph node dissection (26). Overall, the data suggests that minimally invasive approaches are associated with decreased morbidity compared to open nephroureterectomy, but further data is needed to evaluate the use of a robotic-assisted approach.

ONCOLOGIC OUTCOMES

Recurrence after nephroureterectomy can occur within the urinary tract, in the resection bed, or distantly. Most data on recurrence have focused on the open approach, but there are several series that have examined outcomes in patients undergoing laparoscopic or robotic-assisted nephroureterectomy. Most series report that approximately 30% to 40% of patients recur within their bladder. Several variables have been explored to understand this risk of recurrence. This includes the management of the distal ureter (resection with bladder cuff versus pluck technique) as well as early clipping of the ureter in cases of proximal and renal pelvis urothelial carcinoma. Most series have not demonstrated an increased risk of recurrence by bladder cuff approach. Xylinas (41) and the Upper Tract Urothelial Carcinoma Collaboration reported outcomes in 2,681 patients undergoing nephroureterectomy. Intravesical, extravesical, and endoscopic approach were performed in 68%, 29%, and 3% of patients, respectively. In a multivariable analysis, an endoscopic approach to the distal ureter, laparoscopic technique, prior bladder cancer, higher tumor stage, and associated carcinoma in situ (CIS) were all predictors of intravesical recurrence. This suggests that some aspect of the laparoscopic approach may increase the risk of tumor seeding to the bladder, but further data is needed to elucidate this (41).

One randomized controlled study evaluated the perioperative use of mitomycin in patients undergoing nephroureterectomy to prevent bladder recurrence. A total of 284 patients were randomized to a single intravesical dose of 40 mg of mitomycin versus standard care. Using a modified intent to treat analysis, 17% in the mitomycin arm and 27% in the standard care arm developed a recurrence at 1 year, with an absolute risk reduction of 11% and relative risk reduction of 40% with the number needed to treat to prevent one bladder recurrence being nine patients. No serious adverse events were reported but five patients could not tolerate instillation for the required hour (20). The Upper Tract Urothelial Carcinoma Collaboration built on this finding and developed a decision tool for both surveillance and possible use of mitomycin in the perioperative period. Their model included age, gender, tumor location, surgical technique, bladder cuff management, prior bladder cancer, stage, CIS, and lymph node status. If a cutoff of a 15% chance of recurrence at 2 years is used to determine treatment with mitomycin, then 23% of patients would be spared treatment with only 0.3% developing recurrence (41).

The risk of contralateral recurrence has been well described and is reported in the 2% to 4% range in a review of the SEER data. It is unlikely that the risk of contralateral recurrence is influenced by surgical approach but rather by the stage and grade of the disease (especially CIS), prior history of bladder cancer, and prior treatment with intravesical therapy. Although the risk is low, all patients should undergo surveillance of their upper urinary tract as described earlier. Similarly, there is no data that suggests that there is a difference in locoregional recurrence, development of metastatic disease, or disease-free and overall survival when comparing different surgical approaches to nephroureterectomy. This is again likely due to the fact that it is the grade and stage of the disease that is driving the natural history of upper tract urothelial cancer (42).

SUMMARY

UTUC is a rare entity. Although nephroureterectomy is the standard approach for the management of this disease, alternative approaches can be used in select individuals based on both the grade and stage of the disease as well as patient comorbidities. Minimally invasive approaches to nephroureterectomy include hand-assisted, laparoscopic, and robotic-assisted approaches. The choice of approach depends on the complexity of the procedure, patient comorbidities, as well as experience of the surgeon. Robotic-assisted approaches allow for a minimally invasive technique that replicates the benefits of an open surgical approach. The choice of bladder cuff management is influenced by location of the tumor as well as surgeon preference. An ideal approach ensures complete excision of the ureter with a bladder cuff and avoidance of tumor spillage. Although management of the bladder cuff and surgical approach may influence the risk of bladder recurrence, there is no data to suggest differences in oncologic outcomes with the various approaches to nephroureterectomy, whereas minimally invasive approaches decrease the morbidity of the procedure.

CHAPTER 8 LAPAROSCOPIC RENAL PROCEDURES:RENAL CYSTECTOMY, BIOPSY, AND NEPHROPEXY

MICHAEL MADDOX AND BENJAMIN R. LEE

INTRODUCTION

Laparoscopic Management of Renal Cystic Disease

Simple cysts are a commonly encountered and often incidental finding on abdominal imaging studies. These are acquired lesions postulated to develop from diverticula of the distal convoluted tubule and collecting duct. Previous autopsy reports indicate that 50% of people older than age 50 years have renal cysts (1). With the advent and increased use of spiral computerized tomography (CT), more contemporary studies show an overall prevalence of 41% in the adult population with an increase to more than 60% by age 80 years (2).

DIAGNOSIS

Historically, the diagnosis of renal cysts was made by intravenous urography with tomography. However, ultrasound (US) and CT have supplanted intravenous urography as the primary diagnostic tools for renal cystic disease. Bosniak is credited with describing a spectrum of complexity to renal cystic lesions based on characteristics on abdominal CT. Magnetic resonance imaging (MRI), with its superior contrast resolution compared to CT, may help distinguish between benign and malignant complex cystic lesions. Further, since the introduction of the Bosniak classification of renal cysts, MRI has been validated as a surrogate for CT scan regarding the applicability of the Bosniak classification scheme (3).

The majority of renal cysts are asymptomatic and thus an incidental finding on imaging. However, a small subset of patients may present atypically with a palpable mass, obstructive symptoms, infections, or pain thought to be related to hemorrhage into the cyst or distension of the renal capsule. Cysts associated with autosomal dominant polycystic kidney disease (ADPKD) may manifest as hypertension or renal insufficiency.

BOSNIAK CLASSIFICATION

Prudent to any discussion of management of renal cystic disease is the Bosniak classification scheme. Distinguishing simple renal cysts from solid renal masses with cross-sectional imaging is not difficult. However, cystic lesions of the kidney are heterogeneous entities covering a wide spectrum from benign simple cysts to cystic renal cell carcinomas (RCCs). In fact, 5% to 7% of RCC are cystic, often demonstrating a slower growth rate and more favorable pathologic characteristics compared to solid RCC (4).

Bosniak (5) first described his classification of renal cysts in 1986, in which the lesion's morphology and enhancement characteristics were assessed and lesions were placed into four categories (I to IV) with increasing concern for malignancy. The consensus among urologists and radiologists is that Bosniak I cysts are simple cysts requiring no further follow-up with minimal risk of malignancy, whereas Bosniak IV cysts are complex and managed surgically as a presumed malignancy. However, there is considerable interobserver variability in distinguishing Bosniak II and Bosniak III lesions (6). Bosniak later modified the scheme to include a fifth category of Bosniak IIF to help narrow the gap between II and III renal cysts (7). The current classification is summarized in Table 8.1. CT images of the five Bosniak subclassifications are shown in Figure 8.1A–E.

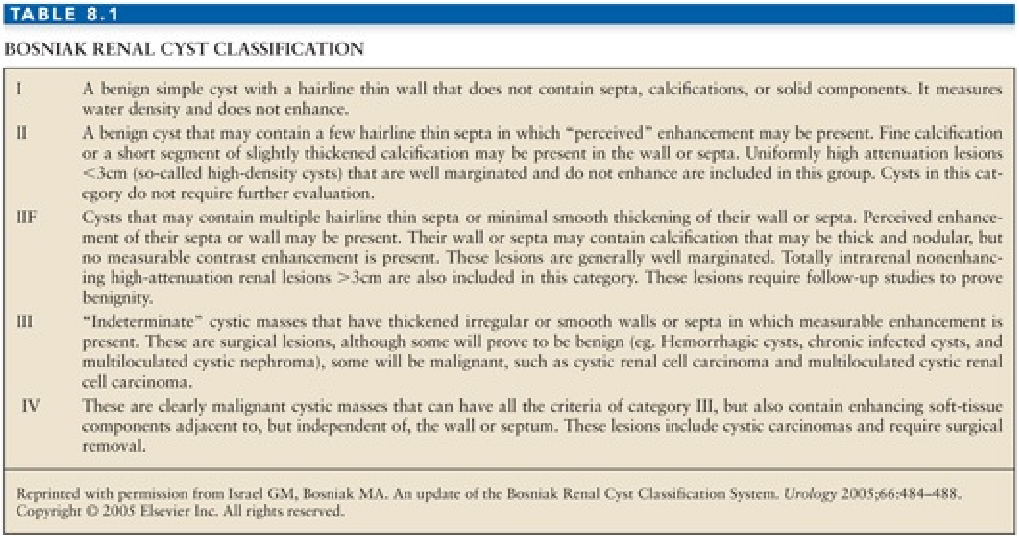

TABLE 8.1

BOSNIAK RENAL CYST CLASSIFICATION

I	A benign simple cyst with a hairline thin wall that does not contain septa, calcifications, or solid components. It measures water density and does not enhance.
II	A benign cyst that may contain a few hairline thin septa in which "perceived" enhancement may be present. Fine calcification or a short segment of slightly thickened calcification may be present in the wall or septa. Uniformly high attenuation lesions <3cm (so-called high-density cysts) that are well marginated and do not enhance are included in this group. Cysts in this category do not require further evaluation.
IIF	Cysts that may contain multiple hairline thin septa or minimal smooth thickening of their wall or septa. Perceived enhancement of their septa or wall may be present. Their wall or septa may contain calcification that may be thick and nodular, but no measurable contrast enhancement is present. These lesions are generally well marginated. Totally intrarenal nonenhancing high-attenuation renal lesions >3cm are also included in this category. These lesions require follow-up studies to prove benignity.
III	"Indeterminate" cystic masses that have thickened irregular or smooth walls or septa in which measurable enhancement is present. These are surgical lesions, although some will prove to be benign (eg. Hemorrhagic cysts, chronic infected cysts, and multiloculated cystic nephroma), some will be malignant, such as cystic renal cell carcinoma and multiloculated cystic renal cell carcinoma.
IV	These are clearly malignant cystic masses that can have all the criteria of category III, but also contain enhancing soft-tissue components adjacent to, but independent of, the wall or septum. These lesions include cystic carcinomas and require surgical removal.

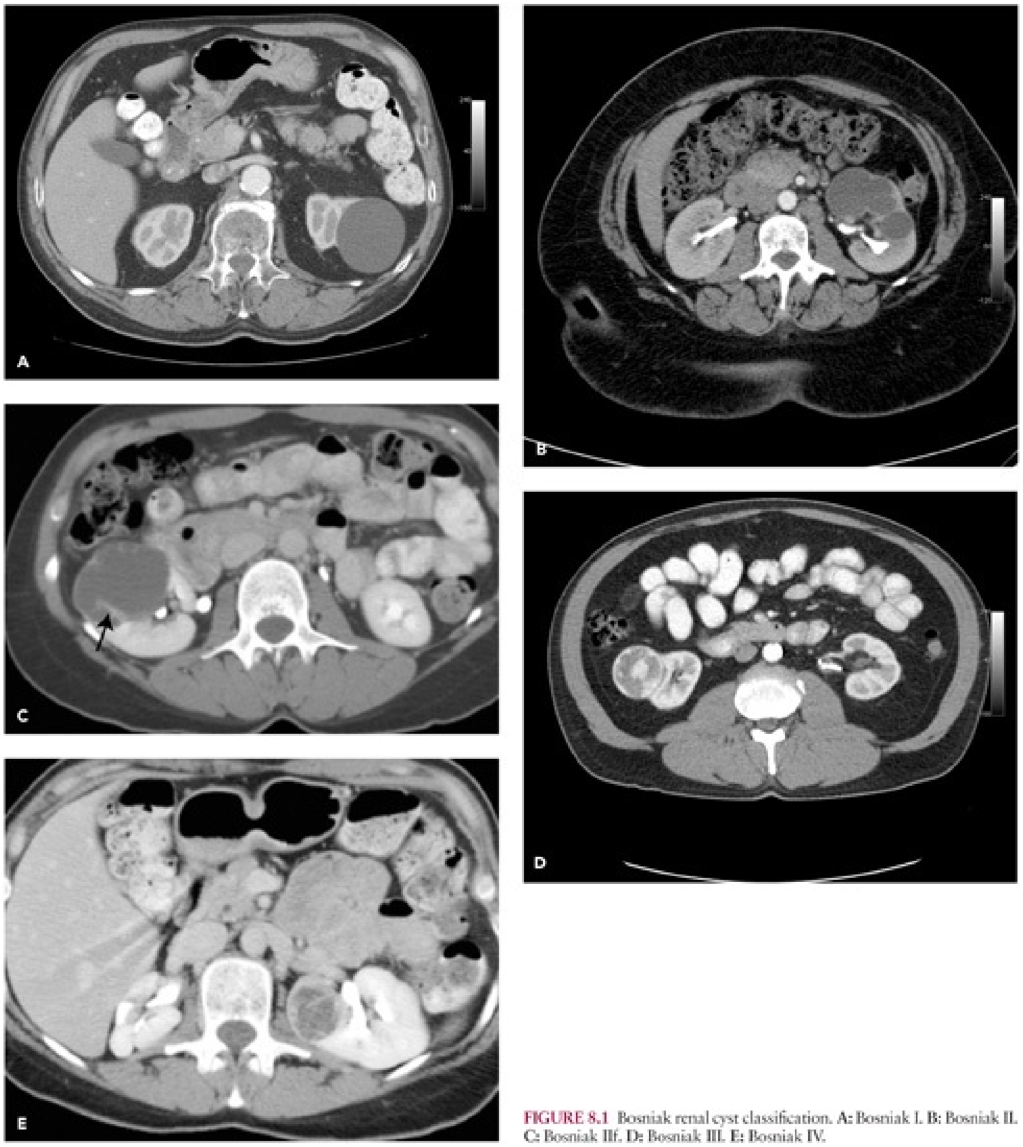

FIGURE 8.1 Bosniak renal cyst classification. A: Bosniak I. B: Bosniak II. C: Bosniak IIF. D: Bosniak III. E: Bosniak IV.

Malignancy Risk by Bosniak Class

The goal of the Bosniak classification was to provide a reproducible and universal description of cystic renal lesions in order to guide therapy. However, the majority of studies attempting to characterize pathologic outcomes by Bosniak classification are retrospective case series and limited by small patient numbers. In addition, preoperative attempts to assess the risk of malignancy based on cytologic evaluation of cyst fluid have not proven to be helpful with only 14% of known cystic RCC having a positive preoperative cytology (8).

A number of studies have quantified the malignancy risk of renal cystic lesions. These studies should be interpreted with some caution because many have used radiographic surveillance with stability of the lesion to define benignity. Koga et al. (9) pooled data from five studies including their own to assess the percentage of lesions that were ultimately malignant based on their CT Bosniak classification. All of these studies included used a pathologic correlate to the imaging findings. Malignancy rates were 2%, 27%, 60%, and 90% for Bosniak I, II, III, and IV, respectively (8–12).

It is important to understand that there is no absolute malignancy risk for all subclasses of renal cysts but rather a continuum in which the imaging characteristics should be interpreted in the context of the clinical situation on an individual patient basis.

SIMPLE CYSTS

It is generally agreed on that simple renal cysts (Bosniak I) are acquired lesions. These cysts are more common in men than women with an incidence ratio of approximately 1.4:1 (2). Terada et al. (13) demonstrated the propensity of these cysts to increase in size and quantity with age. With this progression, a subset of these patients will develop symptoms without other discernible etiologies on imaging. If these patients fail conservative measures with anti-inflammatory agents and narcotic analgesics, they may benefit from further intervention.

Some apply a percutaneous approach initially to assess for relief of symptoms with aspiration to demonstrate a causal relationship. Aspiration alone has shown a significant recurrence rate between 41% and 78% (14–16). Addition of a sclerosing agent at the time of percutaneous aspiration may improve recurrence rates, but these are still unacceptably high ranging between 32% and 100% (5,17). It should be mentioned as well that percutaneous sclerosing agents are contraindicated in parapelvic cysts due to the risk of injury to the collecting system.

Laparoscopic cyst decortication (LCD) offers a more definitive management of symptomatic simple cysts without the morbidity of open surgical decortication. Roberts et al. (18) reported their results of laparoscopic ablation of 32 patients, 11 with parapelvic, and 21 with parenchymal cysts. All patients were symptomatic at the time of intervention. They showed at a mean follow-up of 18.1 months, all patients were without symptom recurrence, and only one patient experienced a radiographic recurrence without symptoms. The complication rate was 13% with one major complication (ureteral stricture) and three minor complications (ileus, intraoperative diaphragm injury repaired without consequence, and a transient peroneal nerve palsy) (18).

In one of the largest series of LCD of simple renal cysts, Atug et al. (19) demonstrated a durable response at a mean follow-up of 58 months. Using pre- and postoperative patient-reported pain scales, the mean scores were 7.66 reduced to 1.21 following surgery. The 91.1% of patients were symptom-free, whereas four patients (8.8%) reported some alleviation of their symptoms. Radiographic success was 95.5% in this series with two of the partial responders developing asynchronous de novo cysts (19).

Okeke et al. (20) investigated their experience with LCD compared to sclerotherapy. At 17 months of follow-up, all patients undergoing decortication were without symptoms, whereas the sclerotherapy cohort had a 100% recurrence of symptoms (20). Laparoscopic cystectomy is proven to be a safe, efficacious, and durable treatment modality for patients with symptomatic simple renal cysts.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Although most simple cysts are sporadic/acquired, ADPKD invariably is responsible for a significant proportion of patients with symptomatic renal cysts. ADPKD affects between 300,000 and 600,000 Americans (21). It is the fourth most common cause of renal failure comprising approximately 10% of all dialysis patients (22). Enlarged cysts compress the renal parenchyma and vasculature, resulting in renal capsular distention and an ischemic activation of the renin-angiotensin-aldosterone system resulting in pain and hypertension (23,24). Therefore, a majority of these patients will become symptomatic and may ultimately require therapeutic intervention.

The urologic literature describing LCD for ADPKD is composed primarily of retrospective case series with many of them having a heterogeneous mix of patients with simple cysts and cysts as a result of ADPKD. We will review the largest series of patients undergoing laparoscopic management of exclusively ADPKD patients.

In a comprehensive review of all relevant series using LCD for ADPKD, Millar et al. (25) addressed the outcomes for pain, hypertension, and renal function. Despite the variable degree of improvement and duration, LCD consistently offers an improvement in chronic pain in the ADPKD population following LCD. Although some studies report an encouraging trend toward improvement in postoperative blood pressure, the literature does not consistently confirm the benefit of LCD for management of hypertension. Finally, the majority of patients can expect an insignificant change in postoperative renal function following LCD, but the authors caution that significant preoperative renal insufficiency may pose a greater risk of postoperative deterioration of renal function (25).

SURGICAL TECHNIQUE

Retroperitoneal Approach

Standard positioning and preparation are carried out with the patient in the flank position. Port placement is depicted in Figure 8.2.

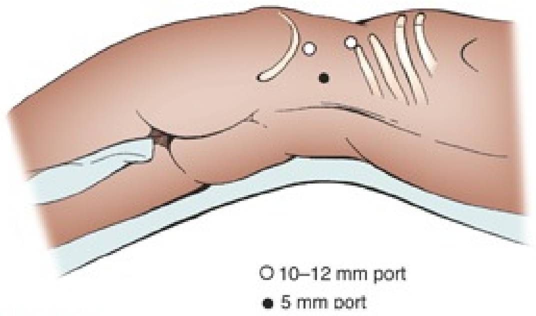

FIGURE 8.2 Port placement for retroperitoneoscopic kidney surgery, such as nephropexy, renal cystectomy, and biopsy.

A 1.5-cm incision is made at the tip of the 12th rib, and the dissection is carried down to the lumbodorsal fascia, which is then pierced with a tonsil clamp to enter the retroperitoneal space. Finger dissection is then performed along the psoas muscle to mobilize the posterolateral aspect of the kidney. A 10- to 12-mm visual balloon dissector trocar is then placed and the space is dilated. The dilating balloon is then removed and a blunt-tip trocar is placed. Pneumoretroperitoneum is established to 15 mm Hg, and a 5-mm trocar is placed in the posterior axillary line below the 12th rib. A third trocar is inserted approximately two fingerbreadths above the iliac crest in the anterior axillary line. Laparoscopic US may be used in cases where cysts are difficult to locate. An additional instrument for dissection and counter traction of large cysts can be placed via a 5-mm trocar midway between the iliac crest and the 12th rib in the posterior axillary line.

Once the cyst is exposed from beneath the perinephric fat, the fluid is aspirated and sent for cytology. A gallbladder needle or Orandi-type needle can be used to accomplish the aspiration. The free wall of the cyst is then excised with dissecting scissors, harmonic scalpel, or hook and sent for pathologic analysis. The wall should be incised as close to parenchyma as possible without entering the parenchyma. The parenchymal base of the cyst is then examined for evidence of neoplastic change using cup biopsy forceps to perform frozen-section analysis if there is clinical suspicion of carcinoma. The edges of the cyst are cauterized and hemostasis is verified after the pneumoretroperitoneum has been lowered to 5 mm Hg. The argon beam coagulator can be used to quickly paint over any raw bleeding surfaces of parenchyma or cyst wall. If the argon beam coagulator is used, care should be taken to vent the entering argon gas to prevent overpressure and barotrauma. Fibrin glue with or without oxidized cellulose can be applied for refractory areas of bleeding.

Transperitoneal Approach

The transperitoneal approach is ideal for treating anterior renal cysts, either simple or multiple. Under general anesthesia, with the patient in a 45-degree lateral flank position, pneumoperitoneum is established at the umbilicus. A 10-mm port is placed under laparoscopic visualization lateral to the umbilicus on the affected side in the lower quadrant. A third 5-mm trocar is placed in the midline halfway between the xiphoid process and umbilicus. A fourth trocar may be necessary for retraction in some cases and can be placed either in the lower midline or close to the xiphoid in the midline. The colon is reflected medially and the fascia of Gerota is incised. The perinephric fat around the cyst is dissected cleanly. In cases of polycystic disease, the kidney must be entirely mobilized inside the fascia of Gerota. Once again, the cyst fluid can be aspirated and sent for cytology. The cyst can then be unroofed as detailed earlier and its walls and base carefully inspected as seen in Figure 8.3. A portion of the cyst wall can be attached to the mobilized edge of peritoneum with either a clip or suture to ensure communication with the peritoneal cavity and decrease the likelihood of recurrence.

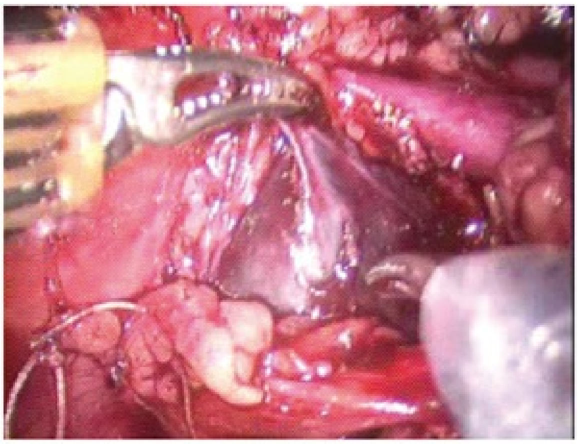

FIGURE 8.3 Transperitoneal laparoscopic cyst decortication.

If the cyst is extremely large, another technique is to fashion a window using dissecting scissors. Retroperitoneal fat or omentum can then be packed into the cyst, thus making it unnecessary to remove a large amount of cyst wall. If during any cyst unroofing, excision, or marsupialization there is concern for collecting system injury, indigo carmine can be administered intravenously or a preoperative ureteral catheter can be placed in complex cases for retrograde irrigation with methylene blue. This may be of particular use when approaching parapelvic cysts abutting the renal hilum.

Complications

Bleeding is always a possible complication of LCD. The argon beam coagulator and fibrin glue, or alternatively cauterization to the base, may help prevent this complication. It is imperative to ensure hemostasis with lowered abdominal pressures upon completion of the procedure.

Reaccumulation of cyst fluid is uncommon as previously indicated with the high radiographic success rates. Nieh and Bihrle (26) demonstrated that the use of fat was helpful in maintaining the patency of the marsupialization window. Other rare complications include prolonged ileus, delayed hemorrhage, urinary fistula, and nerve paresthesias.

CYSTIC RENAL MASSES/INDETERMINANT CYSTS

As previously indicated, with increasing complexity of renal cystic lesions, the risk of ultimate malignant pathology also increases. It is debated whether laparoscopic diagnostic or therapeutic intervention should be attempted in the treatment of Bosniak II and III cysts. This is largely due to the concern for tumor spillage with laparoscopic intervention, particularly for a transperitoneal approach with potential large field seeding. We review the available literature regarding these lesions.

There is a paucity of literature regarding laparoscopic decortication, biopsy, or extirpation for complex cystic masses. There are isolated case reports of significant tumor seeding following cyst decortication for eventually proven cystic RCC (27). However, Limb et al. (28) reported their experience with 57 patients with Bosniak II and III lesions undergoing laparoscopic intervention (28 Bosniak II and 29 Bosniak III). The cysts were aspirated and sent for cytology followed by biopsies of the cyst wall and base for immediate pathology.

Of the entire group, 11 patients ultimately were found to have a malignancy (3 patients/11% of Bosniak II, 8 patients/28% Bosniak III). Ten of the patients proceeded to nephrectomy during the same anesthetic: open partial (five), open radical (four), and laparoscopic radical (two). One patient underwent delayed nephrectomy due to a change in the pathology report postoperatively. There were no recurrences noted during the follow-up period at a mean of 40 months. The authors suggest the risk of tumor seeding may be overstated in the literature and suggest an initial diagnostic evaluation of indeterminate lesions may obviate the need for surgery in many patients with Bosniak II or Bosniak III cystic lesions (28).

Although the risk of tumor seeding in laparoscopic surgery for urologic malignancy is low, some physiologic consequences of laparoscopy deserve mention. Laparoscopy with CO_2 insufflation results in immunologic alterations that may result in increased risk of tumor seeding. Specifically, Ost et al. (29) demonstrated that the peritoneal immunologic response is blunted during laparoscopy with decreased monocytes and macrophages their cytokine release (interleukin-1 and tumor necrosis factor alpha). This may have implications regarding the host cellular immune response to shedding of malignant cells. Preclinical studies demonstrated sterile water irrigation in the peritoneal cavity and port sites prevented port site metastasis (30). Lee et al. (31) reviewed and suggest potential preventive measures when performing laparoscopy for urologic malignancy as seen in Table 8.2.

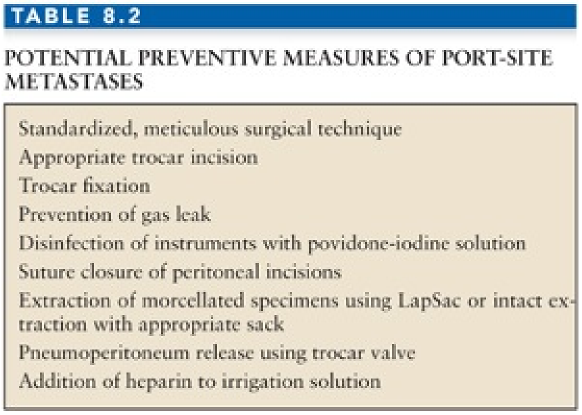

TABLE 8.2

POTENTIAL PREVENTIVE MEASURES OF PORT-SITE METASTASES

Standardized, meticulous surgical technique
Appropriate trocar incision
Trocar fixation
Prevention of gas leak
Disinfection of instruments with povidone-iodine solution
Suture closure of peritoneal incisions
Extraction of morcellated specimens using LapSac or intact extraction with appropriate sack
Pneumoperitoneum release using trocar valve
Addition of heparin to irrigation solution

Spaliviero et al. (32) performed the largest series of LPN for cystic renal masses. In this series, 50 patients with complex cystic masses (Bosniak II-9, IIF-4, III-12, IV-21) underwent LPN and were compared to 50 matched consecutive patients with solid renal masses. LPN was technically feasible in all patients without tumor spillage, and malignancy was confirmed in 22%, 25%, 50%, and 90% of the Bosniak II, IIF, III, and IV lesions, respectively. With a mean follow-up of 14 months, there has been one episode of recurrence in the cystic mass cohort compared to none in the solid mass group (32).

Although there is limited experience reported in the literature regarding definitive laparoscopic management of complex or indeterminate cystic masses, there are known advantages to laparoscopic intervention compared to open in renal surgery and one may expect an increased use of minimally invasive modalities in the treatment of this population.

RENAL BIOPSY

Percutaneous Biopsy

An evolving application of renal biopsy is focused on distinguishing between benign and malignant renal lesions. Biopsy is standard in patients suspected of lymphoma or with known secondary extrarenal malignancies. Further, with the increasing diagnosis of the small renal mass (SRM) as well as the use of percutaneous ablative therapies for SRMs, renal biopsy may occupy an important role in this growing subset of patients.

A general reluctance to the adoption of renal biopsy in clinical practice centers on complications, inaccuracy, or inadequacy of biopsy to detect malignancy as well as the risk of tumor seeding. We will address each of these issues with a review of the relevant literature.

The diagnostic accuracy of percutaneous image-guided renal biopsy for the detection of malignancy ranges between 85% and 100%, with the majority of recent studies exceeding a pathologic concordance accuracy of greater than 90% (33). Improved technique and experience with percutaneous biopsy may contribute to the reported increase in accuracy. Specifically, the use of a coaxial guide or cannula significantly increased the biopsy success rate by 15% without increasing complications (34).

Fine needle aspirate (FNA), defined by a 21-gauge or smaller needle, and core needle biopsies are two general categories of needle biopsy. FNA success is dependent on an experienced cytopathologist. FNA is generally thought to have a lower sensitivity for detecting malignancy compared to core biopsies, but the sensitivities range from 76% to 97% in recent series (35–39). In a large contemporary series of FNA of renal lesions, Andonian et al. (39) characterized nondiagnostic FNAs to be due to misdiagnosis in 2%, sampling error in 0.8%, and technical failure (defined as obtaining insufficient cellularity) in 16%. In another study, the diagnostic yield of FNA is considerably higher in adequate specimens compared to inadequate specimens (96.5% versus 41%). The authors also demonstrated a lack of correlation between the number of needle passes performed during FNA of renal lesions and the adequacy of the specimen (40). This emphasizes the importance of having the cytopathologist present at the time of FNA in order to ensure the adequacy of the specimen obtained.

To maximize the success of renal biopsy, both core biopsies and FNA should be used in conjunction when feasible (41,42). This is especially true in the diagnostic evaluation of complex cystic lesions in which the combination of techniques significantly increases the yield. Wunderlich et al. (43) demonstrated that biopsies of larger renal masses (performed ex vivo in their study) should be targeted toward the periphery of the tumor due to the increased propensity toward central tumor necrosis in lesions greater than 4 cm. Important to note is that FNA should be performed prior to any core biopsy in order to minimize the contamination with blood of the FNA specimen. Although FNA may offer the theoretical advantage of decreased complications as a result of the smaller needle gauge, this has not consistently been demonstrated.

Tumor seeding is the most controversial risk associated with renal biopsy. However, Volpe et al. (33) reviewed the literature and found only six case reports in total of this phenomenon, representing an overall risk of less than 0.01%. The use of guiding cannulas minimizes the potential for contact of malignant tissue with the biopsy tract. The risk of urothelial carcinoma tumor seeding may exceed the rates in nonurothelial renal malignancies, and caution should be exercised when performing biopsies of a potential urothelial cancer.

Other reported complications of renal biopsy include hemorrhage, arteriovenous fistula, infection, and pneumothorax. Approximately 44% of patients undergoing percutaneous needle biopsy will have evidence on CT of mild perirenal or subcapsular hematomas (44). However, clinically significant bleeding is rare and usually self-limiting according to contemporary percutaneous biopsy series (37).

Studies of small renal masses having pathologic data after radical or partial nephrectomy indicate approximately one-third of these patients will have a benign tumor (45–48). Further, the majority of patients diagnosed with SRMs are between 70 and 89 years of age. This population may benefit most from conservative treatment or observation alone for SRM. This has contributed to the controversy surrounding the role for preoperative renal biopsy. In addition, up to 39% of those patients with indeterminate cystic lesions (Bosniak III) may avoid unnecessary surgery with the use of preoperative renal biopsy (48).

Laparoscopic Biopsy

The majority of renal biopsies, independent of the indication, are performed percutaneously with image guidance. Real-time CT imaging has further increased the disparity between the percutaneous and laparoscopic or open approach. However, some clinical circumstances such as severe hypertension, bleeding diathesis, anticoagulation, morbid obesity, refusal of blood transfusions, and difficult renal anatomy dictate the use of more controlled access and better visualization of the kidney during biopsy. Hence, laparoscopic renal biopsy can be of great clinical value for some patients.

Adequate tissue samples are obtained in 96% to 100% of patients in the largest reported series. The majority of these patients are discharged from the hospital within 24 hours of the procedure. Complications directly related to the procedure are infrequent due to the ability to obtain hemostasis intraoperatively. Delayed bleeding is reported in 3% to 4% of patients and often is associated with coagulopathies and anticoagulants as a result of the population requiring laparoscopic biopsy (49,50). Arteriovenous fistula formation is not a concern due to the more superficial cortex sampled with laparoscopy and the avoidance of deeper, more significant renal vasculature.

Surgical Technique

Preoperative US, CT, or MRI can help characterize the kidney and better identify its location to adjacent structures during surgery. The procedure is ideally performed through a retroperitoneal approach. Patient preparation and positioning are identical to that described for laparoscopic retroperitoneal cystectomy. However, in many cases, only a camera port and single instrument port are necessary. Minimal blunt dissection through the perinephric fat to expose the lower pole of the kidney is then performed. Laparoscopic US may be necessary in some cases to identify the lower pole of the kidney. Cold-cup biopsy forceps or spoon forceps are used to obtain several samples of tissue, and these are sent to the pathologist for frozen-section analysis to confirm adequate tissue sampling.

This is depicted in Figure 8.4. A large-core Tru-Cut–type biopsy needle can also be passed through a trocar or percutaneously to obtain the sample.

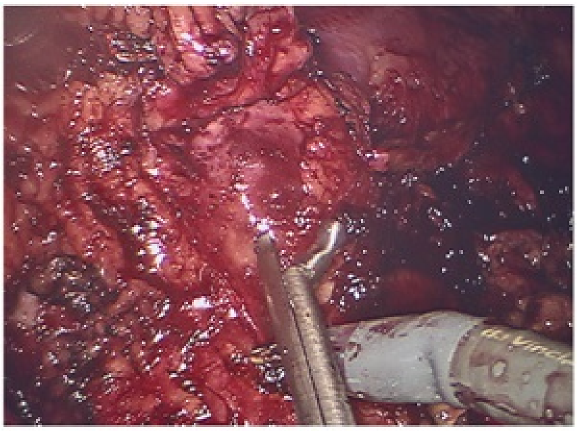

FIGURE 8.4 Renal biopsy using 5mm laparoscopic cup forceps.

Hemostasis can be achieved with electrocautery or an argon beam coagulator, and if necessary, the sites can be packed with oxidized cellulose. The retroperitoneal pressure should be lowered to 5 mm Hg and the biopsy sites and dissected space examined for hemostasis.

LAPAROSCOPIC NEPHROPEXY

Nephroptosis is a condition of great historical interest. It is classically defined as descent of the kidney >5 cm (or two vertebral bodies) when moving from supine to upright positions. The condition is much more common in female patients and more commonly affects the right kidney, but it can be bilateral in up to 20% of cases. Most affected patients are thin women and may be attributed to significant and rapid weight loss. Nephroptosis may be an incidental finding and should be treated only when associated with symptoms. Pain is believed to be a result of acute obstruction and/or renal ischemia upon standing due to the hypermobile kidney.

Diagnosis

Currently, many diagnostic modalities are available to establish the diagnosis. An intravenous pyeloplasty with the patient in the supine and standing position may be a useful initial test. The hypermobile kidney will descend in the upright position and may become hydronephrotic. Color Doppler US with measurement of resistive indices (RIs) in the supine and upright position may be helpful. A reduction in RI may be seen when moving from supine to upright, signifying a decrease in renal perfusion (51). Finally, a nuclear scan in the sitting position is useful in detecting an obstructive pattern after renal descent in addition to diminished blood flow to the kidney when the patient is erect. However, nuclear scan imaging systems are not uniformly capable in the upright position, and therefore, the availability of this diagnostic modality may be limited.

Surgical Technique

The surgical management of nephroptosis is controversial and variable. Many historical options exist, ranging from pexy and slings to other organs, ligaments, or the 12th rib. Current techniques usually employ suture fixation to the psoas and/or quadratus lumborum fascia. In general, the techniques require complete mobilization of the kidney inside the fascia of Gerota down to the renal capsule, with sutures placed directly through the fascia.

A transperitoneal approach is the most commonly reported access. The patient is positioned in full flank position, unless performing bilateral nephropexy, in which the patient is positioned supine and the bed tilted side to side to access each kidney. A three-port midline approach is most often used. The kidney is completely mobilized inside the fascia of Gerota and the fascia of the psoas muscle is identified. The operating table is then moved to a head-down position, which causes the mobile kidney to be positioned as cephalad as possible. Beginning at the upper pole, three interrupted nonabsorbable 3-0 sutures are then placed along the lateral margin of the kidney (upper, middle, and lower) through the renal capsule and then through the psoas fascia as seen in Figure 8.5. Care should be taken not to place the sutures too deeply into the renal parenchyma to prevent bleeding. In addition, the genitofemoral nerve running along the psoas fascia should be identified and avoided with placement of the sutures. Intracorporeal suturing can be simplified by the use of LAPRA-TY clips (Ethicon Endo-Surgery, Cincinnati, Ohio) to secure the sutures.

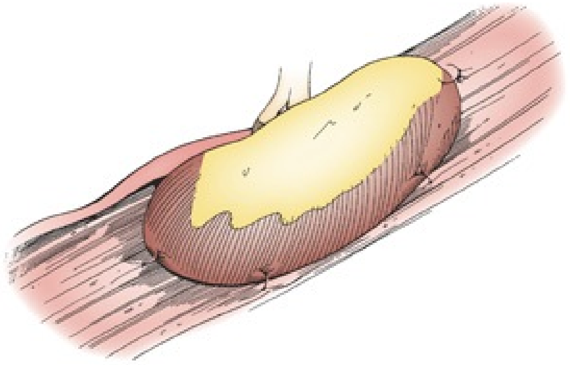

FIGURE 8.5 Nonabsorbable sutures placed through renal capsule and then psoas fascia on upper pole of kidney (medially, superiorly, and laterally).

The retroperitoneal laparoscopic approach provides a direct route to the kidney and may be useful in patients with a history of previous intra-abdominal surgery. However, the working space may be limited, making complete kidney mobilization difficult. Creation of the retroperitoneal space is performed as previously described, and nephropexy proceeds as per the transperitoneal approach. The procedure can be performed on an outpatient basis or under 24-hour observation. Follow-up supine and erect studies are generally performed in 6 to 12 weeks.

OUTCOMES

Success rates are quite high for laparoscopic nephropexy and are comparable to historical open series. Resolution of symptoms occurred in 80% to 100% of patients in the literature of laparoscopic nephropexy (52–54). Correlation of resolution of symptoms with resolution of renal descent on postoperative imaging appears to be high. In one series of 31 retroperitoneoscopic nephropexies, complete symptom resolution was present in 83% of patients, and 87% of patients had no evidence of persistent renal descent on postoperative radiography (55).

The most feared complication is failure to resolve symptoms. However, as noted earlier, failure is uncommon. Other complications include bleeding from the renal parenchyma and postoperative ileus, although they are uncommon.

CHAPTER 9 LAPAROSCOPIC ABLATION OF SMALL RENAL MASSES

DANIEL RAMIREZ AND JEFFREY A. CADEDDU

The pervasiveness of cross-sectional abdominal imaging over the last decade has substantially increased the rate of incidentally diagnosed small renal masses (SRMs). This trend has impelled minimally invasive urologists to examine alternatives to complex extirpative surgical treatments. Cryotherapy and radiofrequency ablation (RFA) were initially described over a decade ago (1,2) with maturation of large, long-term series with these ablative techniques now available. Unfortunately, there currently exist no randomized controlled trials comparing ablative techniques with surgery or active surveillance. Available evidence has largely been mined from retrospective cohort reviews and case series. Ablative treatment particularly offers some advantages over partial nephrectomy, including decreased convalescence and improved preservation of renal function. Comparative studies have shown ablative techniques to have decreased blood loss, decreased length of stay, lower complication rates, and superior renal preservation when compared to partial nephrectomy (3–5). Traditionally, ablation has been reserved for older patients who are poor candidates for surgery or those patients who require maximal preservation of renal function. With oncologic outcomes and treatment efficacy of RFA and cryotherapy nearing that of surgical extirpation, many academic hospitals are now offering ablative techniques as first-line treatments for SRMs in the young and healthy patient. This chapter will focus on the rational and indications for renal ablative therapy with specific emphasis on a laparoscopic approach to applying RFA and cryotherapy for the treatment of SRMs.

INDICATIONS FOR LAPAROSCOPIC APPROACH

Ablation of SRMs, in general, is largely reserved for tumors measuring less than 4 cm in size. The authors of this chapter typically reserve ablation for tumors measuring less than 3.5 cm because oncologic efficacy is inferior for tumors larger than this size (6). Historically, ablative therapy has also been reserved for patients with limited renal functional capacity, bilateral or multiple masses, and patients with genetically inherited renal cell carcinoma (RCC) syndromes requiring management of multiple metachronous or synchronous lesions. Typically, ablative therapy for SRMs has been employed via a percutaneous technique because it minimizes morbidity. Nevertheless, there are specific instances where a percutaneous approach may not be feasible or is too dangerous to pursue. A laparoscopic approach is indicated when there is a necessity to physically mobilize critical structures away from the area of ablation and to allow for direct visualization of the ablated area in relation to other structures. For these reasons, the rate of intraoperative complications during laparoscopic ablative treatment of SRMs is low (7–11). A laparoscopic approach is usually indicated for masses in an anterior or lateral location because this is where many vital structures converge and where percutaneous probes cannot reach. Posterior tumors can generally be treated percutaneously, although a retroperitoneal laparoscopic approach may also be applied.

The only absolute contraindication to laparoscopic ablation of SRMs is irreversible coagulopathy. Relative contraindications include inability to tolerate insufflation necessary for laparoscopic abdominal surgery, tumors with cystic components, large diameters, and close approximation to hilar structures. Ablation of endophytic renal lesions not seen on ultrasound preoperatively should not be attempted via a laparoscopic approach because identification of the mass is dependent on the surgeon’s ability to identify it on intraoperative ultrasonic imaging.

MECHANISMS OF ACTION OF ABLATIVE THERAPIES

Cryotherapy

Cryoablation is the most studied ablative procedure for renal masses and was first described in canine models in 1994 by Uchida et al. (12). Since that time, cryoablation techniques have improved with the introduction of small probes and use of argon and helium gas, enhancing the accuracy of the freeze-thaw cycle. The smallest available probes needles are 17-gauge (1.47 mm) in size (Endocare, Irvine, California).

Once probe placement is confirmed on intraoperative imaging, argon gas is rapidly injected through the tip of the needle which briskly creates an ice ball. Once the freezing cycle is complete, pressurized helium is then forced through the needle probe to induce thawing. This precipitous freezing of renal tissue results in extracellular and intracellular ice crystal formation leading to acute intracellular pH changes, protein denaturation, decreased intracellular osmotic concentration, and immediate physical mechanical destruction of the cellular membrane (13). Injury to vascular endothelium is also exhibited which results in demonstrable microvascular thrombosis and ischemia leading to delayed necrosis over hours and days after treatment. Freeze-thaw cycles reliably and reproducibly cause necrosis of renal parenchyma at temperatures at or below −19.4°C (14). Malignant lesions may require even lower temperatures to result in cellular death, thus most clinical protocols call for freezing temperature of −40.0°C (15). Experimental models have demonstrated that ice balls produced via cryotherapy only reach these extreme temperature 3.1 mm within their inner edge (16). Because of this, the ice ball is allowed to extend 5 to 10 mm beyond the boundary of the renal lesion in clinical practice.

Ice ball size and temperature monitoring are verified with intraoperative imaging (computerized tomography [CT], magnetic resonance imaging [MRI], or ultrasound [US]) and thermocouples found at the end of the ablation probes. The majority of large clinical series describing outcomes of cryoablative treatments of SRMs use a double freeze-thaw cycle to ensure cellular death. This has been shown to increase oncologic efficacy compared to single-cycle protocols (17).

Radiofrequency Ablation

The mechanism of RFA relies on the transformation of high-frequency electromagnetic waves into heat causing thermal damage. The increase in temperature is not applied directly by the probe. An alternating monopolar current is passed from the electrode in to the target lesion, resulting in ionic disturbance and molecular friction which, in turn, causes a release of energy as heat (18). This increase in thermal energy results in permanent protein denaturation and desiccation which occurs instantly at a temperature greater than 60°C (19). These extreme temperatures also lead to breakdown of cell membrane, nuclear instability, microvascular thrombosis, and, ultimately, ischemia and necrosis of target tissue (20). The currently available platforms for RFA differ in the manner in which they modulate energy delivery. Temperature-based feedback inhibition (AngioDynamics, Latham, New York) measures the temperature at the edge of the ablation field in order to avoid overheating. Impedance-based feedback inhibition (RF 3000, Boston Scientific, Natick, Massachusetts; Cool-tip, Covidien, Mansfield, Massachusetts) reduces delivered current by sensing the increased resistance in target tissue. These feedback inhibition mechanisms reduce the production of charred tissue, thus improving efficacy and maintains the size of the ablation zone.

Concurrent intraprocedure monitoring of the lesion with CT, US, or MRI is problematic due to the production of microbubbles and poor innate delineation on imaging between normal renal parenchyma and tissue ablated via RFA (21). However, real-time imaging may be unwarranted as the efficacy of RFA is determined by the deployment diameter of the probe tines and maximum temperature reached. In contrast to the ice ball seen in cryoablation, the size of the lesion does not grow with increased activation time beyond the minimum threshold.

SURGICAL TECHNIQUE AND POSTOPERATIVE CARE

Perioperative Preparation and Considerations

Careful assessment of the patient’s past surgical history and evaluation of cross-sectional imaging should be performed in each case to identify the best surgical candidate for laparoscopic ablation. Appropriate consent should be obtained from the patient after the risks and benefits of ablation and other alternative procedures are discussed in detail. A transperitoneal approach is employed for superior and anterior renal masses. A retroperitoneal method may be considered for posterior and lateral tumors when a percutaneous technique is not possible. Renal ultrasound should also be performed on masses that are found to be endophytic on cross-sectional imaging in order to assess whether intraoperative ultrasonic evaluation can be successfully performed. Completely endophytic masses that are not seen on preoperative renal ultrasound should not be treated with laparoscopic ablation as intraoperative identification may not be feasible.

Positioning, Port Placement, and Operative Technique for Exposure of the Tumor

Once the patient is bought to the surgical theater, a Foley catheter is placed to ensure complete decompression of the bladder and the patient is appropriately positioned. For a transperitoneal approach, the patient is placed in a modified flank position. A standard flank position is applied when a retroperitoneal approach is proposed.

Abdominal insufflation may be obtained with a Veress needle or with open placement of a Hasson trocar. For a transperitoneal approach, three laparoscopic ports are inserted in the same arrangement as for transperitoneal laparoscopic nephrectomy. For a retroperitoneal approach, access to the retroperitoneum is achieved with the use of a visual obturator trocar or by an open method with the placement of an index finger through a small incision overlying the tip of the 12th rib in order to develop the retroperitoneal plane between the peritoneum and psoas muscle. The retroperitoneal space can further be developed with the use of a space-expanding dilation balloon or with laparoscopic development.

Once intraperitoneal access is obtained, exposure of the renal mass is achieve initially by incising the white line of Toldt in order to medially reflect the colon off of Gerota fascia. The ureter and gonadal vessel should be identified in order to ensure preservation and limit injury. The renal hilum should also be identified in order to facilitate control of main renal arterial supply in the case that uncontrollable renal hemorrhage is encountered during ablation because this could be a life-saving maneuver. Once the kidney is visualized, Gerota fascia is opened and the tumor exposed by careful dissection and removal of perinephric adipose tissue. The opposite side of the kidney should also be exposed in cryoablation cases to allow for ultrasonic monitoring of probe placement and to visualize the tumor margins at time of ablation. This is especially vital in treatment of tumors that are found to be completely endophytic.

Laparoscopic Radiofrequency Ablation

Once the kidney is exposed and the lesion is exposed, a location on the abdominal wall should be identified to permit entry of the RFA probe to the tumor at a right angle to its most exophytic juncture (Fig. 9.1). We prefer to use the temperature-based system which will be described herein. Once the probe is inserted, the tines are opened and allowed to spread to a diameter encompassing 5 to 10 mm outside the tumor margin in order to ensure complete ablation. Ablation with radiofrequency energy is performed in two cycles to a target temperature of 105°C. The length of each cycle is determined by the size of the tumor (Table 9.1). After ablation is concluded, the probe is carefully separated from the tumor and an incisional biopsy is performed. Biopsy of the tumor after completing RFA minimizes the risk of bleeding and potential seeding of the tumor. A study from our institution demonstrates that histologic architecture is maintained in the tissue sufficient for diagnosis after RFA is performed (22). The site of biopsy is evaluated for hemostasis. Application of hemostatic agent may be applied at this point as needed for mild bleeding. When bleeding is not controlled with use of hemostatic agents alone, electrocautery or argon beam coagulation may be use.

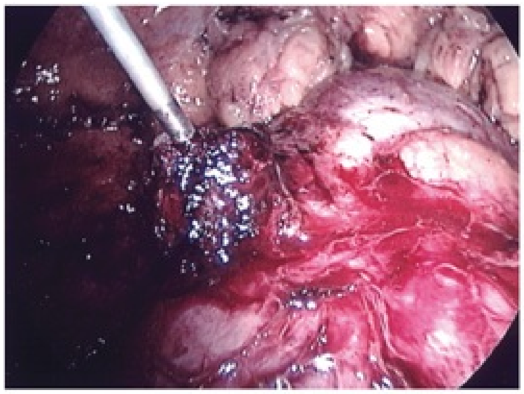

FIGURE 9.1 Example of single RFA probe near of ablation cycle with evident tissue dessication.

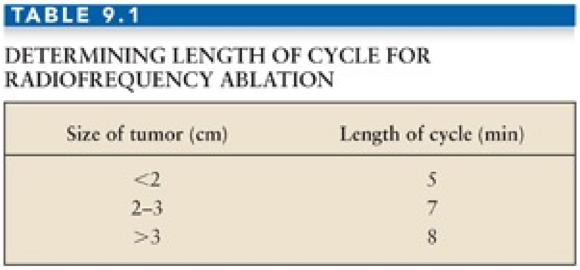

TABLE 9.1

DETERMINING LENGTH OF CYCLE FOR RADIOFREQUENCY ABLATION

Size of tumor (cm)	Length of cycle (min)
<2	5
2–3	7
>3	8

Once ablation is complete and hemostasis is maintained, Gerota fascia is reapproximated with the use of Weck Hem-O-Lok clips (Teleflex, Research Triangle Park, North Carolina) in order to place the kidney back into a retroperitoneal position. The colon is placed back in its anatomic location and the trocars are removed under direct vision to ensure hemostasis.

Laparoscopic Cryoablation

Once the tumor is identified and margins are demarcated, core needle biopsies are obtained prior to ablation. The biopsy needle should be passed through a laparoscopic trocar in order to avoid the hypothetical risk of seeding. Central placement of a single 4.8 mm cryoablation probe can be used to treat tumor 2 cm or less in diameter. For tumor greater than 2 cm in diameter, ablation can be accomplished with the use of three 17-gauge (1.47 mm) probes placed in a triangulated fashion within the lesion to ensure the formation of the ice ball extends beyond the tumor margin. Two freeze-thaw cycles are employed for completion of cryoablation, as discussed previously. Ice ball formation is monitored continuously via laparoscopic ultrasonography and under direct vision (Fig. 9.2). Intraoperative temperature monitoring can be accomplished with the use of 18-gauge thermocouple placed at the tumor margin. Temperatures below −20°C must be achieved in order to ensure cellular death. Once both freeze-thaw cycles are complete, the probes are removed and hemostatic agents applied to puncture sites as needed. It is paramount that the second thaw cycle is complete prior to removal of the cryoprobes in order to avoid cracking of the lesion that can lead to hemorrhage.

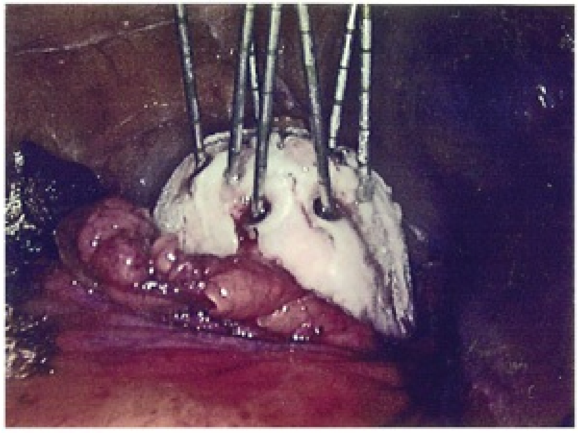

FIGURE 9.2. Example of multiple cryoablation probes with ice ball enveloping tumor.

Postoperative Care

Postoperative care is similar to laparoscopic nephrectomy. Hematocrit should be assessed and deemed stable prior to discharge home. The patient may be admitted for standard care on the floor and allowed to have their diet advanced as tolerated. Patients should be ambulating, passing flatus, and tolerating a regular diet prior to discharge. This is frequently accomplished by the first postoperative day.

COMPLICATIONS

Complications of Cryotherapy

The most common complications associated with laparoscopic cryoablation include intraoperative hemorrhage, delayed perinephric hematoma, infection, hematuria, flank pain, paresthesia, and urinary tract infection. A recent study by Cestari et al. (23) reviewed 104 cases of laparoscopic cryoablation and only reported three major complications, including hematoma requiring transfusion, perinephric abscess requiring CT-guided drain placement, and ureteropelvic junction (UPJ) obstruction requiring open pyeloplasty. Lehman et al. (24) performed a retrospective review of 44 patients with 51 tumors who underwent laparoscopic cryoablation for SRMs. The patients were divided into two cohorts: 23 patients with 30 masses <3 cm in size (mean size 1.8 cm) and 21 patients with 21 masses ≥3 cm in size (mean size 4.0 cm). The first group with smaller renal masses suffered no complications, whereas the second group with masses larger than 3 cm had a complication rate of 62% including two fatalities. The most common complication in this series was postoperative hemorrhage requiring transfusion (38%).

In regard to percutaneous versus laparoscopic cryoablation, Johnson et al. (25) reviewed 139 cases of cryoablation and described a total of 20 complications (16 after a percutaneous approach, 4 after a laparoscopic approach) for an overall rate of 14.4%. The two major Clavien 3b complications reported included one significant retroperitoneal hemorrhage requiring open exploration after percutaneous cryoablation, and one case that were converted to open partial nephrectomy when the mass was found to be inaccessible via laparoscopic approach. The minor complications in this series included 10 patients with postprocedure flank pain, 2 with urinary tract infections, 1 with small hematoma, 1 with persistently elevated serum creatinine, and 1 with postoperative pneumonia. Finley et al. (26) performed a retrospective review comparing outcomes between percutaneous and laparoscopic cryoablation. The reported rate of transfusion was 11.1% and 27.8%, respectively. A laparoscopic approach was associated with a significantly longer operative time (147 versus 250 minutes) as well as a longer hospital stay (1.3 versus 3.1 days). Overall complication rate was higher in the laparoscopic group (40%) versus the percutaneous group (22%).

Complications of Radiofrequency Ablation

The most common serious complications associated with RFA include urinoma, UPJ obstruction, and probe site pain. A study by Johnson and Cadeddu (27) in 2004 reviewed 133 patients who underwent RFA and found an overall complication rate of 7.6%, three major complications and seven minor. All three major complications were found in the group that underwent laparoscopic RFA and involved urinoma requiring ureteral stent placement, UPJ obstruction requiring open pyeloplasty, and postoperative ileus. In 2007, Zagoria et al. (28) described two cases of proximal ureteral strictures from a series of 73 SRMs treated with RFA. A recent study out of our institution reviewed 111 SRMs treated via laparoscopic RFA and found an overall complication rate of 8.8% (*n* = 7) (11). Of those complications, four were minor (Clavien 1–2) and three were major (Clavien 3b). Of the major complications, two patients suffered UPJ obstruction requiring repeat surgery and one patient with urine leak requiring stent placement.

A recent meta-analysis comparing cryoablation and RFA found no difference in the rate of complication between the two modalities (29). They found a pooled overall complication rate of 19.9% in the cryoablation group (19 studies, 431 cases) and a pooled complication rate of 19.0% of the RFA group (11 studies, 426 cases). A comparison of complications between cryoablation and RFA can be found in Table 9.2.

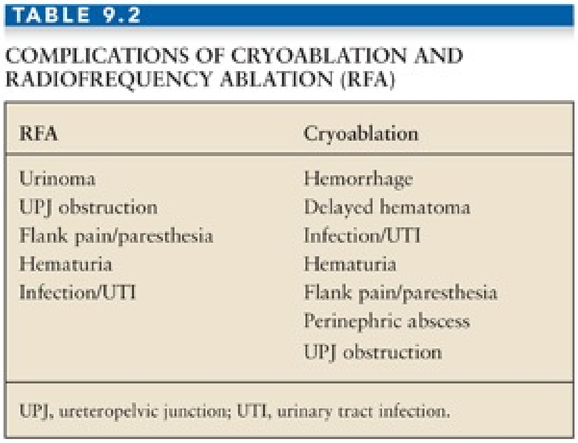

TABLE 9.2

COMPLICATIONS OF CRYOABLATION AND RADIOFREQUENCY ABLATION (RFA)

RFA	Cryoablation
Urinoma	Hemorrhage
UPJ obstruction	Delayed hematoma
Flank pain/paresthesia	Infection/UTI
Hematuria	Hematuria
Infection/UTI	Flank pain/paresthesia
	Perinephric abscess
	UPJ obstruction

UPJ, ureteropelvic junction; UTI, urinary tract infection.

ONCOLOGIC OUTCOMES

Outcomes after Cryoablation

Among the studies reviewing the 5-year oncologic outcomes for cryoablation of SRMs, long-term disease-free survival rates are 80% and higher with reported cancer-specific survival of 90% or greater. A study by Guazzoni (30) in 2010 reviewed 44 patients who underwent percutaneous cryoablation of SRMs with a mean follow-up of 61.3 months. They reported one case of local recurrence, 100% disease-specific survival, and 93.2% overall survival. In 2007, Weld et al. (31) published a series of 31 patients with a mean follow-up of 46 months and reported a 100% disease-specific survival and only one case of local recurrence. Only 22 patients in the study had biopsy confirmed malignancy. The series with the longest available follow-up for patients who have undergone laparoscopic cryoablation for SRMs was published in 2010 by Aron et al. (32). This study reviewed 55 patients with biopsy proven RCC with a median follow-up of 93 months and found a 5-year disease-free survival of 81%, cancer-specific survival of 92%, and overall survival of 84%.

Outcomes after Radiofrequency Ablation

Oncologic outcomes after RFA are similar to cryoablation. A meta-analysis published in 2012 by El Dib et al. (29) demonstrated a pooled proportional oncologic efficacy of 89% with cryoablation (457 cases) and 90% with RFA (426 cases). Levinson and colleagues (33) included 18 patients with biopsy proven RCC with a mean follow-up of 57.4 months. They found a recurrence-free survival of 90.3% and a cancer-specific and metastatic-free survival of 100%. McDougal et al. (34) reported a 91% recurrence-free survival in a series of 16 patients with pathologic confirmed RCC with 4 years follow-up. Metastatic and disease-specific survival were also 100% in this series. In a study from our institution, Tracy et al. (35) reviewed 243 renal tumors that were treated via percutaneous ablation with a mean follow-up of 27 months. Among the 179 masses that were biopsy proven RCC, 5-year recurrence-free survival was 90%, metastatic-free survival was 95%, and disease-specific survival was 99%. Another more recent study from our institution reported specifically on 77 patients who underwent laparoscopic RFA for management of 111 renal masses with a median follow-up of 59 months. Among the patients who had biopsy proven RCC, 5-year recurrence-free survival was 92% with 5-year metastatic-free survival being 100% (11).

CHAPTER 10 LAPAROSCOPIC AND ROBOTICALLY ASSISTED PYELOPLASTY IN ADULTS

J. STUART WOLF JR.

Pyeloplasty is a first-line option for the management of ureteropelvic junction (UPJ) obstruction. The reconstructive techniques have evolved over the years, and most recently, the laparoscopic approach (with or without robotic assistance) has been introduced. In properly selected cases and with requisite expertise, laparoscopic pyeloplasty provide the same technical success as open surgical laparotomy and is associated with a shorter and less intense convalescence. The technique is well-established and reproducible, although there are situations that might prompt consideration of the open surgical approach such as extensive tissue deficit in the setting of prior surgery. Laparoscopic suturing is the most technically demanding portion of the procedure, such that manual suturing devices or robotic assistance can facilitate the procedure. This chapter summarizes the pre-, intra-, and postoperative considerations for laparoscopic pyeloplasty.

DIAGNOSIS

UPJ obstruction can present symptomatically, or it can be detected incidentally. Flank pain is the most common presenting symptom. Infection, urolithiasis, and/or impaired renal function can result as well. The radiographic finding of unilateral hydronephrosis and a normal ureter (on computerized tomography, magnetic resonance imaging, or ultrasonography) together with ipsilateral flank pain (classically episodic and related to fluid or alcohol intake) is sufficient to make the diagnosis. When the diagnosis is uncertain or if surgery is considered, however, further information such as estimation of differential renal function and quantification of outflow obstruction might be desirable and can be obtained with nuclear medicine renal scintigraphy. At the time of pyeloplasty, or in some cases as a separate procedure, retrograde ureteropyelography is recommended to confirm the diagnosis and determine the UPJ anatomy.

INDICATIONS AND CONTRAINDICATIONS

Indications for pyeloplasty include symptomatic UPJ obstruction or UPJ obstruction resulting in pyelonephritis, urolithiasis, and/or impaired renal function. Repair of asymptomatic UPJ obstruction that has not led to these sequelae can be offered, with the intention of preventing future problems. There are no absolute contraindications to the laparoscopic approach to pyeloplasty except the usual surgical contraindications (untreated coagulopathy, active infections, etc.). Significant prior infections, intrarenal pelvis, or prior pyeloplasty will make the laparoscopic approach more challenging, but with experience, these cases can be managed laparoscopically. The combination of any of these with extensive tissue deficit, however, should prompt consideration of open surgery. In the absence of significant urinary leakage, prior endopyelotomy is not usually problematic.

ALTERNATIVE THERAPIES

The most common alternative to pyeloplasty is endopyelotomy, which is the endoscopic incision of the obstructed UPJ and intended healing of the ureter over a stent to provide a wider lumen. Following initial enthusiasm, there is now recognition that endopyelotomy for primary UPJ obstruction does not have favorable long-term results (1–6). Its best role may be in the management of pyeloplasty failures (secondary UPJ obstruction). In ill patients, chronic ureteral stenting may be considered as an alternative to definitive surgery.

PREOPERATIVE PREPARATION

Treat bacteriuria prior to surgery. Bowel preparation is not necessary. After the patient has taken nothing by mouth for 6 hours, and after administering intravenous antibiotics effective against skin and genitourinary organisms, place the patient under general anesthesia with oral endotracheal intubation.

INSTRUMENTATION FOR NONROBOTIC LAPAROSCOPY

The following list includes all of the instrumentation needed for all of the surgical steps described. Not all equipment is needed in all cases, and a variety of preferences will alter the list.

- Nondisposable
    - Laparoscope, 30- or 45-degree lens
    - Video instrumentation and light source
    - Surgical instruments
        - Scissors: standard and microscissors (right-angle scissors are helpful but not necessary)
        - Needle holders
        - Graspers: Maryland, bowel, and bipolar
        - Fascial closure device
        - Needle-suture passer
- Disposable
    - Laparoscopic ports, 5- and 12-mm
    - Veress needle or other abdominal access device
    - Insufflation tubing
    - Irrigator-aspirator
    - Dissection device (monopolar or bipolar cautery, ultrasonic, others)
    - Endo Stitch (Covidien, Norwalk, Connecticut)
    - Umbilical tape or vessel loop
    - Sutures
        - 4-0 Polysorb for Endo Stitch
        - 4-0 braided, monofilament, or barbed suture for free-needle suturing
        - Keith needle for retraction
        - Skin closure suture (or wound glue)
    - 10Fr round closed suction drain catheter
    - Internal ureteral stent
    - Urethral catheter

SURGICAL STEPS

Cystoscopy, Retrograde Ureterography, and Ureteral Stent Placement

Confirm ureteral and renal pelvic anatomy with cystoscopy and retrograde ureterography (can be omitted if retrograde ureterography has already been performed) and place a ureteral stent. Some surgeons place the stent in an antegrade fashion laparoscopically. Insert a urethral catheter to drainage.

Position for Laparoscopy

Place the patient in a modified lateral decubitus position, 45 degrees from horizontal, with the ipsilateral side up on a flat table without flexion. Pad all pressure points well. Bring the ipsilateral arm over the chest and fix it in a neutral position.

Laparoscopic Entry and Port Placement

The transperitoneal route is most popular because it provides more room for suturing and better angles for transposition of the UPJ anterior to crossing vessels when felt necessary. Figure 10.1 illustrates typical port placement for a right-sided laparoscopic pyeloplasty. The midline ports are for the laparoscope (middle port) and the surgeon (working through the umbilical port and the most cephalad port). The fourth port is in a lateral position, in line with the umbilicus, for the assistant surgeon. In an obese patient, displace the ports laterally and cephalad. All ports are 5 mm initially, assuming a 5-mm laparoscope is available. The umbilical port is placed directly through the base of the umbilicus. If the Endo Stitch device is used for the repair, then increase the umbilical port from 5 to 12 mm. Obtain access at the lateral port site using your preferred method and place the remaining ports. Consider infiltrating all port sites with 0.5% bupivacaine (7).

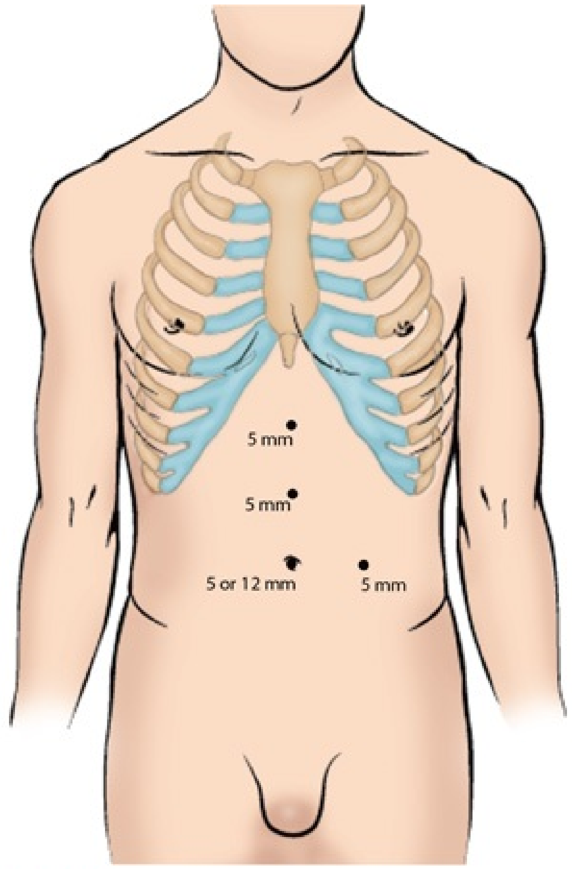

FIGURE 10.1 Port placement for left-sided transperitoneal laparoscopic pyeloplasty.

Exposure of Operative Field

If the UPJ is visible under the colonic mesentery when performing a left-sided pyeloplasty, consider a transmesenteric route, which is more expedient. In most cases, however, reflect the colon and mesentery, staying outside Gerota fascia until reflection is complete. Liver or splenic retraction usually is not needed. Bowel mobilization is complete when the medial aspect of the lower pole of the kidney, up to the renal hilum, can be seen without active retraction of bowel (in obese patients, a bowel retractor may be required). Then, incise Gerota fascia to expose the renal pelvis, UPJ, and proximal ureter.

Dissection of Ureteropelvic Junction

Expose the UPJ either by identifying the renal pelvis and dissecting caudally or by identifying the ureter and proceeding cephalad. Free up the lower aspect of the renal pelvis, UPJ, and proximal ureter from surrounding tissue. The degree of mobilization required depends on the selected repair. Preserve any lower pole crossing vessels. Stabilize the ureter and/or renal pelvis as needed with a vessel loop placed through the abdominal wall with a needle-suture passer or a suture on a Keith needle.

Decide on Type of Repair

Select the type of repair before incising the UPJ. The Anderson-Hynes dismembered pyeloplasty (Fig. 10.2) is the most versatile repair because the obstruction is completely resected and the UPJ transposed in front of any anterior crossing vessels. Although the renal pelvis can be tapered during a nondismembered repair, doing so is more straightforward with dismemberment. If transposition in front of crossing vessels is not required, then a nondismembered repair can be used. The most common nondismembered repairs are the Fengerplasty (using the Heineke-Mikulicz principle, Fig. 10.3) and the Y-V plasty (Fig. 10.4). The latter can be used for long obstructed segments (Fig. 10.5), although it is usually applied for short obstructions. If the obstructed segment is long and the tissue cannot be mobilized enough for an Anderson-Hynes pyeloplasty or a Y-V plasty, then consider a flap pyeloplasty (Fig. 10.6) if there is adequate renal pelvis. This type of repair is more difficult, however, and should be attempted laparoscopically only if there is generous tissue of good quality. In selected cases, ureterolysis and vasculopexy (freeing up the ureter and crossing vessel[s] and relocating the vessel[s] to a new position using sutures placed in the perivascular tissue) can be considered (8–10), but more commonly, this is combined with another type of repair. Finally, when small renal stones are present, they can be removed using the simple technique of laparoscopic pyelolithotomy.

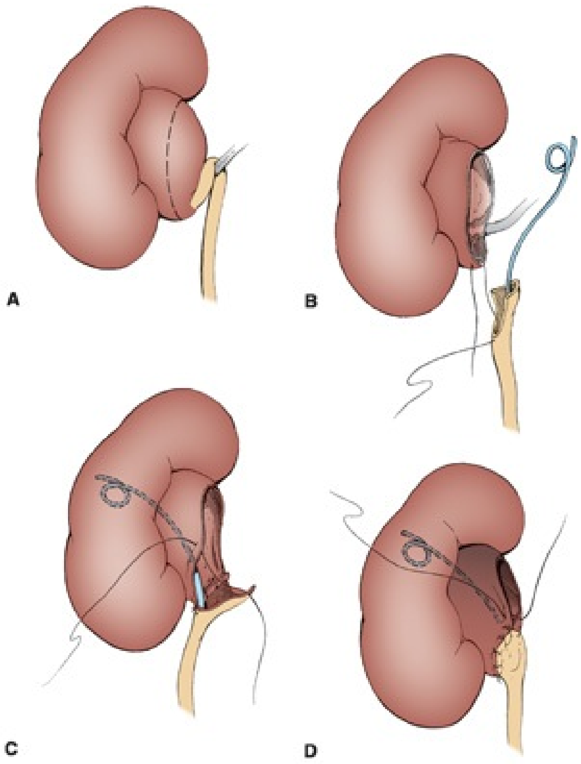

FIGURE 10.2 Anderson-Hynes dismembered pyeloplasty.

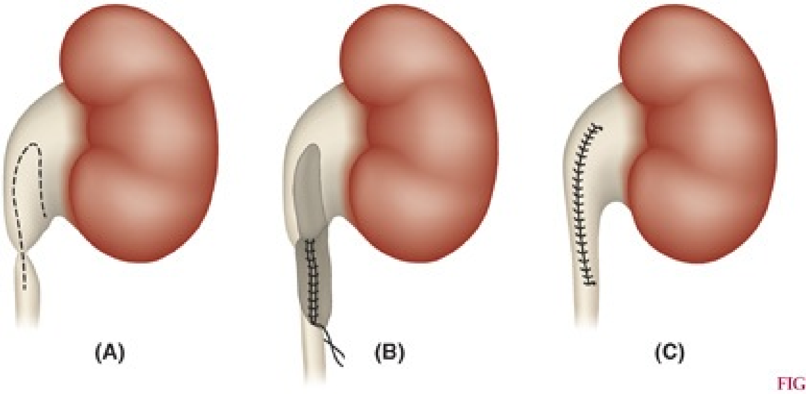

FIGURE 10.6 Flap pyeloplasty.

Anderson-Hynes Dismembered Pyeloplasty

Make the initial incision into the renal pelvis with a scissors placed through the cephalad port. First, create the anterior pyelotomy, cutting from the upper medial aspect of the renal pelvis toward the lateral corner of the UPJ, being aware that the lateral extent of the incision determines the inferior aspect of the renal pelvis for anastomosis, so care must be taken not to carry this incision too close to the kidney. Include the renal pelvic tissue to be discarded (i.e., tapering of the renal pelvis) inferior to this incision, leaving it on the ureter. If the angles allow (or if right-angle scissors are available), then spatulate the proximal ureter on its lateral side after completing the anterior pyelotomy. Stabilization of the ureter (by attachment to the renal pelvis) facilitates this step. If the spatulation cannot be performed now, then do it after completing the dismemberment. Incise the posterior pyelotomy in line with the anterior pyelotomy to completely dismember the UPJ. Leaving the flap of renal pelvic tissue that will eventually be discarded on the ureter for now serves as “handle” for manipulating the ureter. Transpose the renal pelvis and ureter in front of the crossing vessels (when present). Mobilize the proximal ureter and/or renal pelvis as necessary to achieve a tension-free repair.

Options for suturing with non–robotic-assisted laparoscopy include the Endo Stitch and free-needle suturing. If the tissue has adequate thickness and is not friable, and if the ureteral lumen is adequate, then using the Endo Stitch for the Anderson-Hynes pyeloplasty facilitates suturing and knot tying (Fig. 10.7). In all other situations, however, free-needle suturing is recommended because the needle is smaller and can be placed more delicately and at more varied angles. Use a barbed suture to obviate the need to constantly reapply tension.

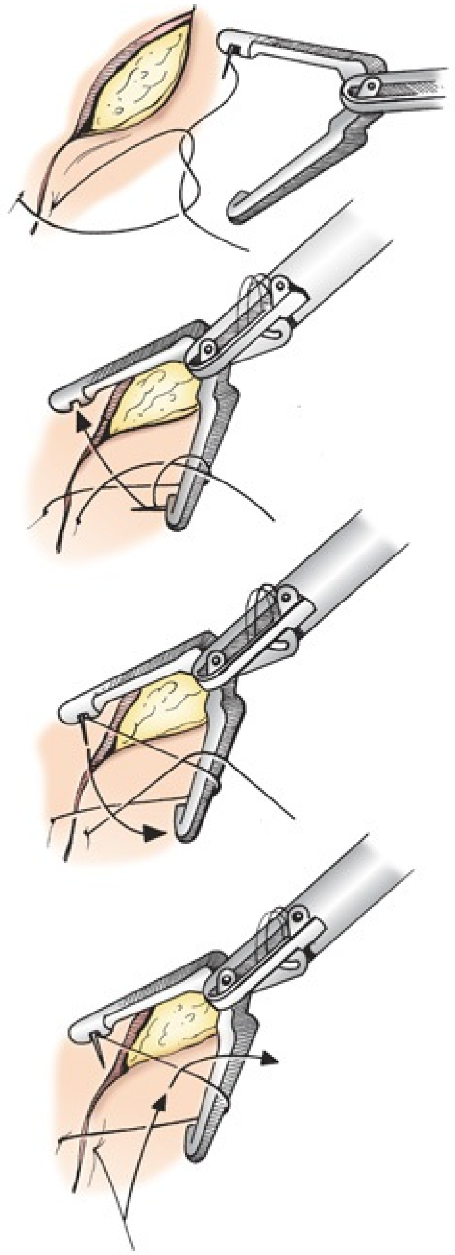

FIGURE 10.7 One of several methods of knot tying with the Endo Stitch device.

Place the first suture of the Anderson-Hynes pyeloplasty outside-in at the inferior apex of the renal pelvis and then inside-out at the inferior apex of the ureteral spatulation. For the first knot, which sets up the remaining repair, a simple knot will suffice if there is no tension but using a surgeon’s knot or a slip knot will ensure good tissue coaptation. Throw this first knot with the suture anterior to the renal pelvis. Because it is easier to close the posterior aspect of the anastomosis first, transfer the needle lateral to the ureter to move it posteriorly. Run the suture to complete the posterior anastomosis of the spatulated ureter to the renal pelvis. Make the bites close together to create a watertight closure. Excise the portion of the flap of pelvic tissue to be discarded, tapering it to match the angle of the anterior closure. With a new suture, complete the anterior anastomosis of the spatulated ureter to the renal pelvis in a running fashion, starting from the caudad aspect, and then continue cephalad to eventually suture renal pelvis to renal pelvis. If a large amount of renal pelvic tissue has been excised, then a third suture might be needed to complete the pyelotomy closure. When the repair is complete, the renal pelvis is tapered and the funnel-shaped UPJ is dependent.

Y-V Plasty

Use a microscissors, if available, to make the fine incisions for Y-V plasty. For the typical short obstruction, initially incise at the anterior aspect of the UPJ at the site of obstruction. Create the lateral arm of the "Y," starting at the initial incision and angling cephalad and toward the kidney. Then, incise the medial arm of the "Y" at about a 60-degree angle. The arms should be of about equal length, and for a short obstruction only need to be a centimeter or so long. Create the caudal stem of the "Y" inferiorly along the anterior aspect of ureter until healthy ureter is reached. Place the initial suture between the apex of the ureteral incision and the tip of the renal pelvic flap. Free-needle suturing is optimal for Y-V plasty. Advance the pelvic flap into the ureteral incision with the first knot and then the approximate appearance of the repair can be appreciated. Place additional interrupted sutures to close the lateral and medial aspects of the repair.

Laparoscopic Pyelolithotomy

If renal stones are present, then insert a flexible cystoscope through a laparoscopic port and through the pyelotomy (before anastomosis) into the renal pelvis. Irrigate through the cystoscope with normal saline. Engage stones with a nitinol tipless basket and remove the cystoscope and stone together out the laparoscopic port.

Drain Placement and Exit

Reduce the pneumoperitoneum pressure to 5 mm Hg and assess for bleeding. Close the fascia of any 12-mm port sites. Place a 10Fr round closed suction drain at the umbilical site, which hides the more prominent scar that occurs when the skin is not closed at the drain site (a 10Fr round drain can fit through the fascia even if the fascia of a 12-mm site has been closed). Desufflate and then close the skin with sutures or wounds glue.

SURGICAL ALTERNATIVES

Laparoendoscopic Single-Site Surgery, Natural Orifice Transluminal Endoscopic Surgery, and Mini-Laparoscopy

Surgical modifications have been made in attempts to improve the cosmesis of laparoscopic pyeloplasty, especially given that the procedure is often performed in young healthy patients for whom this is an important consideration. Options include laparoendoscopic single-site surgery (11), natural orifice transluminal endoscopic surgery (NOTES), and mini-laparoscopy (12). The experience with all of these techniques is limited (in fact, pure NOTES pyeloplasty has been reported only in the experimental setting as of the time of this writing), but further advances might bring them more into the mainstream.

Robotic-Assisted Laparoscopy

The robotic-assisted approach to laparoscopic pyeloplasty has achieved great popularity in recent years, owing to both proliferation of robotic systems used for other (more common) procedures and the aforementioned difficulty with standard laparoscopic suturing. The da Vinci robotic surgical system (Intuitive Surgical, Sunnyvale, California) provides magnification, three-dimensional stereoscopic vision, motion scaling, and tremor filtering to assist suturing. Patient positioning is as described previously. Ports include a 12-mm port for the camera, a 5-mm port for the assistant (to insert suture, provide irrigation and aspiration, etc.), and two or three 5- or 8-mm robotic ports (the third robotic arm, if available, is primarily used for retraction, but not all surgeons use the third arm for this procedure). One configuration for port placement is illustrated in Figure 10.8. Mobilization of the colon and exposure of the UPJ are performed using standard laparoscopic instrumentation as described previously. Robotic assistance can be used for the entire procedure, or only for the suturing +/− the UPJ dissection portions of the procedure. A common robot docking position is from the patient's back at a 45-degree angle from the ipsilateral shoulder toward the umbilicus such that the robotic arms reach across the patient's abdomen and angle back toward the ipsilateral upper quadrant. The 30-degree down-angled da Vinci laparoscope is used. The procedure is then performed as described earlier. Surgeons should be familiar with the standard laparoscopic approach so that the procedure can be completed in the (unlikely) event of robotic malfunction.

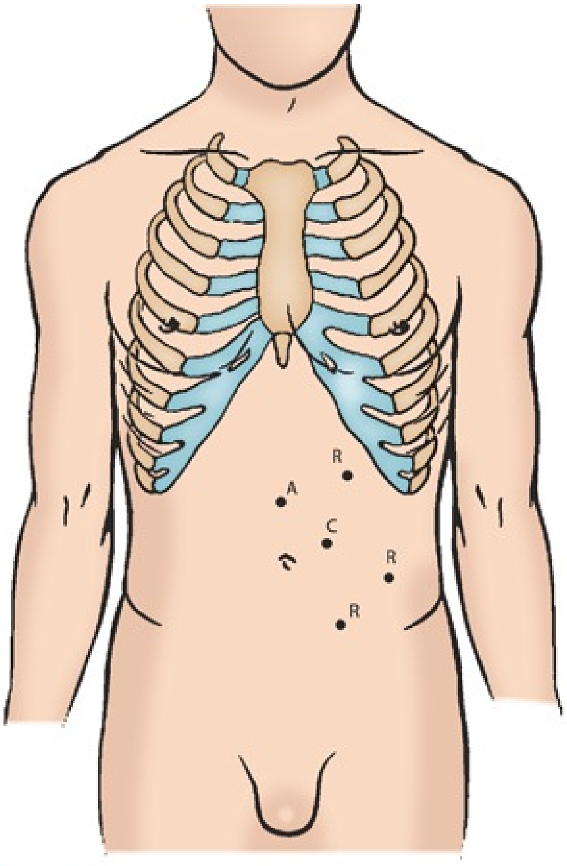

FIGURE 10.8 Port placement for left-sided transperitoneal robotic-assisted laparoscopic pyeloplasty. *A*, 5-mm port for assistant; *C*, 12-mm port for videolaparoscope; *R*, 5- or 8-mm robotic ports (the most inferior robotic port is optional, for robots with a third arm).

POSTOPERATIVE CARE

Advance the patient's diet as tolerated. Use parenteral ketorolac and narcotics as needed for pain control, transitioning from parenteral to oral medications as tolerated. Maintain the urethral catheter and drain until the morning of the second postoperative day (or the first postoperative day if the patient is doing well and might be ready for discharge that day). First remove the urethral catheter and then remove the suction drain and discharge the patient a few hours later after the patient has voided and if the drain output remains low. If there is concern about urine leak, measure creatinine level of the drain fluid and do not remove the drain if the level is elevated.

INTRAOPERATIVE COMPLICATIONS

Aside from general concerns during laparoscopic abdominal surgery, pay specific attention to potential complications regarding the upper tract collecting system and renal vasculature. Approach hemostasis of the incised collecting system tissue cautiously, using bipolar or ultrasonic energy to reduce the risk of devascularization. Tolerate minor oozing. Similarly, take great care when dissecting any crossing vessels. Finally, carefully plan the incisions into the renal pelvis to set up the repair, especially regarding the initial renal pelvic incision. If the incision is too cephalad, especially at the lateral aspect, then the bottom of the renal pelvis that is to be closed to the ureter is inadequate.

POSTOPERATIVE COMPLICATIONS

If the drain contains urine, reinsert the urethral catheter and send the patient home with the drain in place. Remove the drain when output ceases. A leak for more than a week is rare.

PUBLISHED LITERATURE

A multi-institutional comparison of standard and robotic-assisted laparoscopic pyeloplasty, which included 759 procedures that could be included in the multivariate analysis, confirmed no difference in outcomes between standard and robotic-assisted laparoscopic pyeloplasty, and that only prior endopyelotomy and crossing vessels reduced freedom from secondary procedures following laparoscopic pyeloplasty (13). A similar finding was made in a systematic review and meta-analysis that assessed 9 published series of 196 standard laparoscopic pyeloplasties and 277 robotic-assisted laparoscopic pyeloplasties; the two approaches were similar in terms of perioperative complications, hospital stay, and success rate, but robotic assistance was associated with shorter operative time (14). This latter report also suggested that laparoscopic pyeloplasty (standard or robotic-assisted) had similar complication and success rates to that of open surgical pyeloplasty, whereas providing shorter hospital stay and a trend toward reduced analgesic requirements (14).

SUMMARY

Laparoscopic pyeloplasty is a well-established and reproducible surgical procedure with extensive worldwide experience. Results are generally excellent, although the procedure is more difficult in certain situations. The most technically challenging aspect is laparoscopic suturing, which can be performed with free-needle suturing (the most demanding technique), using handheld suture assistance devices such as the Endo Stitch device (which is not optimal for all repairs) or with robotic assistance. Laparoscopic pyeloplasty is a first-line option for the management of UPJ obstruction.

CHAPTER 11 LAPAROSCOPIC ADRENALECTOMY

ARVIN K. GEORGE AND LOUIS R. KAVOUSSI

Since Gagner et al. (1) first described laparoscopic adrenalectomy in 1992, this approach has become the preferred technique in the surgical management of most adrenal lesions. Laparoscopic adrenalectomy demonstrates the classical benefits of minimally invasive surgery, with multiple studies supporting reduction in postoperative pain, analgesia requirements, and postoperative morbidity with equivalent functional outcome when compared with traditional open surgery. Advances in minimally invasive surgical techniques have generated the development of multiple approaches to adrenalectomy, including transperitoneal, retroperitoneal, transthoracic/transdiaphragmatic, and most recently robot-assisted surgery. The benign nature of the majority of adrenal disease, combined with the deep retroperitoneal location of the adrenal gland, has lent itself ideally to a minimally invasive approach.

INDICATIONS

Laparoscopic adrenalectomy is a definitive surgical treatment modality for the broad spectrum of adrenal disease. It has been proven safe and effective in the management of benign functioning and nonfunctioning adrenal conditions as well as the majority of malignant neoplasms (Table 11.1). As surgeon experience has increased, the contraindications to the laparoscopic approach have decreased. In the hands of a proficient and practiced surgeon, contraindications have become relative, and the advantages of minimally invasive techniques have afforded urologists the opportunity of a more aggressive approach in treatment (Table 11.2).

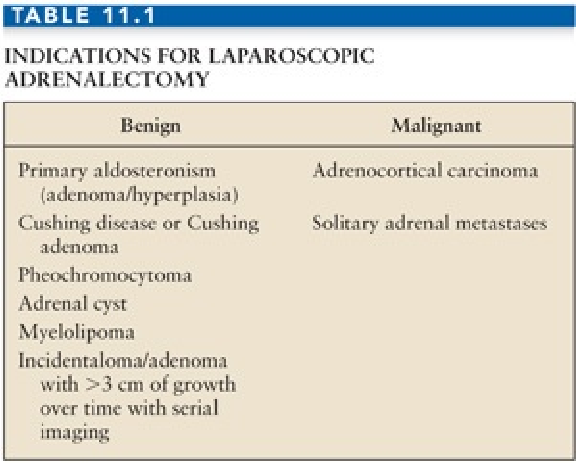

TABLE 11.1

INDICATIONS FOR LAPAROSCOPIC ADRENALECTOMY

Benign	Malignant
Primary aldosteronism (adenoma/hyperplasia)	Adrenocortical carcinoma
Cushing disease or Cushing adenoma	Solitary adrenal metastases
Pheochromocytoma	
Adrenal cyst	
Myelolipoma	
Incidentaloma/adenoma with >3 cm of growth over time with serial imaging	

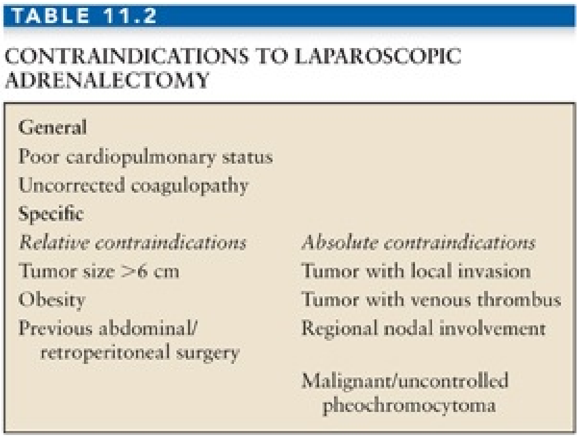

TABLE 11.2

CONTRAINDICATIONS TO LAPAROSCOPIC ADRENALECTOMY

General	
Poor cardiopulmonary status	
Uncorrected coagulopathy	
Specific	
Relative contraindications	*Absolute contraindications*
Tumor size >6 cm	Tumor with local invasion
Obesity	Tumor with venous thrombus
Previous abdominal/ retroperitoneal surgery	Regional nodal involvement
	Malignant/uncontrolled pheochromocytoma

DIAGNOSIS

Evaluation generally begins with serum and urine chemistry to distinguish between functioning and nonfunctioning tumors. More specific investigations, combined with the clinical presentation, assist in isolation of a specific pathology when present (Table 11.3). Imaging with computerized tomography (CT) or magnetic resonance imaging (MRI) is an integral step in preoperative assessment, as it provides detailed characterization of adrenal lesions. The presence of significant retroperitoneal and periadrenal fat allows for ready identification of the gland. CT may help delineate malignant versus benign lesions based on their attenuation characteristics, with accuracy approaching 90% in suspected adrenal disease. CT with assessment of washout is the most useful study in categorizing adrenal incidentalomas with a sensitivity and specificity of 98% and 92%, respectively (2). Attenuation of <10 Hounsfield units on noncontrast imaging is sufficient to identify lipid-rich adenomas <4 cm. Contrast-enhanced imaging at 1 and 15 minutes allows for calculation of absolute percentage washout (APW) and relative percentage washout (RPW) to help characterize lipid-poor adenomas. An APW of >60% and RPW of >40% is typical of benign adenomas (3). Chemical shift MRI with axial in- and out-of-phase images can also be used to differentiate incidental adrenal lesions. MRI has a reported sensitivity and specificity of 89% and 99%, respectively, with adenomas exhibiting a lipid-rich composition in distinction to the lipid-depleted nature of nonadenomatous lesions. Intraoperative ultrasound can elicit detailed information regarding internal acoustic appearance, tumor size, extent of invasion if present, and adjacent anatomy. Its use is a defined element in adrenal-sparing surgery and can assist in cases where it is difficult to distinguish the periadrenal fat from the gland proper. Progress in imaging techniques and their interpretation has increased diagnostic accuracy, and they are an essential adjunct in determining diagnosis, operability, and surgical approach.

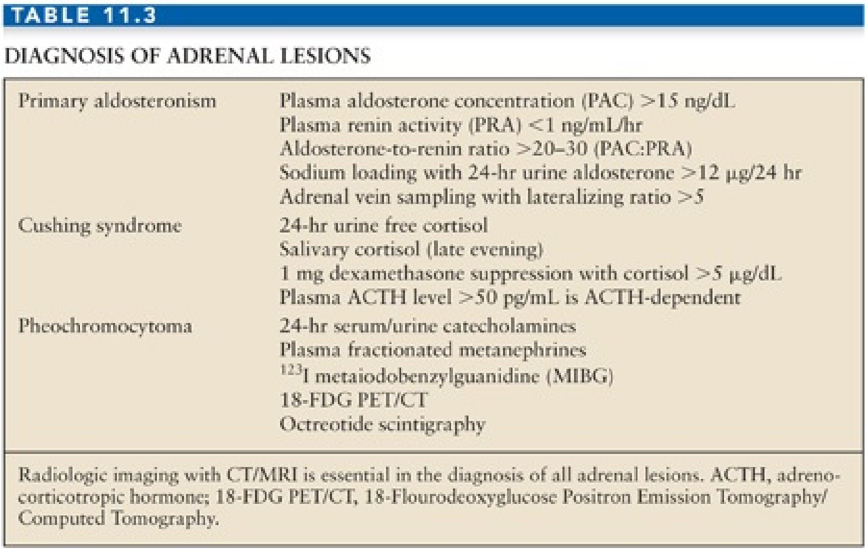

TABLE 11.3

DIAGNOSIS OF ADRENAL LESIONS

Primary aldosteronism	Plasma aldosterone concentration (PAC) >15 ng/dL
	Plasma renin activity (PRA) <1 ng/mL/hr
	Aldosterone-to-renin ratio >20–30 (PAC:PRA)
	Sodium loading with 24-hr urine aldosterone >12 µg/24 hr
	Adrenal vein sampling with lateralizing ratio >5
Cushing syndrome	24-hr urine free cortisol
	Salivary cortisol (late evening)
	1 mg dexamethasone suppression with cortisol >5 µg/dL
	Plasma ACTH level >50 pg/mL is ACTH-dependent
Pheochromocytoma	24-hr serum/urine catecholamines
	Plasma fractionated metanephrines
	^{123}I metaiodobenzylguanidine (MIBG)
	18-FDG PET/CT
	Octreotide scintigraphy

Radiologic imaging with CT/MRI is essential in the diagnosis of all adrenal lesions. ACTH, adrenocorticotropic hormone; 18-FDG PET/CT, 18-Flourodeoxyglucose Positron Emission Tomography/Computed Tomography.

ALTERNATIVE THERAPY

Alternative treatment for adrenal lesions include conventional open surgery via a transabdominal or retroperitoneal approach, radiofrequency ablation (RFA), and cryoablation (4). Ablative therapies are currently reserved for those patients who are not surgical candidates or who refuse surgery.

RFA provokes local ion agitation and heat, inducing coagulative tissue necrosis. In one recent study, Mayo-Smith and Dupuy (5) demonstrated the successful treatment of hormonally active tumors and small (5 cm) solitary adrenal metastases/adrenocortical carcinoma. RFA has also shown promise in the management of adrenal metastases and select patients with functional masses. In a study of 23 ablations, technical success and good local control in 81% of patients with short-term follow-up was reported, but eventual disease progression occurred in 16 of 19 patients treated for metastatic disease (6).

Cryoablation relies on the Joule-Thomson effect, or the change in temperature that accompanies expansion of a gas (argon) with resultant cooling and formation of intracellular ice crystals. Munver et al. (7) described the first case of cryoablation as an adrenal-sparing procedure for hyperaldosteronism, with subsequent reduction in the need of antihypertensives postoperatively. A retrospective series of 12 patients undergoing cryoablation for adrenal metastases demonstrated local control in 92% of patients, although 50% experienced hypertensive crisis highlighting the need for preoperative alpha blockade (8).

RFA and adrenal cryoablation show potential as less invasive surgical alternatives for small lesions and adrenal-sparing procedures in patients who are not ideal surgical candidates. The current experience as described in the literature is limited and further evaluation of such alternative therapies is needed.

SURGICAL TECHNIQUES

The transperitoneal approach is preferred by most surgeons due to the greater working space and familiarity of anatomic landmarks. Retroperitoneoscopic adrenalectomy is generally considered by the more experienced surgeon but may prove useful in patients with significant prior intra-abdominal surgery and/or morbid obesity. Thoracoscopic adrenalectomy was described by Gill et al. (9) for the treatment of select patients with adrenal pathology and significant abdominal and retroperitoneal scarring from previous surgery through access via the virgin thoracic cavity and transdiaphragmatic approach. In an effort to further minimize operative morbidity and improve cosmesis, the introduction of laparoendoscopic single-site (LESS) adrenalectomy has been evaluated. A systematic review of LESS adrenalectomy versus conventional laparoscopic adrenalectomy revealed equivalent complication, conversion, and transfusion rates despite a longer operative time in those undergoing a single-site procedure, likely related to the early experience of this novel technique (10). Additionally, there were comparable cosmetic satisfaction scores, although LESS adrenalectomy demonstrated lower visual analog pain scores. The introduction of robotic technology in the minimally invasive arena has proven to be a successful alternative to other surgeries with specific benefits. Robotic systems aid in eliminating surgeon fatigue, tremor, and provide a three-dimensional visualization of the operative field. However, they represent a more costly option to the healthcare system and require additional training by the surgeon. A prospective trial of laparoscopic versus robot-assisted adrenalectomies failed to show significant benefit in the latter (11). The study demonstrated that robot-assisted adrenalectomy is a feasible alternative to standard laparoscopic surgery with appropriate robotic experience. Ultimately, the choice of surgical technique is dependent on surgeon experience, the patient's past surgical history, and preoperative findings.

Preoperative Considerations

Prior to operative intervention, metabolic abnormalities associated with hormonally active tumors must be addressed to optimize the patient for surgery. A multidisciplinary approach integrating the patient's primary care provider, endocrinologist, and urologist ensures appropriate care in the preoperative setting and maintains follow-up after surgery. Hypertension and hypokalemia seen with aldosteronomas are managed with spironolactone. The patient should be maintained normoglycemic with cortisol-secreting adenomas, and stress-dose steroid administration must occur perioperatively. The preoperative management of pheochromocytomas requires special consideration, as inadequate blockade of circulating catecholamines can trigger hypertensive crises secondary to anesthesia or intraoperative manipulation. Patients should receive 14 days of blockade with phenoxybenzamine hydrochloride titrated to control blood pressure. Additional blockade may be indicated if arrhythmias persist or prior treatment proves insufficient.

A mechanical bowel preparation is optional the night prior to surgery for bowel decompression. Single-dose parenteral antibiotic prophylaxis is given prior to incision. Invasive monitoring via arterial lines and central venous lines is performed as indicated. A urinary Foley catheter allows for bladder decompression and intraoperative urine output assessment. Pneumatic compression stockings are placed on the lower extremities for deep venous thrombosis prophylaxis.

Transperitoneal Laparoscopic Adrenalectomy

The patient is placed in the 45-degree modified flank position and secured with silk tape; all bony pressure points are padded prior to the initial incision. The ipsilateral arm can be folded across the chest or placed in an arm rest (Fig. 11.1).

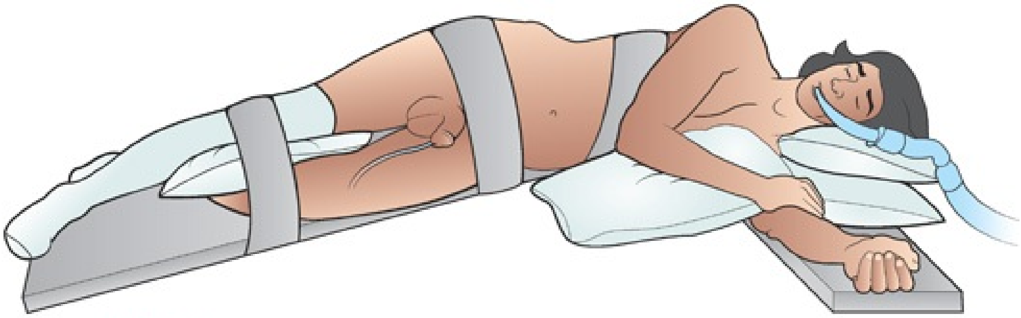

FIGURE 11.1 Laparoscopic transperitoneal adrenalectomy. Patient is positioned in the modified or full flank position for transperitoneal and retroperitoneal approaches, respectively. All bony pressure points are adequately cushioned and the patient is secured in position with silk tape.

Four ports are used for laparoscopic instrumentation. Initial access is obtained at the level of the umbilicus. A Veress needle is inserted and with CO_2 insufflation, intra-abdominal pressure is increased to 20 mm Hg. This is replaced with a 12-mm laparoscopic port into which a 30-degree lens laparoscope is introduced. The remaining trocars are placed under direct vision at the ipsilateral rectus and 4 cm below the costal margin, and midclavicular line and 6 cm below the costal margin, and additional 4 cm below the xiphoid (Fig. 11.2). The camera is placed in the midclavicular line, and the umbilical port site is used for cephalad retraction of the liver or insertion of a paddle retractor for bowel manipulation. Pneumoperitoneum can be subsequently reduced to 15 mm Hg for the remainder of the operation.

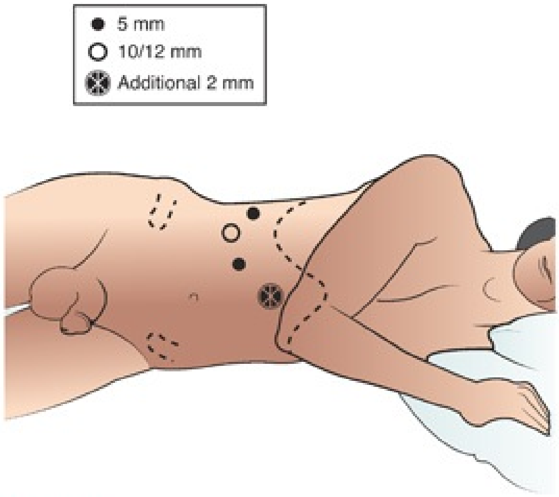

FIGURE 11.2 Laparoscopic transperitoneal adrenalectomy. The primary camera port site is located 6 cm below the costal margin at the midclavicular line. The remaining trocars are placed under direct vision 4 cm below the costal margin in the anterior axillary line and 4 cm below the xiphoid, and additional assistant/retraction port is placed at the umbilicus as illustrated.

Transperitoneal Left Adrenalectomy

Adrenal exposure begins with incising the line of Toldt with endoscopic scissors/electrocautery, which allows for medial mobilization of the splenic flexure and descending colon (Fig. 11.3). The splenocolic and lienorenal ligaments are divided and the spleen is mobilized medially to expose the adrenal in the retroperitoneal space (Fig. 11.4). The fascia of Gerota is opened at the upper pole of the kidney and the periadrenal fat is visualized. Dissection is continued to develop the plane between the tail of the pancreas and the renal hilum. The adrenal vein is identified emptying into the renal vein. The adrenal vein is clipped and divided with a minimum of two clips on the medial aspect (Fig. 11.5). Early ligation prevents systemic insult of catecholamines associated with adrenal manipulation and limits the potential for tumor micrometastases. Superiorly, care is taken to control contributions of the inferior phrenic artery to the adrenal. Larger vessels may be clipped and transected or coagulated with the harmonic scalpel. The adrenal gland is freed from its lateral and inferior attachments with gentle inferior traction on the kidney (Fig. 11.6), at which point renal artery branches to the adrenal can be seen and controlled (Fig. 11.7). The adrenal gland and periadrenal fat are then placed in a laparoscopic retrieval bag and delivered through the largest port site (Fig. 11.8). The surgical field is examined at 5 mm Hg for adequate hemostasis. Finally, the fascial layer of the 12-mm port site is repaired with absorbable suture, and laparoscopic exit is completed in standard fashion.

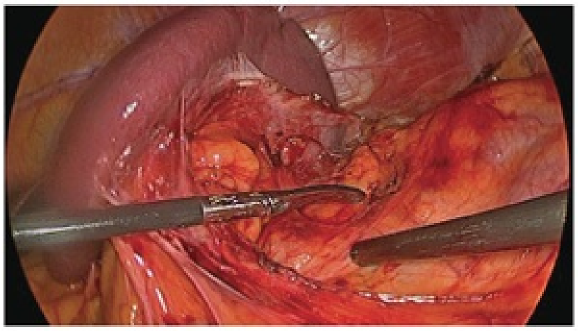

FIGURE 11.3 Transperitoneal left adrenalectomy. Initial exposure begins with incising the white line of Toldt with endoscopic scissors/electrocautery, which allows for gravity-assisted medial mobilization of the splenic flexure and descending colon.

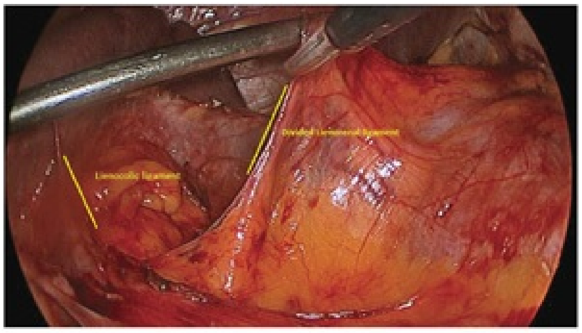

FIGURE 11.4 Transperitoneal left adrenalectomy. The lienocolic and lienorenal ligaments are divided to expose the adrenal in the retroperitoneal space.

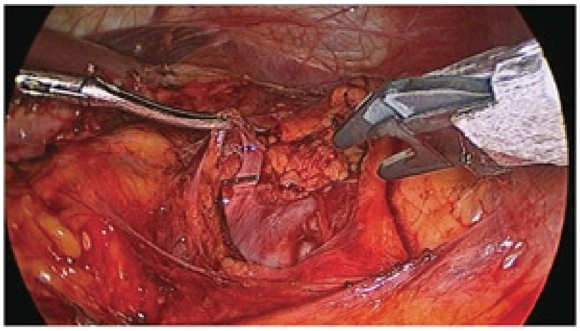

FIGURE 11.5 Transperitoneal left adrenalectomy. The left adrenal vein is ligated with two clips on the side of the renal vein and sharply divided.

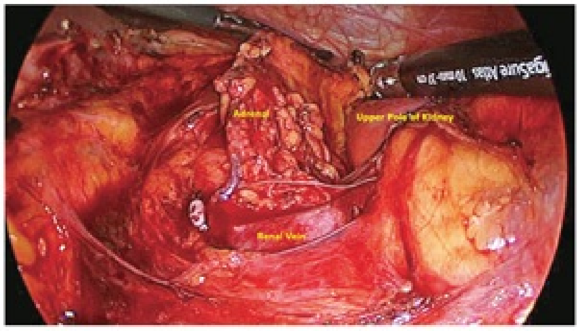

FIGURE 11.6 Transperitoneal left adrenalectomy. The avascular plane between the adrenal and renal upper pole is developed.

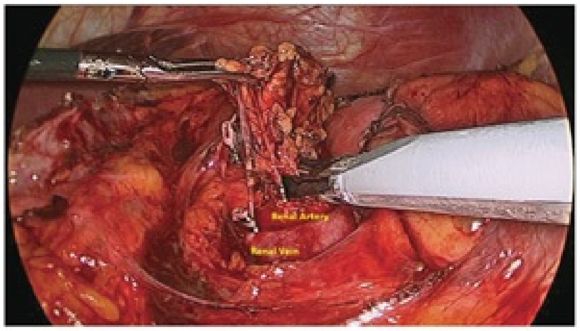

FIGURE 11.7 Transperitoneal left adrenalectomy. Care is taken to control the arterial contributions from the aorta, renal, and inferior phrenic arteries.

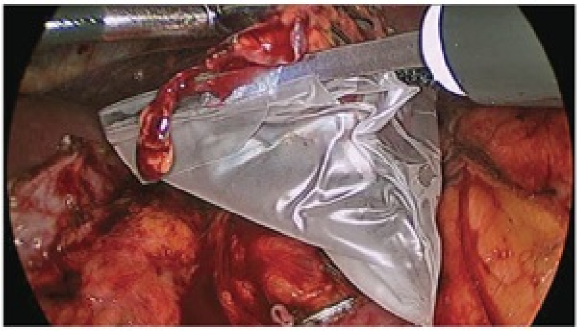

FIGURE 11.8 Transperitoneal left adrenalectomy. The freed specimen is placed in a laparoscopic retrieval bag and removed via the primary port site.

Transperitoneal Right Adrenalectomy

Initial exposure of the adrenal gland begins with cephalad elevation of the liver, which may be completed with a fan retractor or self-retaining locking graspers. The peritoneum is incised at the upper pole of the kidney, close to the liver edge, and the peritoneotomy is extended medially toward the inferior vena cava (Fig. 11.9). In many cases, complete colon mobilization is not necessary, and reflection of the hepatic flexure as needed is sufficient for adequate exposure. At this stage, the adrenal gland should be readily visible and retracted laterally to expose the adrenal vein (Fig. 11.10). It is clipped proximally and distally with two clips on the caval side and divided. Dissection is completed with lateral retraction and elevation of the adrenal to allow mobilization of its superior, medial, and inferior attachments. Careful control of supplying vessels is achieved with hemostatic clips or the harmonic scalpel. The free specimen is then placed in a laparoscopic retrieval bag and delivered through the largest port site. The final steps are completed as described with the left side.

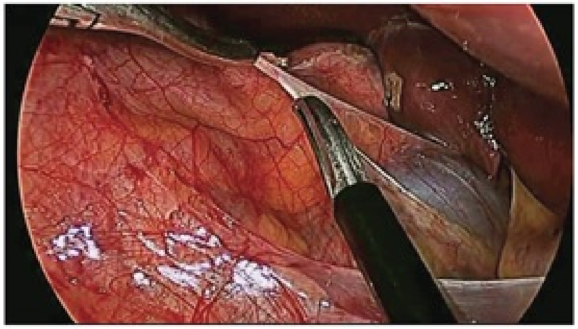

FIGURE 11.9 Transperitoneal right adrenalectomy. The peritoneum at the upper pole of the kidney and overlying the inferior vena cava is incised to expose the retroperitoneum.

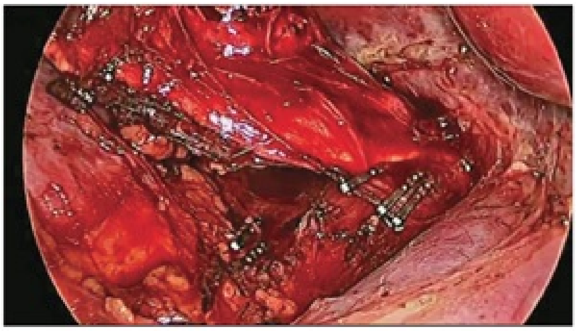

FIGURE 11.10 Transperitoneal right adrenalectomy. After identification of the renal hilum, superior dissection along the inferior vena cava will demonstrate the short, horizontally lying adrenal vein.

Retroperitoneal Laparoscopic Adrenalectomy

The patient is positioned in the lateral decubitus position, stabilized with an inflatable beanbag, and secured and protected as described for the transperitoneal approach. The table is flexed to maximize the operative working space.

A 12-mm transverse skin incision is made at the tip of the 12th rib. The flank muscles are split until the thoracolumbar fascia can be palpated (Fig. 11.11). The fascia is opened and a finger is inserted to allow digital dissection and to develop the retroperitoneal space. A balloon dilator is introduced into the retroperitoneum and inflated to 800 mL. The dilator may then be repositioned more cephalad and reinflated to enable access/vision between the posterior adrenal outside the fascia of Gerota and the diaphragm (Fig. 11.12). The dilator is replaced with a balloon-tipped trocar and sealed against the abdominal wall, and CO_2 pneumoretroperitoneum is created to 15 mm Hg. Under direct laparoscopic visualization with a 30-degree lens laparoscope, an additional port is placed above the iliac crest in the midaxillary line. The final port is placed at the inferior border of the 12th rib where it meets the paraspinal musculature. The anatomic landmarks are identified to ensure localization of the adrenal before mobilization is begun. These include the psoas muscle posteriorly, the fascia of Gerota anteriorly, and the diaphragm superiorly (Fig. 11.13). On the left side, the pancreas lies medially, whereas on the right, it is the liver. Pneumoretroperitoneum is subsequently maintained at 12 mm Hg for the remainder of the operation.

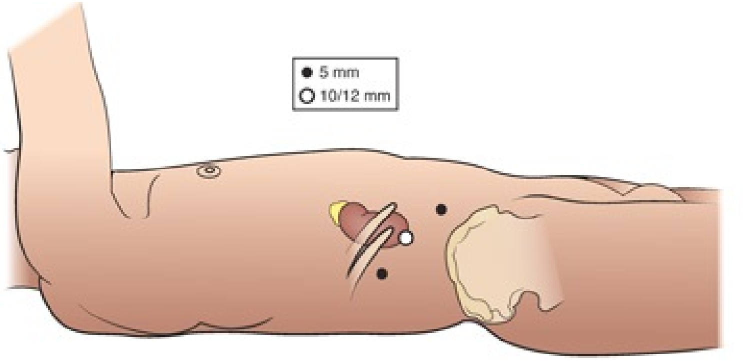

FIGURE 11.11 Laparoscopic retroperitoneal adrenalectomy. Primary port placement is at the tip of the 12th rib. Additional ports are placed under direct laparoscopic vision in the midaxillary line above the iliac crest and the inferior border of the 12th rib, where it meets the paraspinal musculature.

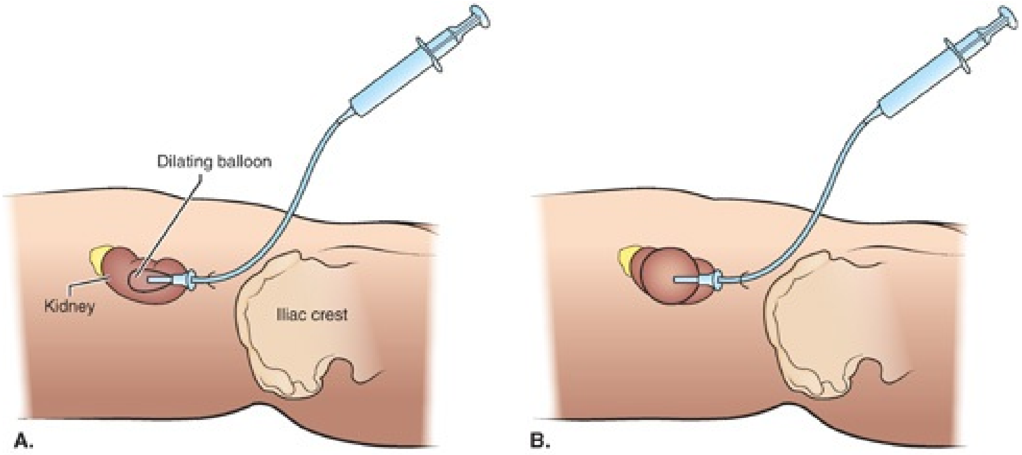

FIGURE 11.12 Laparoscopic retroperitoneal adrenalectomy. **A:** A balloon dilator is inserted into the retroperitoneum and (**B**) inflated to 800 mL. It may be repositioned superiorly and reinflated to maximize exposure and working space before creation of CO_2 pneumoretroperitoneum.

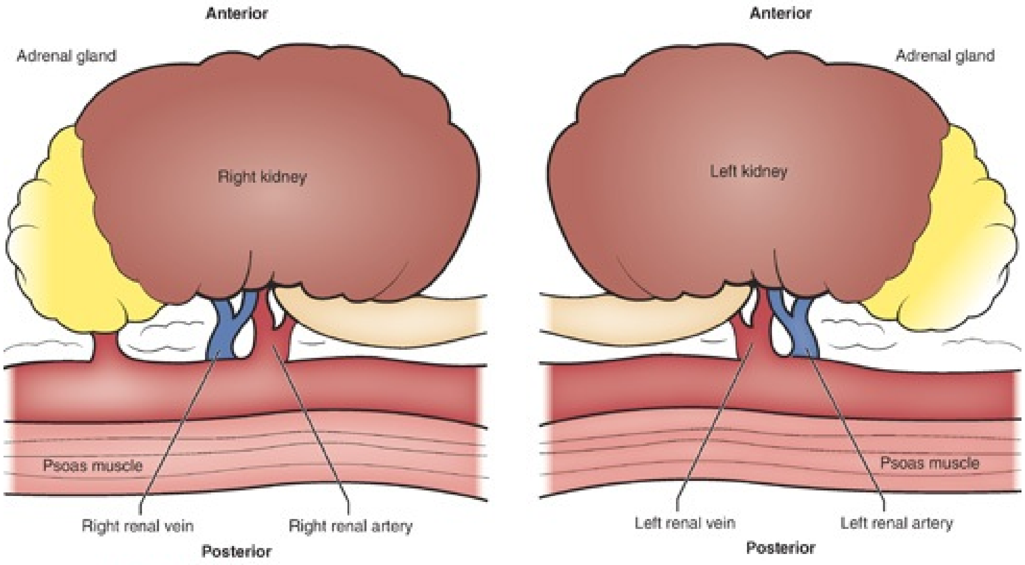

FIGURE 11.13 Laparoscopic retroperitoneal adrenalectomy. Prior to incision of the fascia of Gerota, identification of the anatomic landmarks confirms adequate localization and access to the adrenal. On the right, the liver lies medially, whereas on the left, it is the tail of the pancreas.

Retroperitoneoscopic Left Adrenalectomy

An initial 1.5-cm incision is made transversely along the fascia of Gerota toward the renal upper pole with hook cautery. The perirenal fat is cleaned from the adjacent structures. The plane between the upper pole and adrenal gland is identified and developed with superior retraction of the adrenal and inferior retraction of the kidney. Dissection is continued medially toward the renal hilum, and exposure of the left renal vein facilitates isolation of the adrenal vein arising from the inferomedial border of the gland. The adrenal vein is clip-ligated with two clips on the side of the renal vein and divided. The adrenal is dissected free from the psoas posteriorly and the diaphragm superiorly with ligation of adrenal branches of the inferior phrenic vessels, which may obscure the operative field if not controlled appropriately. Aortic branches arising medially are controlled in a similar fashion with the harmonic scalpel or hemostatic clips. The anterior surface of the adrenal is mobilized from the overlying peritoneum, and the free specimen can then be placed in a laparoscopic retrieval bag for removal via the primary port site.

Retroperitoneoscopic Right Adrenalectomy

Initial access in retroperitoneal right adrenalectomy is similar to the left side. After incision of the fascia of Gerota and clearance of perirenal fat, the vena cava is readily visualized. Dissection is continued superiorly along the cava until the adrenal vein is encountered. The adrenal vein draining from the posteromedial portion of the gland is shorter and more horizontal than its left-sided counterpart and consequently should be approached with caution to avoid tearing. The vein is ligated and divided as previously described. The adrenal is then freed from its remaining attachments with meticulous control of multiple supplying vessels from the aorta, renal hilum, and inferior phrenic artery. Adrenalectomy is then completed as described on the left side.

Robotic Adrenalectomy

The patient is positioned in the lateral decubitus position, stabilized with an inflatable beanbag, and secured and protected as described for the transperitoneal approach. The table is flexed to maximize the operative working space. Four or five ports may be used for robotic instrumentation. Initial access is obtained as described previously. For left robotic adrenalectomy, the initial port placement is a 12-mm camera port placed in the midclavicular line midway between the xiphoid and umbilicus. Two robotic 8-mm trocars are placed; midway between the anterior superior iliac spine and costal margin in the anterior axillary line, and three fingerbreadths below the camera port in the midclavicular line. An assistant port (5 to 12 mm) is placed at the level of the umbilicus. On the right side, an additional 5-mm assistant or robotic port can be placed below the xiphoid for liver retraction completing a quincunx or dice configuration (Fig. 11.14). The robot is docked from the head of the bed, posterior to the patient and at angle to allow for optimal working space and retroperitoneal access. The remainder of the procedure is as outlined for the transperitoneal laparoscopic approach.

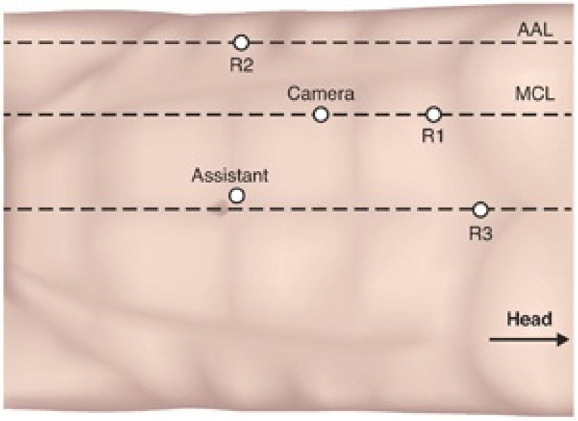

FIGURE 11.14 Robotic right adrenalectomy. Five-port configuration consists of a 12-mm camera port placed in the midclavicular line (*MCL*) midway between the xiphoid and umbilicus. Two robotic 8-mm trocars placed midway between the anterior superior iliac spine and costal margin (*R2*) in the anterior axillary line (*AAL*), and three fingerbreadths below the camera port in the midclavicular line (*R1*). An assistant port (*5* to 12 mm) is placed at the level of the umbilicus. On the right side, an additional *5* mm assistant or robotic port can be placed below the xiphoid for liver retraction (*R3*).

OUTCOMES

Numerous studies have illustrated the safety and efficacy of endoscopic adrenal surgery. Laparoscopic surgery has produced excellent outcomes in hormonally active lesions. Adrenalectomy for aldosteronomas effectively reduces blood pressure in the majority of patients, with long-term cure in 33% to 60% of patients. Patients with subclinical Cushing syndrome showed improvement in glucose control, blood pressure, and obesity following laparoscopic adrenalectomy. Initial concerns regarding laparoscopic treatment of pheochromocytoma and complications which have potential to increase catecholamine release including pneumoperitoneum have been dismissed; one study even described a reduction in intraoperative hypertensive events (35% versus 63%) (12). Controversy also exists regarding the laparoscopic treatment of primary adrenal malignancy. The increased incidence of malignant tumors >6 cm requires careful consideration in surgical approach. Small organ-confined lesions (<6 cm in size) are amenable to laparoscopic excision, but recent series have described conflicting results regarding oncologic efficacy. Miller et al. (13) reported a 30% positive margin rate versus 16% in laparoscopic versus open adrenalectomy groups and a shorter time to recurrence for both stages II and III in the minimally invasive cohort. In contrast, a multi-institutional Italian study revealed no significant differences in local recurrence, time to recurrence, 5-year disease-free survival, or overall survival in a matched cohort of patients controlling for age, sex, lesion size, and stage (14). The current role of laparoscopic adrenalectomy must be tailored to each individual patient without compromising patient safety and ensuring optimal surgical technique with minimal complications (15).

There are several clinical benefits of performing laparoscopic versus open adrenalectomy. Assalia and Gagner (16) demonstrated reduced blood loss (154 versus 309 mL), complication rate (10.9% versus 35.8%), and hospital stay (2.9 versus 7.2 days) when comparing laparoscopic and open surgeries. Additionally, this study demonstrated that laparoscopic surgery utilized less analgesia and had improved cosmesis. These key characteristics translate into increased patient satisfaction as compared to open surgery. Operative times for laparoscopic adrenalectomy are generally longer; this is largely dependent on surgeon experience and has been shown to equilibrate with increased number of cases completed (17). The transperitoneal approach is more often employed by urologists due to familiarity with laparoscopic technique and anatomic landmarks. A prospective randomized study by Rubinstein et al. (18) showed no significant disparity in perioperative morbidity or operative time, emphasizing that the choice of laparoscopic approach lies primarily with the surgeon’s comfort with the procedure coupled with the clinical characteristics of the individual case.

Growing popularity with robotic surgery, mainly through experience with radical prostatectomy, has resulted in feasibility studies of robotic adrenal surgery, and now, comprehensive, robust data sets have become available. A meta-analysis of robotic versus conventional laparoscopic adrenalectomy did not display significant differences in operative time, conversion rate, or postoperative complications (19). Robotic surgery was shown to have a shorter length of hospital stay and lesser estimated blood loss, although patients in the conventional laparoscopy cohort did have a higher body mass index, representing an expected degree of selection bias associated with the early experience of robotic surgery.

Complications

The largest meta-analysis of complications in laparoscopic and open adrenalectomy, by Brunt (20), reported overall complication rates of 10.9% and 25.2%, respectively. Bleeding was the most common complication associated with laparoscopic surgery. Organ injury, including splenic injury requiring splenectomy and pancreatic, diaphragmatic, and large bowel injury, was also decreased. The greatest reduction in morbidity was seen in the incidence of wound (0.6% versus 3.1%), pulmonary, and infectious complications. Thromboembolic phenomena were predominant in obese patients and those with prolonged operative times. The mean conversion rate to open surgery was 3.6%; conversion was most often secondary to intraoperative bleeding, although large tumor size, adhesions, and malignancy with local invasion were also commonly cited reasons. The mean combined mortality rate for laparoscopic adrenalectomy in an analysis of 2,550 cases was 0.2%, and although slightly less than open surgery, the difference has not proven significant. An analysis of National Surgical Quality Improvement Program data for Clavien grades 4 and 5 complications demonstrated an incidence of 7.6% in open surgery and 1.8% for laparoscopic adrenalectomy ($P < .001$); the difference persisted on multivariate analysis when controlling for American Society of Anesthesiologists (ASA) class, wound classification, preoperative functional status, preoperative albumin, and tumor type (OR 3.3) (21). Patients undergoing adrenalectomy for hormonally active tumors must be followed carefully postoperatively because contralateral adrenal suppression can result in metabolic derangements requiring replacement of electrolytes, mineralocorticoids, or glucocorticoids.

CHAPTER 12 RENAL TRAUMA

JILL C. BUCKLEY AND JACK W. MCANINCH

Renal injuries are relatively uncommon, comprising approximately 2% to 3% of all traumatic injuries (1). The vast majority of renal injuries occur as a result of blunt trauma, are grades I to III, and can be managed nonoperatively (1,2). Penetrating renal trauma usually occurs in conjunction with other intra-abdominal injuries where laparotomy may be required. A grade V renal injury can be life-threatening and may require immediate operative exploration for severe hemorrhage and hemodynamic instability, often resulting in a nephrectomy. The renal injury staging classification was developed by the American Association for the Surgery of Trauma (AAST) to reflect the severity of a renal injury and clinical salvage rates of the injured renal unit. The increasing grade of injury reflects a progressive loss of renal unit with a 100% salvage of grades I and II injuries and only a 4.3% renal salvage rate of grade V injuries (3,4). Grade IV renal injuries represent the most controversial management issue in renal trauma care. Many blunt and penetrating grade IV renal injuries can be successfully managed nonoperatively if the patient has been appropriated staged with computerized tomography (CT) and can be closely monitored in a step down or intensive care unit (ICU) (5,6). If radiographic renal staging is not available or the patient requires immediate abdominal laparotomy for an associated nonurologic injury, renal exploration may be indicated after obtaining an intraoperative single-shot intravenous pyelogram (IVP) to confirm the presence of a contralateral renal unit. In hemodynamically stable patients, renal reconstruction at the time of laparotomy provides excellent functional results in the majority of cases (7). The goal of all renal trauma care is preservation of enough functioning nephron mass to avoid end-stage renal failure if the contralateral renal until was lost or absent. Nephrectomy is reserved for a life-threatening injury where damage control is necessary.

DIAGNOSIS

As with all trauma situations, the patient should undergo an acute assessment and resuscitation as defined by the AAST. The hemodynamic stability of the patient will determine if an immediate operative exploration is required versus radiographic CT staging. The type of trauma (blunt versus penetrating), mechanism of injury (e.g., deceleration injury), physical examination (presence of a rib fracture or spinous process fracture, abdominal or flank tenderness, flank ecchymosis, etc.), associated nonurologic injuries, hemodynamics, and degree of hematuria are important to obtain in the initial assessment. If gross hematuria is not present and the patient is hypotensive, a urine dipstick analysis or formal urine analysis should be performed to detect microscopic hematuria. The degree of hematuria does not correlate with the degree of renal injury but is useful in guiding the initial emergency department assessment.

IMAGING

All penetrating trauma should undergo CT radiographic imaging. Any patient sustaining a blunt trauma injury with a positive physical examination, a deceleration injury, gross hematuria, microscopic hematuria in the setting of hypotension (systolic blood pressure <90 mm Hg in the field or in the emergency department), or serial decreasing hematocrits should undergo radiographic CT imaging to stage the renal injury (1,8). Triple-phase CT radiographic imaging allows detailed staging of the renal injury by evaluating the renal hilum, parenchyma, collecting system, and surrounding tissue as well as detecting other intra-abdominal injuries. It is important to obtain delayed images to document that the collecting system is intact, with contrast passing down into the distal ureter without extravasation (9).

In pediatric trauma patients, special attention should be given to the degree of microscopic hematuria present, as this alone may warrant CT radiographic imaging. Children are often able to maintain their hemodynamics despite underlying hypovolemia; thus, blood pressure readings can be falsely reassuring. Unlike with the adult patient, isolated significant microscopic hematuria defined as >50 red blood cells per high-powered field should prompt radiographic CT imaging (10,11). As stated earlier, the type of trauma (blunt versus penetrating), mechanism of injury (e.g., deceleration injury), physical examination (presence of a rib fracture or spinous process fracture, abdominal or flank tenderness, flank ecchymosis, etc.), and associated nonurologic injuries in hemodynamic stable children should all undergo radiographic CT staging of the renal injury.

If immediate laparotomy is required, a single-shot IVP should be performed in the operating room. A bolus IV injection of 2 mL per kg of radiographic contrast is given followed by a 10-minute plain film of the abdomen and pelvis. It is critical to document a functioning contralateral kidney should a nephrectomy be required of the injured renal unit. With a normal single-shot intraoperative IVP demonstrating two intact renal units and a nonexpanding retroperitoneal hematoma, exploration can be avoided (12).

MANAGEMENT

Management of the injured kidney is based on consideration of the patient’s mechanism of injury, hemodynamic stability, associated injuries, and accurate radiographic staging of the injury (1). The vast majority of blunt traumatic renal injuries are clinically insignificant. Fewer than 2% of patients with blunt renal trauma require renal exploration (1,2) (Fig. 12.1).

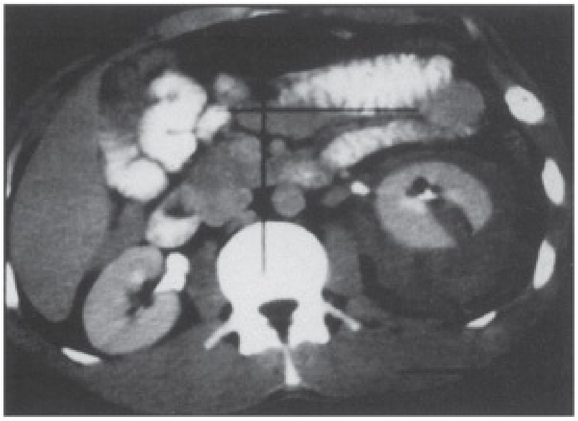

FIGURE 12.1 Abdominal computerized tomography (CT) reveals left renal laceration after blunt trauma (grade III). Even major renal lacerations occurring after blunt trauma are usually amenable to nonoperative management. Renal CT provides detailed information regarding the depth of laceration, size of perirenal hematoma, tissue viability, urinary extravasation, and status of the contralateral kidney.

Historically, all penetrating abdominal injuries underwent laparotomy. Now, with improved diagnostic radiographic imaging, many intra-abdominal and renal injuries can be staged and managed with nonoperative active surveillance combined with repeat imaging (5,13). If conservative management is chosen, it is the responsibility of the treating physician to document a stable or improving situation through clinical parameters and repeat imaging. All patients who sustain a major renal trauma and demonstrate stable hemodynamics should be admitted to the ICU for serial hematocrits, placed on bedrest, and have repeat CT imaging performed 48 hours after the initial staging CT scan or earlier if there is a significant change in their clinical course (5). Active surveillance ensures appropriate management either by demonstrating resolution of the renal injury or by prompting intervention, such as ureteral stent placement for nonresolving urinary extravasation or angioembolization of a segmental artery for persistent arterial extravasation (6,14,15). In all cases of severe renal injury, nonoperative management should only occur after radiographic CT renal staging in hemodynamically stable patients with close peritraumatic monitoring.

Urinary Stenting/Drainage

Urinary extravasation itself is not an indication for a urinary stent or percutaneous drainage. The need to intervene depends on the extent of urinary leakage, signs of infection (sepsis), and presence of a collecting system clot. If a large amount of urinary extravasation is seen, a repeat CT scan is recommended 48 hours after to assess if the urinary extravasation is improving. If the amount of urinary extravasation is decreasing and the patient shows no sign of infection, then continued observation is appropriate and the injury will likely resolve without intervention. If urinary extravasation is unchanged or worsening, then an attempt at a ureteral stent is recommended. If the fluid collection persists despite ureteral stent, a percutaneous drain can be placed to maximize drainage. Findings of a collecting system hematoma, fractured kidney, sepsis, and large segment of devascularized parenchyma (>25%) are more likely to require urinary stenting or percutaneous drainage (6).

Risk Factors for Hemodynamic Instability Intervention

A major reason that renal injuries continue to be explored is the presence of associated intra-abdominal injuries that require exploration. If a major renal injury is seen, this unfortunately often results in a nephrectomy (6). With proper and complete renal staging, renal exploration and thus nephrectomy can be avoided. Renal trauma patients that do undergo CT imaging in order to grade the degree of renal injury have certain CT imaging characteristics that can help predict the likelihood of an intervention. Parkland Hospital (Dallas, Texas) has identified three radiographic findings on CT imaging that predict the need for interventions for patients sustaining a blunt trauma injury: active vascular extravasation, perinephric hematomas >3.5 cm, and medial lacerations (16). Two centers looking to validate these radiographic predictors of intervention found that the presence of active intravascular extravasation and/or perinephric hematoma rim >3.5 cm on CT imaging increased the risk of intervention significantly. The location of the laceration was not found to be predictive of intervention individually (17,18). When all three risk factors are present, the likelihood of intervention varies from 50% to 67% (18). Likewise, patients with no high-risk criteria rarely require intervention (17).

ANGIOEMBOLIZATION

The minimally invasive technique of angioembolization along with radiographic CT imaging has led to a dramatic shift in trauma care in large urban centers where interventional radiology expertise is available. A clear role has emerged for selective segmental arterial embolization in a subset of severe renal injuries to control significant bleeding (19–21). Renal hilar injuries are life-threatening and require immediate operative exploration (22). As with all severe renal injuries, selection is critical for successful management, along with having available and capable interventional radiologists or trained vascular or trauma surgeons. Indications include non–life-threatening bleeding isolated to a segmental renal artery or vein in the setting of an expanding perirenal hematoma or refractory hypovolemia (>3 units of blood transfusion). The embolized vessel is typically a segmental artery, as venous bleeding will often tamponade provided Gerota fascia is still intact (Fig. 12.2). Embolization will lead to nephron loss and should be restricted to active arterial extravasation. Selective embolization has demonstrated excellent preservation of the remaining kidney for not only renal trauma injuries but also for symptomatic angiomyolipomas, spontaneous perirenal bleeds, pseudoaneurysms, and iatrogenic renal vascular injuries; this has resulted in shorter hospital stays, decreased pain, and fewer complications by avoiding open exploration (20,23,24). Endovascular procedures will continue to expand their role in the acute trauma setting as comfort and experience with these minimally invasive techniques grow.

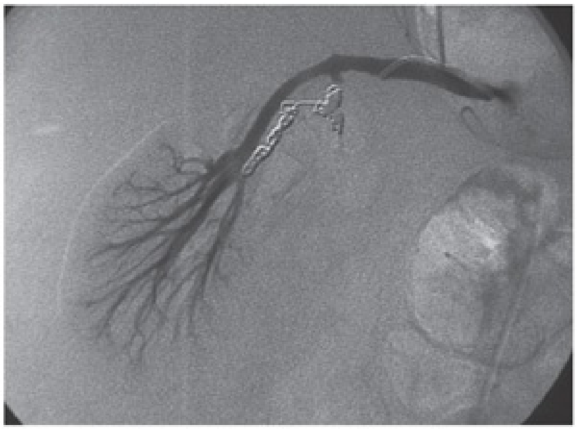

FIGURE 12.2 Angioembolization of active segmental arterial extravasation.

INDICATIONS FOR RENAL EXPLORATION

An absolute indication for renal exploration is life-threatening hemorrhage from a severely injured renal unit. Relative indications for operative exploration include ureteropelvic junction disruption, extensive nonviable renal parenchyma with urinary extravasation, incomplete radiographic staging, and limited observational facilities (Table 12.1). In the setting of a concomitant exploratory laparotomy by the trauma surgeons, our preference is to formally explore and reconstruct any significant renal injury (grade III or greater) in a hemodynamically stable patient. Minimal time is added to the operation, and outcomes are excellent (7). Successful reconstruction can be undertaken despite spillage from bowel injury, pancreatic injury, or other associated injuries (25).

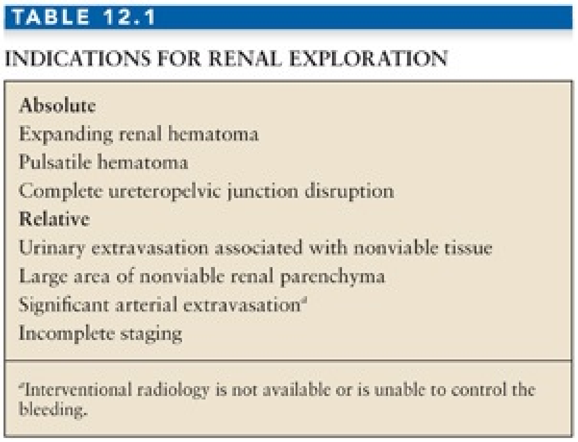

TABLE 12.1

INDICATIONS FOR RENAL EXPLORATION

Absolute
Expanding renal hematoma
Pulsatile hematoma
Complete ureteropelvic junction disruption
Relative
Urinary extravasation associated with nonviable tissue
Large area of nonviable renal parenchyma
Significant arterial extravasation[a]
Incomplete staging

[a] Interventional radiology is not available or is unable to control the bleeding.

In both blunt and penetrating isolated severe renal trauma (no other significant intra-abdominal injuries), selective management is employed to determine if exploration is indicated based on the hemodynamics of the patient, radiographic CT staging of the renal injury, and clinical assessment (5,26). In our large series of grade IV renal injuries, 28% were isolated kidney injuries, 42% underwent exploration, and the remaining 58% were managed nonoperatively. Persistent bleeding requiring multiple blood transfusions was the primary indication for renal exploration (average transfusion requirement of 8.5 U packed red blood cells [prbc]). Guidelines for intervention are hemodynamic instability causing severe hypotension and shock, a rapidly expanding renal hematoma, persistent hemodynamic instability despite 3 U prbc, and clinical decompensation (5). Renal salvage rates were high (>85%) for both operative and nonoperative management, demonstrating the use and importance of selective management.

NEPHRECTOMY

Nephrectomy should be reserved for critically ill patients during a damage control situation and/or renal pedicle avulsions that require complex vascular reconstruction. In these acute settings, it is critical to document a functioning contralateral kidney with a single-shot IVP. These patients are often in shock, have high injury severity scores, receive large volumes of blood transfusions, and overall experience a high mortality rate. As stated by Nash et al. (27), “It is not the exploration that results in the nephrectomy but the injury itself.”

SURGICAL TECHNIQUE

Renal exploration in the trauma setting should be carried out through a standard midline abdominal incision (Fig. 12.3). This approach provides complete access to the intra-abdominal viscera and vasculature and also gives the greatest flexibility to assess and repair a variety of genitourinary injuries. Major bleeding noted on opening the abdominal cavity should be controlled immediately with laparotomy packs followed by surgical control and repair. Associated injuries to other abdominal organs are usually addressed before examination of the kidneys if the patient is stable. The bowel, liver, spleen, pancreas, and other organs should be inspected systematically and carefully. During this period, Gerota fascia maintains its natural tamponade effect on the perinephric hematoma.

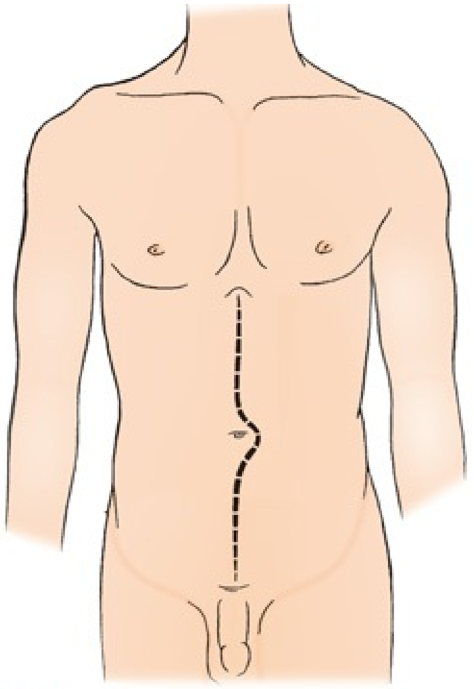

FIGURE 12.3 A midline incision provides the optimal exposure for abdominal exploration, vascular control, and repair of a variety of genitourinary injuries.

The renal vasculature is routinely isolated before entering the retroperitoneal hematoma surrounding the injured kidney. This reduces the risk of uncontrolled renal bleeding and unplanned nephrectomy (28,29). To facilitate access to the retroperitoneum, the transverse colon is lifted out of the abdomen superiorly and placed on moist laparotomy packs. The small bowel is rotated to the patient’s right and extracted from the body to allow access to the great vessels. An incision is made in the retroperitoneum over the aorta from the level of the inferior mesenteric artery to the ligament of Treitz, which can be divided for additional exposure. If a large retroperitoneal hematoma obscures the aorta, the inferior mesenteric vein is identified and the incision into the retroperitoneum is placed just medial to this important landmark. Once the aorta is identified in the lower part of the incision, it is followed superiorly to the left renal vein, which reliably crosses anteriorly. The renal arteries can be found just posterior to the left renal vein on either side of the aorta. The right renal artery can be isolated in the interaortocaval location. If it is difficult to identify the right renal artery through this approach, the second portion of the duodenum can be reflected to expose the right renal hilum. The artery is located posterior to the right renal vein.

The renal artery and vein associated with the injured renal unit are individually isolated with vessel loops. These vessels are not occluded initially unless uncontrollable bleeding is encountered. Most bleeding is successfully controlled with manual compression alone. Because the vessels are not routinely clamped, renal perfusion is continuous and warm ischemia is avoided.

Following proximal vascular control, the kidney is exposed by incising the retroperitoneum just lateral to the colon. The colon is reflected medially. Gerota fascia is sharply opened, and the kidney is expeditiously mobilized to allow complete exposure of the renal surface (Fig. 12.4). Only after complete exposure can the extent and number of injuries be determined (Figs. 12.5 and 12.6). Maintaining the renal capsule during mobilization is important as it provides hemostasis and tensile strength for the closure. If necessary for uncontrollable hemorrhage, clamping of the previously isolated vessels can be done with vascular clamps or bulldogs.

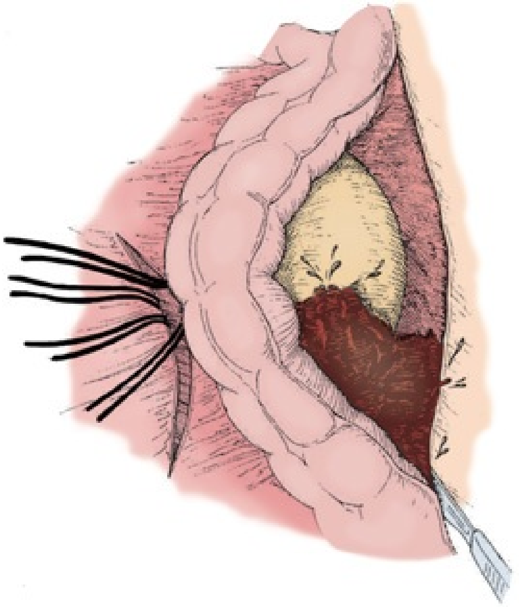

FIGURE 12.4 The colon is reflected medially to allow access to the retroperitoneum. Gerota fascia is sharply opened.

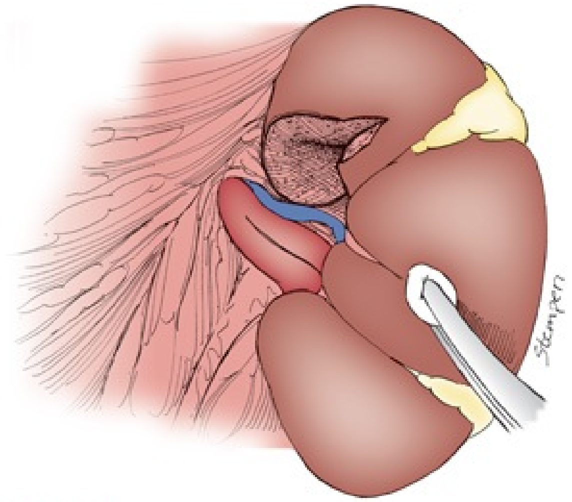

FIGURE 12.5 The kidney is explored. A small gunshot entrance wound on the anterior aspect of the left kidney is identified.

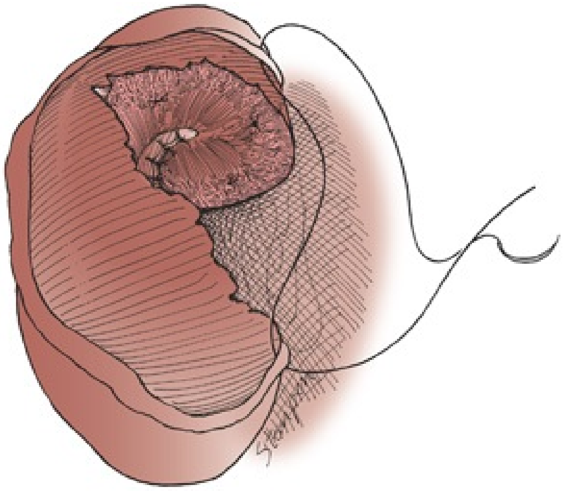

FIGURE 12.6 On the posterior surface of the same kidney in Figure 12.5, a complex gaping exit wound is identified. Nonviable tissue is sharply debrided, segmental vessels are individually suture-ligated, and the collecting system is closed with a continuous absorbable suture. Capsular 3-0 Vicryl sutures are used to reapproximate wound edges.

The following principles are applied to all renal reconstructions: early vascular control, complete renal exposure, sharp debridement of nonviable tissue, oversewing of bleeding vessels for hemostasis, and watertight collecting system closure. If available, the renal capsule is loosely reapproximated over thrombin-soaked Gelfoam or another thrombogenic substance. Ideally, an omental flap is placed over the reconstructed kidney for additional protection and its absorptive properties.

Major polar injuries are best approached by a polar partial nephrectomy. The kidney should be sharply debrided back to viable bleeding tissue. End vessels are individually suture-ligated with 4-0 absorbable sutures to gain hemostasis. The collecting system is then closed with a continuous watertight 4-0 absorbable suture. Methylene blue may be injected into the renal pelvis with simultaneous compression of the ureter to elucidate any leaks in the collecting system, which may then be oversewn; oversewing, however, is not routinely performed. The renal parenchymal defect is covered with thrombin-soaked Gelfoam or another thrombogenic bulking agent to enhance hemostasis and is covered with loosely approximated, interrupted 3-0 absorbable renal capsular sutures. If no capsule is available or the defect is too large to close primarily, an omental pedicle flap can be used to cover the defect (Fig. 12.7). Its absorbent properties and rich vascular supply make it an excellent alternative to the renal capsule. Another substance we commonly use to cover the renal defect is Vicryl mesh as it is readily available, absorbable, and can easily be tailored to the size and shape of the renal defect. A passive drain is placed and then removed in 48 to 72 hours after confirming closure of the collecting system.

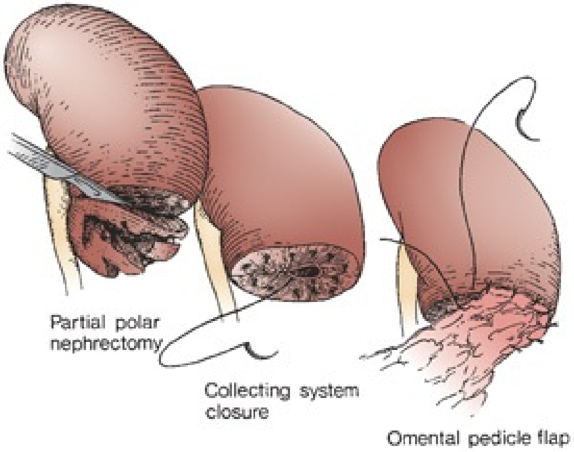

FIGURE 12.7 During a polar partial nephrectomy with reconstruction, if the renal capsule is not available for defect closure, a Vicryl mesh patch or the omentum can be used to cover the defect.

Major injuries to the midportion of the kidney are best repaired by sharp wedge resection of the nonviable tissue and renorrhaphy. Devitalized tissue is sharply removed. Sites of bleeding are individually ligated with fine absorbable sutures and the collecting system is closed with a continuous suture. Thrombin-soaked Gelfoam bolsters are placed into the defect to enhance hemostasis and reduce tension on the capsular sutures (Fig. 12.8). Interrupted absorbable 3-0 sutures are placed through the renal capsule, excluding the underlying parenchyma, as it provides no additional strength. Omentum or Vicryl mesh can be used if primary renal capsular closure cannot be achieved.

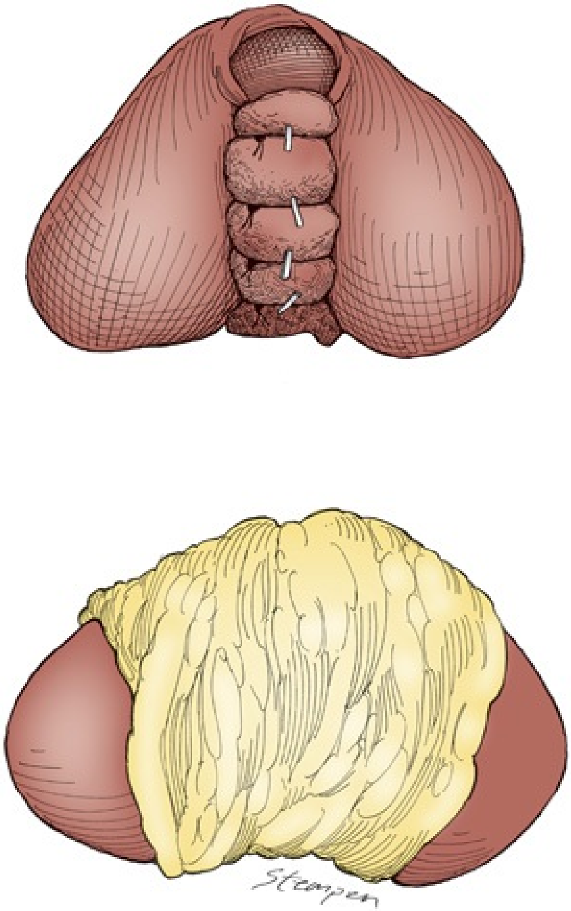

FIGURE 12.8 Closure of parenchymal defect after central renal injury. Capsular sutures of 3-0 Vicryl may be used to sew gelatin foam bolsters into the repair site. Titanium clips may be placed along the repair line to identify the area of reconstruction on subsequent imaging studies. Alternatively, if primary renal closure cannot be achieved, an omental flap may be tacked over the defect using small interrupted chromic sutures.

Renal stab wounds often do not result in displaced or missing renal tissue. Frequently, entrance and exit wounds can be oversewn, and liquid thrombogenic agents such as FloSeal can be applied, resulting in excellent hemostasis (Figs. 12.9 and 12.10). Collecting system injuries that may have occurred will usually resolve with closure of the overlying parenchyma and should not be aggressively pursued. If delayed urinary extravasation is detected by a perirenal drain or radiographic imaging, a ureteral stent can be placed with anticipated collecting system closure (5,14).

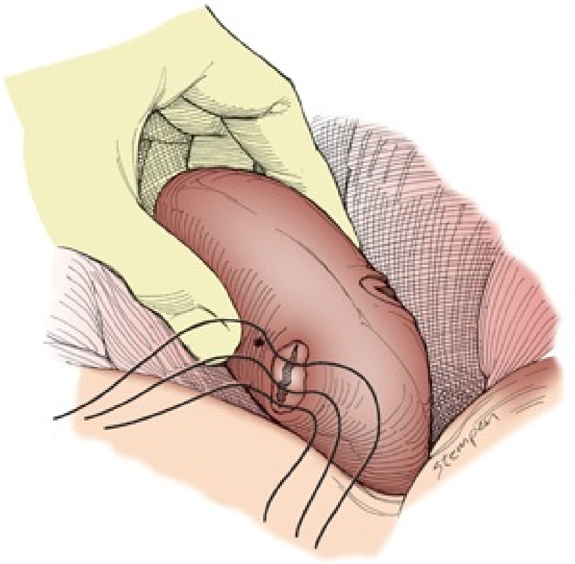

FIGURE 12.9 Technique of renorrhaphy after stab wound. Gelfoam bolsters are laid into the capsular defect, and overlying 3-0 Vicryl sutures are placed superficially to approximate the adjoining renal capsule, thus sealing the reconstructed area.

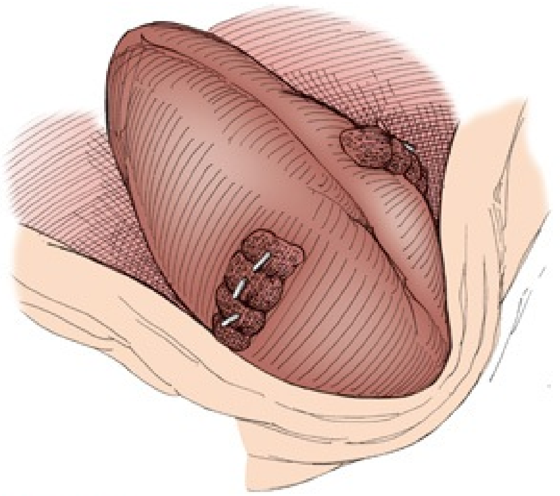

FIGURE 12.10 Completed renal reconstruction after stab wound. The entire kidney has been mobilized and evaluated for associated wounds. Titanium clips along the capsular sutures denote the area of repair.

RENOVASCULAR INJURIES

Renovascular injuries are closely associated to the grade of renal injury and are a major cause of partial or total renal loss. Main renal artery or vein avulsion, in the acute trauma situation, is deemed irreparable and results in nephrectomy. Proximal control of the renal pedicle is critical in these injuries to avoid life-threatening hemorrhage. Attempts at complex hilar arterial or venous reconstruction have shown poor results and should be reserved for the solitary kidney or bilateral renal hilar injuries in a non–damage-control situation (1,26,30). If necessary, the left main renal vein can be suture-ligated with sufficient drainage through the left adrenal and gonadal vessels. Reconstruction of a partial venous or arterial hilar injury can be performed with a continuous fine nonabsorbable suture after obtaining vascular control (Fig. 12.11).

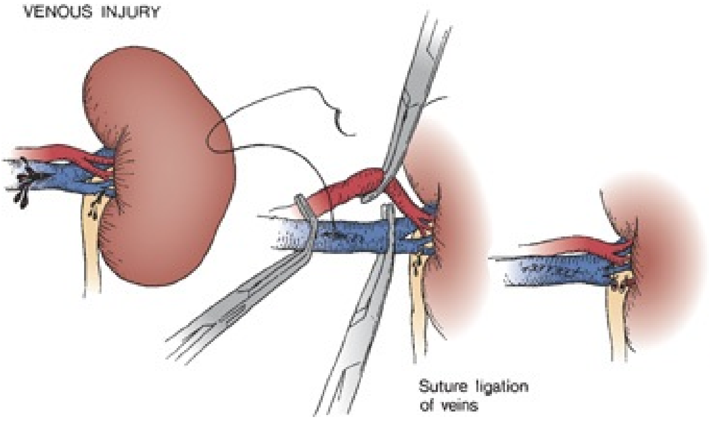

FIGURE 12.11 Repair of partial main renal vein or artery injury using a nonabsorbable continuous suture after gaining vascular control.

POSTOPERATIVE CARE

Gross blood in the urine usually clears within 24 hours, and patients should be observed on bedrest until this occurs. Ambulation is resumed once the urine is clear. Routine laboratory studies are obtained. In the event of a delayed bleed, renal angiography and selective angioembolization can be utilized to control the hemorrhage. Retroperitoneal drains are normally removed within 48 to 72 hours. If drainage is excessive, an aliquot may be checked for creatinine; a level similar to that of serum suggests peritoneal fluid rather than urine. All strenuous activity is suspended for a minimum of 3 months, at which time a radiographic CT imaging study is obtained to document complete renal healing. A radionuclide study can be obtained to assess renal function.

COMPLICATIONS

Delayed renal hemorrhage or development of an arteriovenous malformation (AVM) or pseudoaneurysm usually occurs in the acute peritrauma period and presents with flank pain and/or gross hematuria (cardiovascular issues may also develop with AVM). These situations are best managed by selective angioembolization, which is a safe and effective treatment modality. Mild to moderate urinary extravasation is rarely clinically significant and can be followed by repeat CT imaging to ensure resolution. Large urinomas can be treated with percutaneous drainage and may require a ureteral stent if repeat CT imaging demonstrates persistent or worsening urinary extravasation. Hypertension after renal trauma is classically associated with a Page kidney injury and is otherwise infrequent. Delayed nephrectomy or preferably, capsulectomy and drainage can successfully manage hypertension secondary to a Page kidney injury, as this is an anatomic compression of the renal parenchyma. Medical therapy is otherwise utilized as indicated for essential hypertension.

SUMMARY

Radiographic CT staging, improved endovascular minimally invasive techniques, and growing experience have allowed more successful nonoperative renal trauma care to occur. Although limited, the role for renal exploration still exists in critically ill patients with potentially life-threatening hemorrhage and in those who cannot be preoperatively staged by radiographic CT imaging and observed in ICUs. If renal exploration is necessary, early vascular control and adherence to reconstructive principles will ensure high renal salvage rates.

CHAPTER 13 RENAL TRANSPLANTATION

JOHN M. BARRY

When compared to dialysis, kidney transplantation is the better treatment for patients with end-stage renal disease because of its survival advantage, less impairment with everyday living, and lower long-term treatment costs. Contraindications to kidney transplantation are considered to be unsuitable anatomy for technical success, active cancer, active infection, high probability of perioperative mortality, and inability to comply with a treatment plan. The transplant candidate selection process is performed well in advance of the transplant operation to be certain that those issues have been resolved. This process has been an example of interdisciplinary professional collaboration for decades. The kidney transplant operation is a demanding, open surgical procedure that requires knowledge of pelvic anatomy and attention to the technical details of vascular and urinary tract reconstruction.

PATIENT PREPARATION

In addition to the standard preoperative preparation for major surgery, determination of ABO donor–recipient compatibility, and negative lymphocytotoxic donor–recipient crossmatches, the following questions need to be addressed at the time of transplantation:

1. Will additional surgery, such as removal of one or both kidneys, removal of a chronic peritoneal dialysis catheter, or scar revision, be necessary?
2. Is the patient anuric, and will the bladder, reservoir, or urinary conduit need to be irrigated free of mucus and debris?
3. Is there an inflatable penile prosthesis reservoir that must be avoided during urinary tract reconstruction?
4. Are there scars, stomas, dialysis catheters, and/or feeding tubes that will influence surgical site selection?
5. Is there a lower abdominal bruit, decreased femoral or pedal pulses, or a lower extremity arteriovenous dialysis access fistula that will determine which iliac fossa should be used as the operative site?
6. Is the right or left kidney to be transplanted? (Transplantation of a kidney into the opposite iliac fossa is preferred because it will place the renal pelvis and proximal ureter medial and superficial to the vascular pedicle.)
7. Is the patient obese? (The iliac vessels are more superficial on the right than on the left).
8. Is there a central venous hemodialysis catheter in place? (The anesthetist will need to be reminded that each of the two limbs of a dialysis catheter contains concentrated heparin, which must be aspirated before an infusion is started.)
9. Does the patient have a clotting disorder that will require perioperative anticoagulation in addition to the standard recommendations for thromboembolism prevention?

COORDINATION WITH ANESTHESIOLOGY

An information sheet is popular with anesthesia teams (Table 13.1). It includes antibiotic choice, dosage and administration times of immunosuppressants, recommendations for diuresis promotion after renal revascularization, and goals for intravascular volume status and blood pressure.

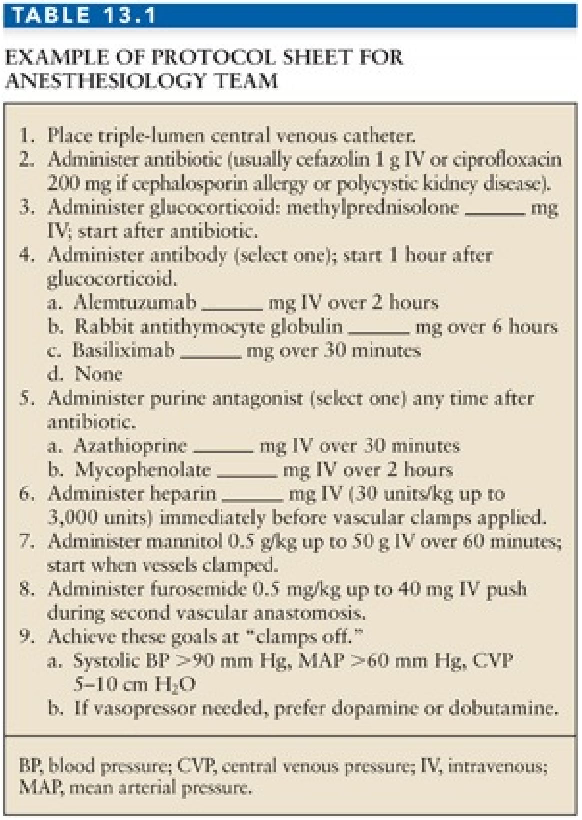

TABLE 13.1

EXAMPLE OF PROTOCOL SHEET FOR ANESTHESIOLOGY TEAM

1. Place triple-lumen central venous catheter.
2. Administer antibiotic (usually cefazolin 1 g IV or ciprofloxacin 200 mg if cephalosporin allergy or polycystic kidney disease).
3. Administer glucocorticoid: methylprednisolone ______ mg IV; start after antibiotic.
4. Administer antibody (select one); start 1 hour after glucocorticoid.
    a. Alemtuzumab ______ mg IV over 2 hours
    b. Rabbit antithymocyte globulin ______ mg over 6 hours
    c. Basiliximab ______ mg over 30 minutes
    d. None
5. Administer purine antagonist (select one) any time after antibiotic.
    a. Azathioprine ______ mg IV over 30 minutes
    b. Mycophenolate ______ mg IV over 2 hours
6. Administer heparin ______ mg IV (30 units/kg up to 3,000 units) immediately before vascular clamps applied.
7. Administer mannitol 0.5 g/kg up to 50 g IV over 60 minutes; start when vessels clamped.
8. Administer furosemide 0.5 mg/kg up to 40 mg IV push during second vascular anastomosis.
9. Achieve these goals at "clamps off."
    a. Systolic BP >90 mm Hg, MAP >60 mm Hg, CVP 5–10 cm H_2O
    b. If vasopressor needed, prefer dopamine or dobutamine.

BP, blood pressure; CVP, central venous pressure; IV, intravenous; MAP, mean arterial pressure.

SURGICAL TECHNIQUE IN ADULTS

The surgical technique for adults and large children will be described in detail because all variations are based on it (1). See Table 13.2 for items that should be quickly available to have a smooth operation. If present, the chronic peritoneal dialysis drain is opened to empty the abdomen of fluid and then closed. The urethral meatus or the urinary conduit stoma is prepped, and a three-way Foley catheter system is placed (Fig. 13.1). This is commonly done while the anesthesia team places a central venous access line. The urinary reservoir or conduit is irrigated with an antibiotic solution, the outflow tube is clamped, and this is placed at the head of the table so the anesthetist can fill and drain the urinary system during the case. This can be helpful when differentiating the bladder, urinary conduit or urinary reservoir from surrounding scar tissue, or an inflatable penile prosthesis reservoir. Adhesive residue, common on the abdomen of patients who undergo peritoneal dialysis, should be removed. The skin of the abdomen and any abdominal tubes are washed with alcohol and painted with an antiseptic skin preparation. The patient is draped so there is surgical access to the entire abdomen in case the selected site turns out to be unsuitable during exposure of the targeted blood vessels.

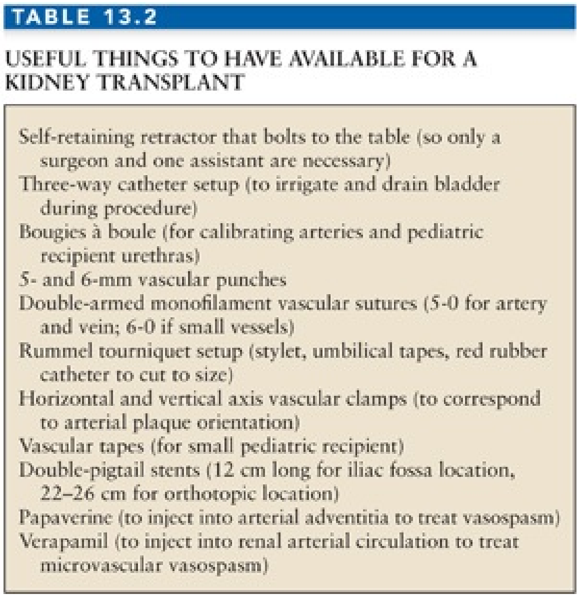

TABLE 13.2

USEFUL THINGS TO HAVE AVAILABLE FOR A KIDNEY TRANSPLANT

Self-retaining retractor that bolts to the table (so only a surgeon and one assistant are necessary)
Three-way catheter setup (to irrigate and drain bladder during procedure)
Bougies à boule (for calibrating arteries and pediatric recipient urethras)
5- and 6-mm vascular punches
Double-armed monofilament vascular sutures (5-0 for artery and vein; 6-0 if small vessels)
Rummel tourniquet setup (stylet, umbilical tapes, red rubber catheter to cut to size)
Horizontal and vertical axis vascular clamps (to correspond to arterial plaque orientation)
Vascular tapes (for small pediatric recipient)
Double-pigtail stents (12 cm long for iliac fossa location, 22–26 cm for orthotopic location)
Papaverine (to inject into arterial adventitia to treat vasospasm)
Verapamil (to inject into renal arterial circulation to treat microvascular vasospasm)

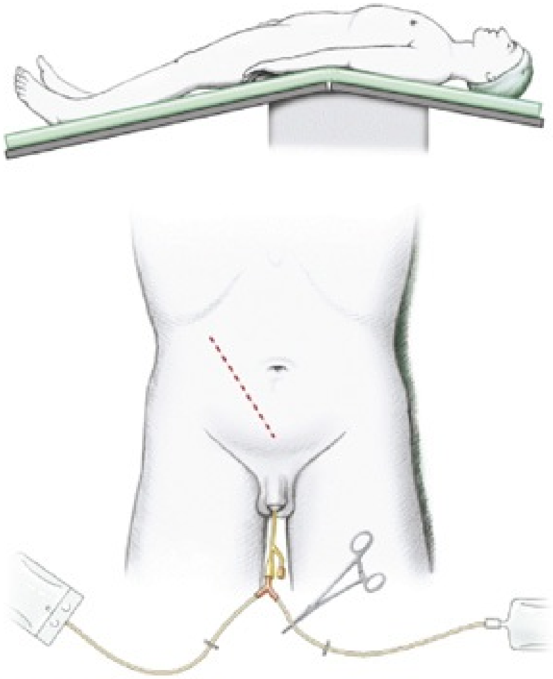

FIGURE 13.1 Patient position, incision site (*dotted line*), and three-way bladder infusion–drainage setup. (Reprinted with permission from Barry JM. Renal transplant recipient surgery. *BJU Int* 2007;99:701–717. Copyright © 2007, John Wiley and Sons.)

Incision and Iliac Fossa Dissection

A Gibson or Rutherford Morison incision from pubic notch toward the costal margin where it intersects the anterior axillary line is common. The anterior rectus sheath is incised, and the underlying rectus muscle is preserved; it will be retracted medially. The quality of the deep fascia and muscles can be judged during the incision, and a decision made about the type of suture material and whether an interrupted or running closure of the deep wound will be done.

After the inferior epigastric vessels are divided between ligatures, an index finger can be used to develop the plane between the partially filled bladder and the iliac vessels. If the kidney transplant has a separate lower pole artery, the inferior epigastric artery is left long in case it is needed to revascularize the inferior renal segment (Fig. 13.2).

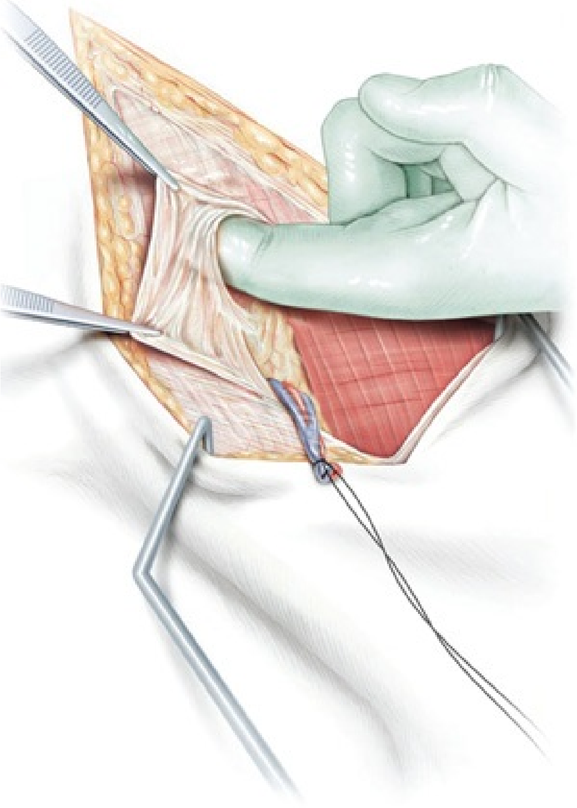

FIGURE 13.2 Development of extraperitoneal space after ligation and division of inferior epigastric vessels. (Reprinted with permission from Barry JM. Renal transplant recipient surgery. *BJU Int* 2007;99:701–717. Copyright © 2007, John Wiley and Sons.)

Rotating the finger upward between the transversalis fascia and the spermatic cord or round ligament will allow the development of the extraperitoneal space. The peritoneal edge is commonly adherent to the lateral edge of the posterior rectus sheath. In a woman, the round ligament is divided between ligatures; in a man, the spermatic cord is preserved and retracted medially. The iliac fossa is developed. Insertion of the first two fingers will identify a "ligament" that attempts to hold the peritoneum in the iliac fossa. Cut this and develop the space. Be careful not to damage the genitofemoral or ilioinguinal nerves. The ureter will naturally cling to the peritoneum. Continue to develop the extraperitoneal space until the index finger of the dissecting hand rests on the sacral promontory just above and medial to the bifurcation of the common iliac artery. Attach the post of the self-retaining retractor to the table, attach the retractor ring, and place the first of the padded retractor blades just medial to the sacral promontory. Place the rest of the retractor blades; it usually takes a total of five. Make certain that a retractor blade does not rest on the psoas muscle and compress the femoral nerve. If the bladder is full, have the anesthetist unclamp the drainage tube to give more space. Palpate the iliac arteries to determine where and what type of vascular clamps can be safely applied and the probable site of the renal artery anastomosis. Iliac arteriosclerosis commonly starts posteriorly at the takeoff of the internal iliac artery.

Dissect the iliac arteries (Fig. 13.3). Watch out for the genitofemoral nerve, which sometimes crosses the external iliac artery, is mistaken for a lymphatic, and divided between ligatures. Lymphatics are best ligated and divided. Clips are sometimes dislodged with the suction device later in the case. If the internal iliac artery has been selected for revascularization of the kidney, dissect it and the common iliac artery so that vascular clamps will be placed on the common and external iliac arteries and not the base of the internal iliac artery. This is to prevent vascular clamp injury to the internal iliac artery. Dissect the external and common iliac arteries. Division of the gluteal and internal iliac veins will allow the external iliac vein to be retracted anteriorly with Rummel tourniquets. This will permit the lateral venous suture line to be easily done from outside the vessels because when the iliac vein is deep and immobile, the lateral side of the anastomosis sometimes has to be done from inside the lumen, and this may leave a ridge and contribute to renal vein thrombosis.

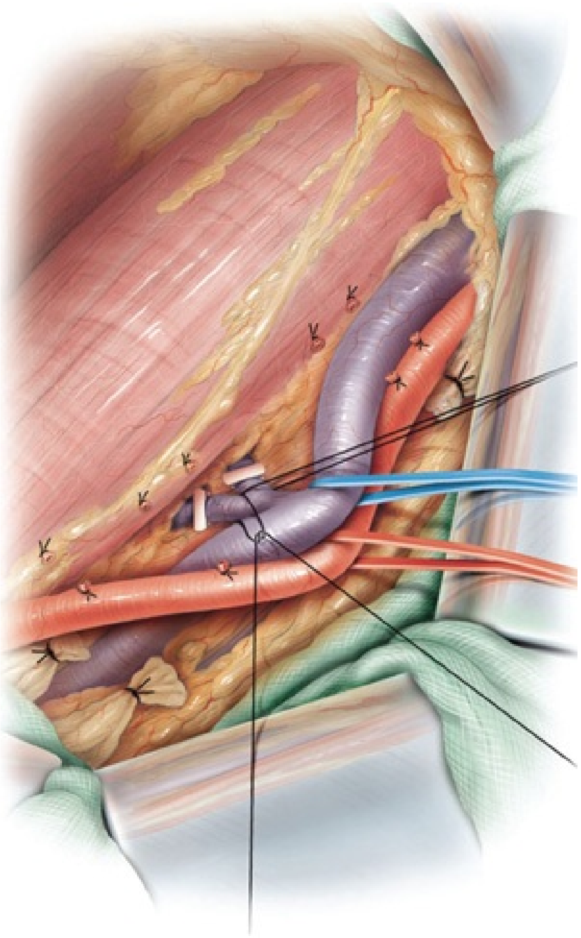

FIGURE 13.3 Dissection of iliac vessels and mobilization of external and common iliac veins. (Reprinted with permission from Barry JM. Renal transplant recipient surgery. *BJU Int* 2007;99:701–717. Copyright © 2007, John Wiley and Sons.)

If the kidney graft has not been prepared at the back table, do it now. If the kidney is from a living donor, it will be without an aortic patch, and the renal artery is commonly spatulated. If there are multiple renal arteries, and they are close together, they are usually joined together to make a common lumen (Fig. 13.4). A deceased donor kidney usually has its renal artery or arteries on an aortic patch, and the patch is used for the arterial anastomosis. If there are two separate veins of equal size in a living donor kidney, they are often joined, pair-of-pants fashion, to make a common lumen. If one is smaller than the other, it can be safely ligated. The right deceased donor kidney usually has the inferior vena cava (IVC) attached to it. It can be reconfigured in several different ways to extend the length of the short right renal vein (Fig. 13.5).

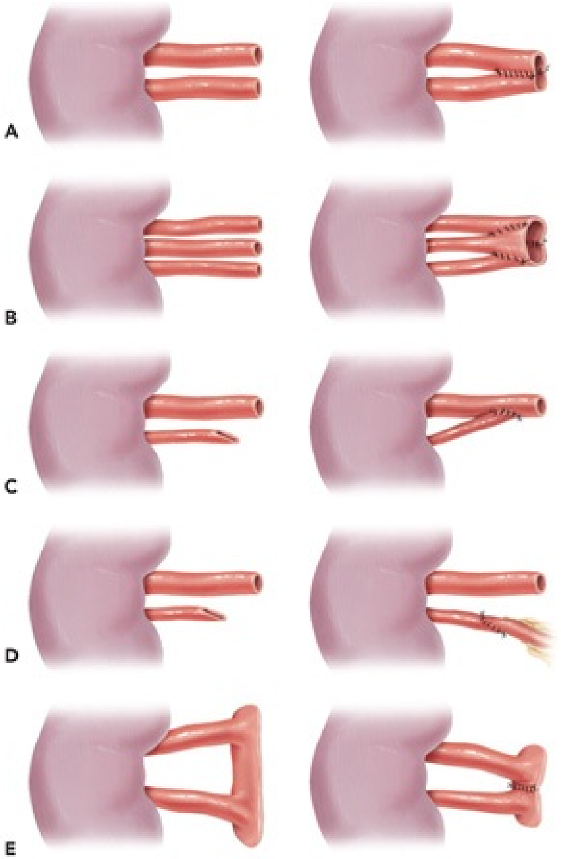

FIGURE 13.4 Options for renal artery reconstruction. (A) shows a "pair-of-pants" arterioplasty with two arteries. (B) shows the same concept with three arteries. (C) shows anastomosis of a lower pole artery to the main renal artery. (D) uses the recipient's inferior epigastric artery. (E) shows segmental aortectomy technique to make the aortic patch smaller in a deceased donor kidney transplant. (Reprinted with permission from Barry JM. Renal transplant recipient surgery. FIGURE 13.5 Three simple methods to lengthen a short right renal vein in a kidney from deceased donor.

Kidney Graft Position and Vascular Anastomoses

Place the kidney into the wound to determine the best fit and to select the sites of the arterial and venous anastomoses (Fig. 13.6). Remove the kidney and replace it in the cold slush–filled pan.

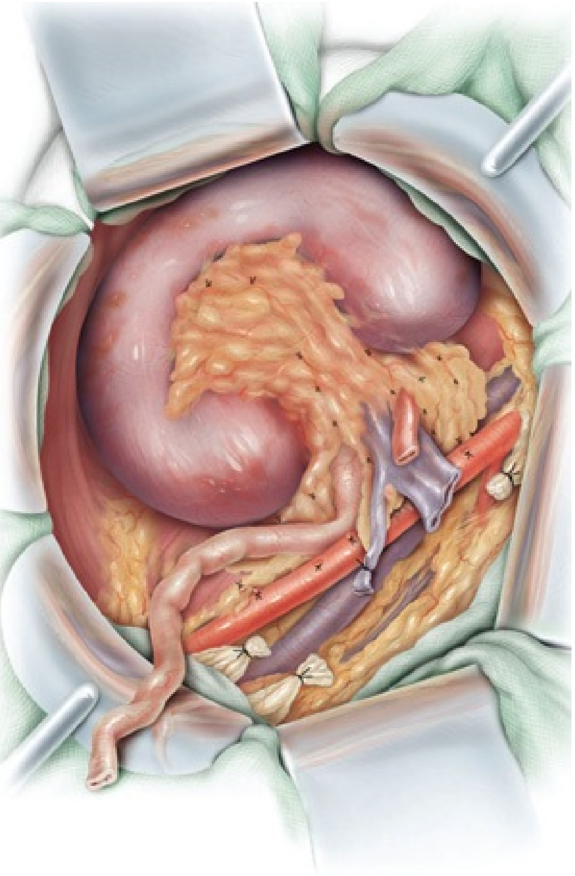

FIGURE 13.6 Placement of kidney transplant into wound to select recipient artery and vein for revascularization. (Reprinted with permission from Barry JM. Renal transplant recipient surgery. *BJU Int* 2007;99:701–717. Copyright © 2007, John Wiley and Sons.)

Check with the anesthetist and determine the status of the administration of the immunosuppressants. Ask for the heparin to be administered. A minute later, apply the arterial clamps. If there is a plaque in a vertical or lateral plane, use a vascular clamp with jaws that correspond to that plane. This is to reduce the risk of a plaque fracture and dissection. It seems preferable to do the arterial anastomosis first because it is the smaller of the two vascular anastomoses and the kidney is relatively mobile while it is being done. (If the venous anastomosis is done first, the kidney becomes fixed in position, the lateral half of the arterial anastomosis sometimes has to be done from inside the vessels, and a ridge from the arterial suture line ridge is more likely to result.) If the common iliac artery is the target, vascular clamps are placed in the common, external and internal iliac arteries, especially if the common iliac artery is relatively short. If the external iliac artery is the site, the clamps can be placed wherever it results in enough room to do the anastomosis. When the kidney is without an aortic patch, and there is to be an end-to-side anastomosis, make a 5- to 6-mm incision in the target artery with a no. 11 blade and enlarge the arteriotomy with a 5- or 6-mm punch; punch size will depend on the diameter of the donor artery. An aortic patch is common when the kidney is from a deceased donor. In such a case, it is not necessary to use a vascular punch in the recipient artery because the renal artery ostium in the donor aortic patch will hold the incised recipient artery open in the event of hypotension. If the internal iliac artery is to be used, place the vascular clamps in the external and common iliac arteries, ligate the internal iliac artery distally, divide it, spatulate it in its anterior surface, and flush it with heparinized saline. If there is a plaque, do an endarterectomy, release the common iliac vascular clamp to flush the lumen, reapply the clamp, and reflush the internal iliac artery with heparinized saline.

Wrap the kidney in a cold sponge or place it in a surgical glove, cut out one of the fingers, pull the vessels through the hole, and put some ice chips in the glove. Place the kidney in the wound.

Do the arterial anastomosis using the quadrant technique (Fig. 13.7). An experienced surgeon will sometimes use a single suture and tie it once at the completion of the anastomosis. At the start of the first anastomosis, ask the anesthetist to start the mannitol infusion.

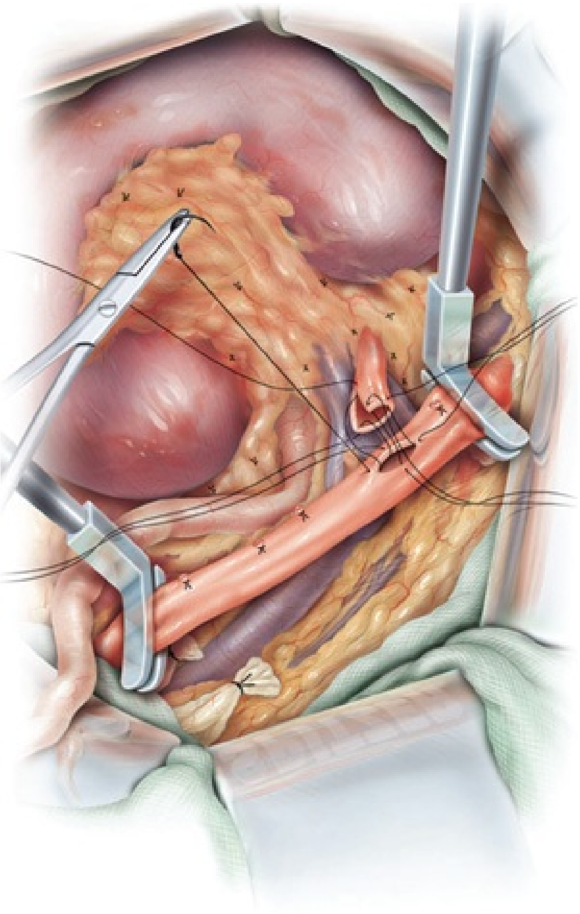

FIGURE 13.7 Renal artery anastomosis after 6-mm vascular punch arteriotomy. Quadrant technique is illustrated. (Reprinted with permission from Barry JM. Renal transplant recipient surgery. *BJU Int* 2007;99:701–717. Copyright © 2007, John Wiley and Sons.)

After the arterial anastomosis is finished, lay the kidney on its side and see where the venous anastomosis should be. Tighten the Rummel tourniquets, incise the vein, and place double-armed vascular sutures in either end of the venotomy and half-length sutures at the halfway points on either side such that the needles are on the inside (Fig. 13.8). Place the previously placed stay sutures inside-out in the renal vein and do the anastomosis, first one side and then the other. When the venous anastomosis is almost done, ask the anesthetist to administer the furosemide.

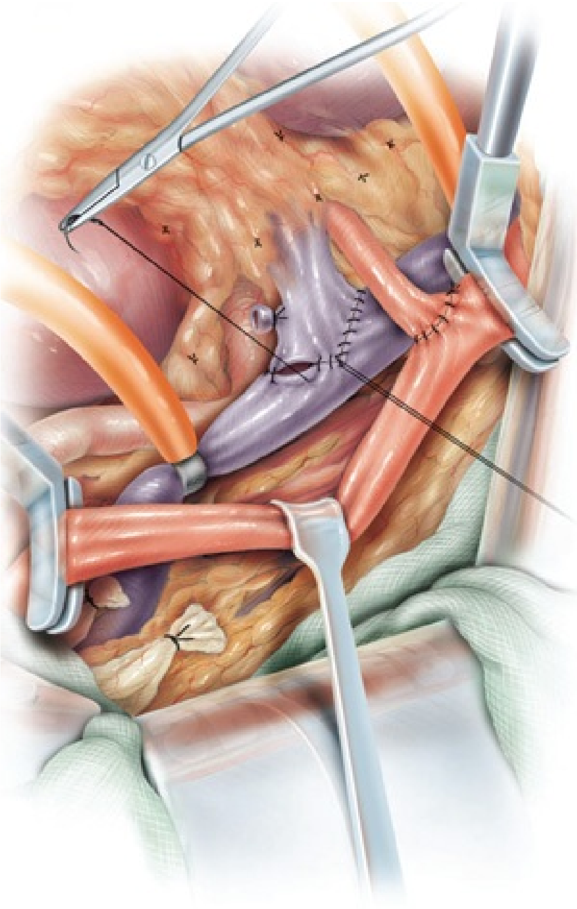

FIGURE 13.8 Renal vein anastomosis to junction of external and common iliac veins. (Reprinted with permission from Barry JM. Renal transplant recipient surgery. *BJU Int* 2007;99:701–717. Copyright © 2007, John Wiley and Sons.)

Remove the vascular tapes and clamps in the following order: proximal vein, distal artery, proximal artery, and distal vein. Put a dry sponge over both anastomoses and let the suture lines adjust. Take a peek after a minute or so and, if necessary, develop a plan for active bleeders. Renal perfusion can be increased by temporarily occluding the external iliac artery distal to the anastomosis. Vasospasm can be treated with the injection of papaverine into the adventitia of the renal artery. If renal microperfusion is of concern, verapamil can be injected into the lumen of the renal artery. When the heparin wears off and the bleeding is controlled, it is time to do the urinary tract reconstruction.

Urinary Tract Reconstruction

Urinary tract reconstruction is usually by extravesical ureteroneocystostomy (Figs. 13.9 to 13.11) (1,2), preferably with a submucosal tunnel to prevent reflux pyelonephritis in the event of a lower urinary tract infection. With either a parallel- or single-incision bladder technique, it is important to anchor the toe of the transplant ureter to the full thickness of the bladder to prevent sliding of the ureter in the submucosal tunnel and loss of the antireflux mechanism. Double ureters are made into one with the "pair-of-pants" technique, the same as for joining two arteries together. Use of a double-pigtail stent, or stents in the case of two ureters, is a matter of surgeon preference. Most agree that a stent will result in a lower incidence of urinary leakage or obstruction (3), but at the risks of increased urinary infection and voiding dysfunction, the latter because of bladder irritation from the distal curl of the stent. A 12 cm × 5Fr is commonly used. The integrity of the ureteroneocystostomy can be checked by filling the bladder through the three-way catheter system and looking for a leak.

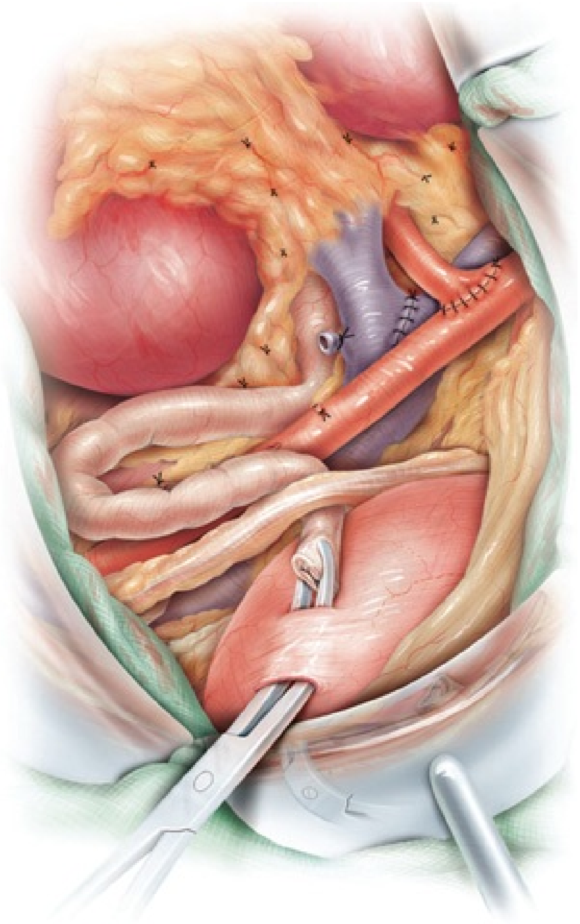

FIGURE 13.9 Completed renal revascularization. The kidney transplant ureter is brought under the spermatic cord and through the submucosal tunnel. (Reprinted with permission from Barry JM. Renal transplant recipient surgery. *BJU Int* 2007;99:701–717. Copyright © 2007, John Wiley and Sons.)

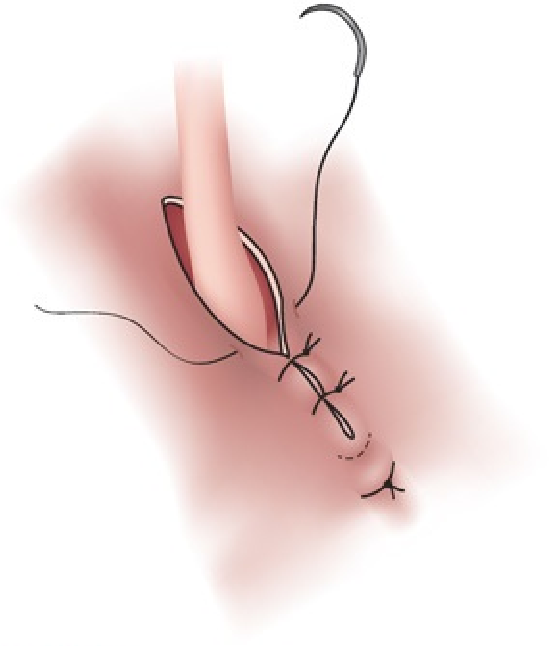

FIGURE 13.11 Single incision extravesical ureteroneocystostomy with full-thickness toe stitch.

The common alternate methods of urinary tract reconstruction are anastomosis of the transplant ureter to the ipsilateral native ureter and anastomosis of the transplant renal pelvis to the native ureter; both of which are usually done around a double-pigtail ureteral stent. The posterior suture line is completed first, the stent passed, and the anterior suture line is completed. Position of the distal curl can be confirmed to be in the bladder by having the anesthetist clamp the bladder catheter's drainage tube and fill the bladder through the three-way system. The recipient ureter need only be longitudinally incised, not ligated and transected. This prevents hydronephrosis of the native kidney if it still makes urine and preserves proximal native ureteral blood supply for the reconstruction.

Anastomosis of the kidney transplant ureter to an intestinal conduit is facilitated by passing a Foley catheter with the tip cut off into the base of the conduit and palpating the balloon through the intestinal wall (Fig. 13.12) (4). An enterotomy is made over the tip of the catheter, a guide wire passed through the enterotomy into the spatulated ureter. A double-pigtail stent is passed over the wire, and the wire is withdrawn to leave curls in the renal pelvis and the conduit. The catheter can be connected to drainage or removed. If the distal curl is left inside the conduit, the stent is less likely to be accidentally removed when the urostomy bag is changed.

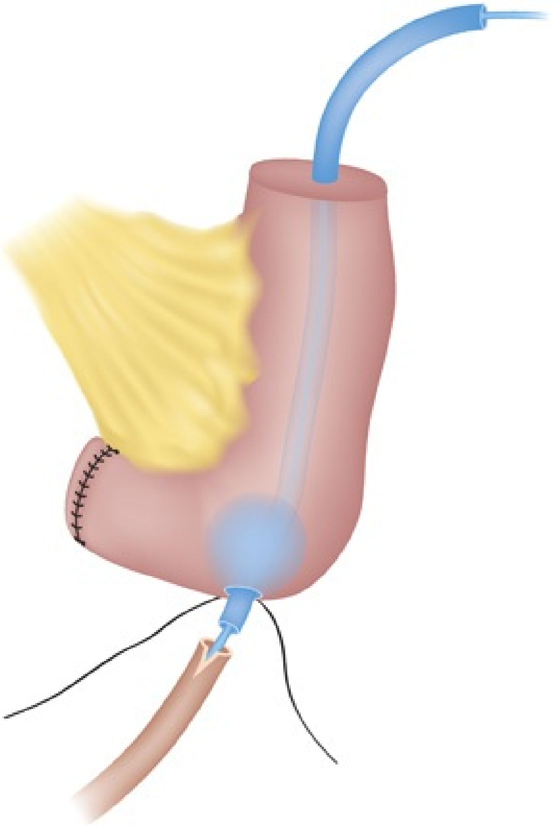

FIGURE 13.12 Urinary tract reconstruction into intestinal segment or pouch. A double-pigtail stent is usually inserted over the wire.

Wound Closure

Different opinions about wound closure and drainage are common. It is usually better to remove a drain than wish you had put one in. If used, a suction drain is placed in the wound, tip by the bladder, midportion just anterior to vascular anastomoses, and the rest curled up over the upper pole of the kidney transplant.

Two 36 inches 0 or no. 1 polyglyconate or polydioxanone running sutures, the first in the transversus and internal oblique muscles and the second in the anterior rectus sheath and the external oblique, will provide an adequate closure for most patients. If the patient is thin, bury the knots. If the deep fascia and muscle are of lesser quality, a wound closure with interrupted sutures with one of the same materials is reasonable. A far-far, near-near, figure-of-eight stitch tied with three knots: two surgeon's knots and a simple knot, all tied flat, one on the other, will not slip. If the patient is obese, a second drain under Scarpa fascia will drain a potential seroma. Scarpa fascia is closed with a running, 3-0 absorbable suture, and the skin is closed with a running subcuticular absorbable suture. This eliminates the need for skin suture or clip removal and is more comfortable for the patient.

Times of bladder catheter, drain and stent removal vary among surgeons. Usually, the bladder catheter can be removed on postoperative day (POD) 3 if the urinary output is less than 3 L per day, or on POD 5 if it is more than that. If there is concern about the possibility of a urine leak, the catheter is left indwelling and a cystogram done to confirm integrity of the urinary tract before catheter removal. If the recipient is a man older than 50 years, it is reasonable to give him a single oral dose of a selective alpha blocker at the time of catheter removal to prevent urinary retention, and it is always a good idea to do postvoid residual urine determinations by ultrasound for the first two or three voids. If a stent was placed, it is usually removed within 6 weeks of transplantation. If it had been attached to the bladder catheter at the time of ureteroneocystostomy, it will come out when that catheter is removed. The drain(s) is (are) usually removed when the 24-hour drainage is <50 mL. If the peritoneum had been entered during the case, a more liberal criterion is used.

Less Frequently Used Kidney Transplant Procedures

Orthotopic Kidney Transplantation

This is usually done when both iliac fossas are unsuitable because of prior surgeries or vascular disease. The usual target vessels in the recipient are the splenic artery and the left renal vein (Fig. 13.13) (5). The left native kidney and splenic artery can be approached through a vertical midline abdominal incision, a left Rutherford Morison incision that has been extended to the left costal margin, or a flank incision. The splenic artery is dissected to the hilum of the spleen, a vascular clamp is applied, and the splenic artery is ligated distally and divided. A splenectomy is not necessary because the short gastric arteries will supply that organ. A left nephrectomy is done after the renal artery has been ligated, and a vascular clamp has been placed on the renal vein. The adrenal and gonadal veins are usually divided between ligatures. The native ureter is divided close to the ureteropelvic junction, and the kidney is removed. The kidney transplant is placed in the wound to determine where it will best fit and how the hilar structures are to be oriented for reconstruction. The renal artery and the splenic artery are spatulated, flushed with heparinized saline, and an end-to-end anastomosis is done. The renal veins are anastomosed to one another, and a ureteroureterostomy or ureteropyelostomy, as described earlier, is done over a stent. Stent placement in the bladder can be confirmed by having the anesthetist clamp the bladder drainage tube and fill the bladder while the surgeon checks for reflux out the holes in the proximal stent curl. Stent length can be estimated from the patient’s height: 22 cm for patients <5 ft 10 inches, 24 cm for patients 5 ft 10 inches to 6 ft 4 inches, and 26 cm for patients >6 ft 4 inches (6).

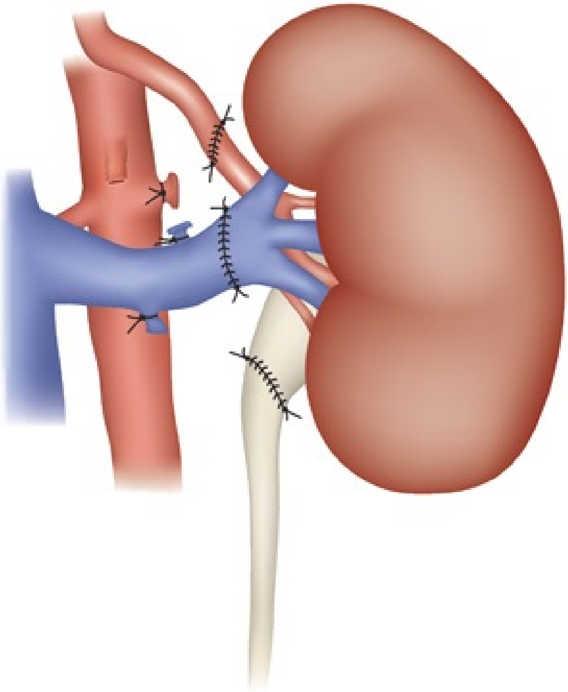

FIGURE 13.13 Orthotopic kidney transplant with splenic artery to renal artery and renal vein to renal vein anastomoses. Urinary tract reconstruction is by stented pyeloureterostomy or ureteroureterostomy.

En Bloc Kidney Transplantation

When two small kidneys from a deceased pediatric donor are transplanted into an adult, an en bloc procedure is usually done (7). Most commonly, the cut cephalic ends of the donor aorta and IVC are closed, and the distal ends of the aorta and IVC are anastomosed to the sides of the external iliac artery and vein, respectively (Fig. 13.14). Other methods of revascularization are anastomosis of the proximal aorta to the internal iliac artery after closure of the distal aorta, longitudinal splitting of the aorta and anastomosis of the aortic patch to the external iliac artery, and interposition of the donor aorta after excision of a section of the recipient's external iliac artery. The ureters are implanted separately or joined together and implanted in a common submucosal tunnel. Ureteral stents are commonly used.

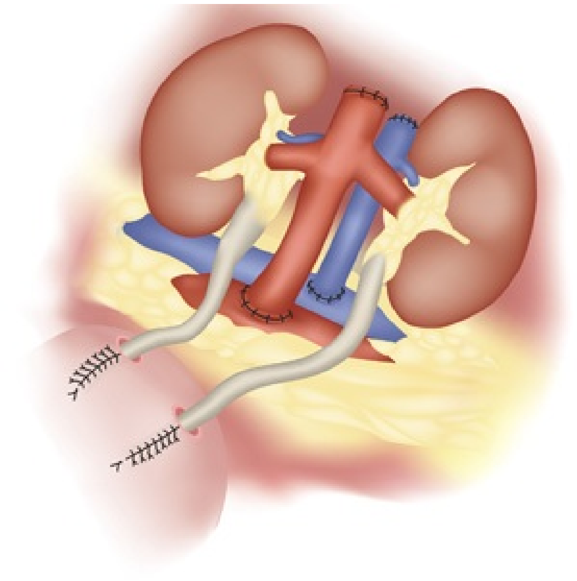

FIGURE 13.14 En bloc transplantation of pediatric kidneys onto the external iliac artery and vein.

Dual Kidney Transplantation

Deceased donor kidneys of poor quality that would prevent their transplantation as separate units are sometimes both transplanted into the same recipient. Each marginal kidney can be transplanted into each iliac fossa, or both can be transplanted, one cephalad to the other, into one iliac fossa and distal retroperitoneum (Fig. 13.15) (8,9). It is easier to do this on the right side.

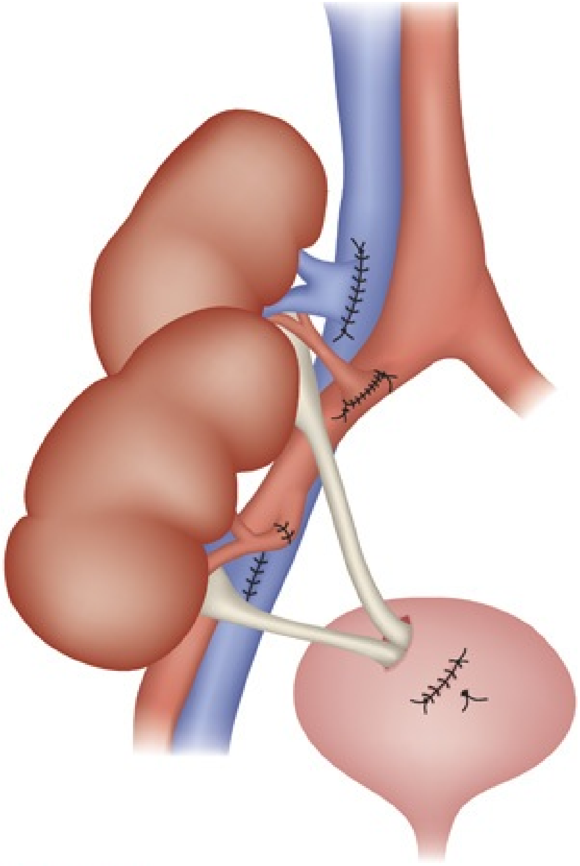

FIGURE 13.15 Dual transplantation of marginal deceased donor kidneys, one on top of the other. Illustrated vascular targets are the IVC and common iliac artery for the upper kidney and the internal iliac artery and external iliac vein for the lower one. The ureters have been joined so they can be implanted through a single submucosal tunnel.

SURGICAL TECHNIQUE IN SMALL CHILDREN

Adult kidneys are transplanted into small children (7). The urethra is calibrated with bougies, and the correctly sized Foley catheter is selected, inserted, and hooked to the three-way system, just as described for the adult recipient. The bladder is irrigated with the antibiotic solution. Placement of a central line, management of abdominal tubes, and skin preparation are the same as for the adult. If additional surgeries, such as a contralateral nephrectomy or bilateral nephrectomies are to be done under the same anesthetic, a vertical midline incision with a transperitoneal approach to the great vessels is usually done (Fig. 13.16). The IVC is exposed to the level of the renal veins, and both common iliac veins are dissected. The right common iliac vein may need to be completely exposed if the renal vein anastomosis will be long enough to require it and the IVC. The aorta, inferior mesenteric artery, and both common iliac arteries are exposed. The middle sacral and lumbar arteries are divided between ligatures. The recipient venous anastomotic target is isolated between Rummel tourniquets on the proximal IVC and common iliac veins, and the aorta, inferior mesenteric artery, and common iliac arteries are encircled with vascular tapes. Some surgeons prefer to use a vascular clamp on the proximal aorta. The previously prepared kidney is held up to drain the preservation solution, which contains high levels of potassium, and placed in the wound to select the sites for the venous and arterial revascularization. The usual targets are the IVC (and sometimes the right common iliac vein) and the aorta (and sometimes the right common iliac artery). Remove the kidney and, if necessary, shorten the renal artery and/or renal vein to assure a good fit without vessel kinks. The relatively large adult kidney has been drained of blood and preservation solution, and at the time of revascularization in a small child, it has to fill with blood from the child's circulatory system. This results in the acute blood loss of 50–100 mL into the kidney transplant. After tightening the clamps and/or tapes, use a 5- or 6-mm vascular punch on the aorta or common iliac artery, so that if hypotension ensues, the new renal artery ostium will not close and result in renal artery thrombosis. Irrigate the lumen with heparinized saline and do the arterial anastomosis as previously described. Tighten the Rummel tourniquets, incise the IVC and, if necessary, the right common iliac vein, irrigate the lumen, and do the venous anastomosis as described for the adult procedure (Fig. 13.17). Ask for the furosemide to be administered.

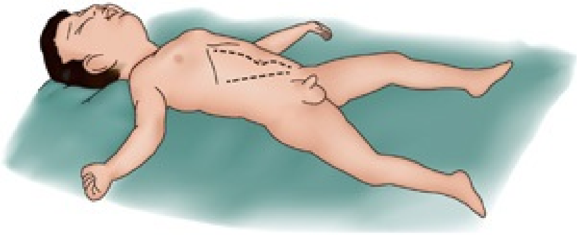

FIGURE 13.16 Incision options for transplantation of an adult kidney into a small child. The midline incision is usually chosen when other surgeries are to be undertaken under the same anesthetic.

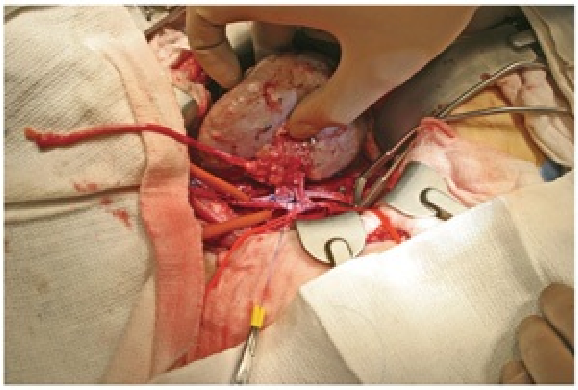

FIGURE 13.17 Revascularized adult kidney transplant in small child; viewed from the patient's left. The renal vein has been anastomosed to the IVC, and the renal artery to the distal aorta. Red vessel loops are around the common iliac arteries and the inferior mesenteric artery. Horizontally oriented vascular clamps are on the mid-aorta and IVC.

Do the ureteroneocystostomy with or without a stent. Place a soft suction drain and bring it out through a stab wound. Close the deep wound, usually with running sutures as described for the adult procedure, and close Scarpa fascia and the skin with fine, absorbable sutures. Some surgeons leave a window in the peritoneum to prevent the accumulation of perinephric lymph. If there is immediate function of the kidney transplant, many surgeons will remove the patient’s peritoneal dialysis catheter. An exception is for very small children in a transplant program with an aggressive fluid management protocol. The “third spacing” may result in significant ascites and respiratory compromise. Intermittent drainage of the ascites via the chronic peritoneal dialysis catheter can prevent the need for intubation and mechanically assisted respiration. The management of the tubes and drains is the same as for the adult recipient.

COMPLICATIONS

Table 13.3 describes how to deal with surgical problems that occur shortly after transplantation.

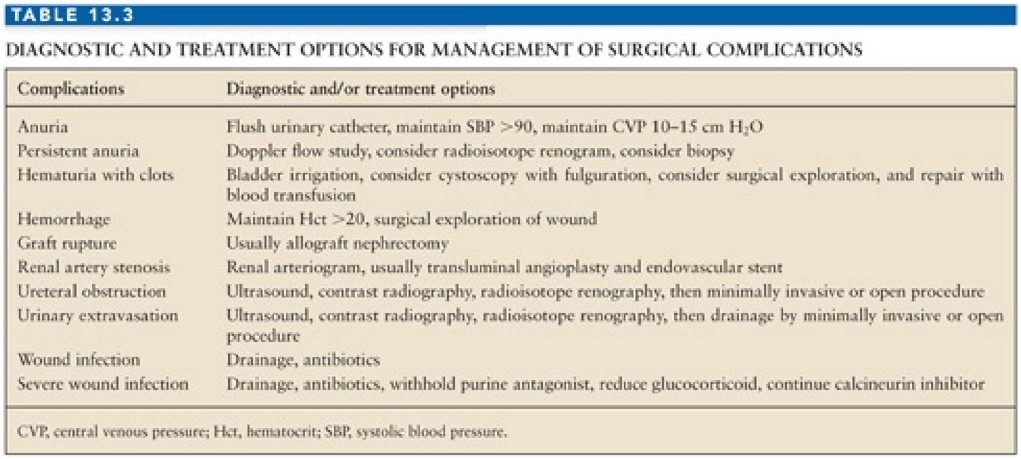

TABLE 13.3

DIAGNOSTIC AND TREATMENT OPTIONS FOR MANAGEMENT OF SURGICAL COMPLICATIONS

Complications	Diagnostic and/or treatment options
Anuria	Flush urinary catheter, maintain SBP >90, maintain CVP 10–15 cm H_2O
Persistent anuria	Doppler flow study, consider radioisotope renogram, consider biopsy
Hematuria with clots	Bladder irrigation, consider cystoscopy with fulguration, consider surgical exploration, and repair with blood transfusion
Hemorrhage	Maintain Hct >20, surgical exploration of wound
Graft rupture	Usually allograft nephrectomy
Renal artery stenosis	Renal arteriogram, usually transluminal angioplasty and endovascular stent
Ureteral obstruction	Ultrasound, contrast radiography, radioisotope renography, then minimally invasive or open procedure
Urinary extravasation	Ultrasound, contrast radiography, radioisotope renography, then drainage by minimally invasive or open procedure
Wound infection	Drainage, antibiotics
Severe wound infection	Drainage, antibiotics, withhold purine antagonist, reduce glucocorticoid, continue calcineurin inhibitor

CVP, central venous pressure; Hct, hematocrit; SBP, systolic blood pressure.

Later, when a kidney transplant recipient has a genitourinary problem, determine what diagnostic and treatment plan would be appropriate if the patient did not have the transplant and then modify it based on the location of the kidney transplant, immunosuppression, and an assessment about whether the proposed treatment plan would make the patient's remaining lifetime better or longer.

OUTCOMES

Ten-year graft survival after living donor kidney transplantation is 60%, and that after deceased donor kidney transplantation is 46% (10). The differences are due to histocompatibility between donor and recipient and kidney quality.

CHAPTER 14 URETERIC COMPLICATIONS FOLLOWING KIDNEY TRANSPLANTATION

H. ALBIN GRITSCH AND ERIC G. TREAT

Contemporary surgical techniques and improved medical management decreased ureteric complications following kidney transplantation from historical incidence rates of 12% to more conservative modern estimates around 5% (1–4). Albeit different centers and varying practices lead to fluctuating incidence rates seen in the literature, in today's clinical realm, ureteric complications still persist. Many of these complications if promptly diagnosed and managed can be resolved with minimal impact to the patient's long term outcome; however, sometimes they lead to significant morbidity, potential decrease in graft function and survival, and rarely mortality. In recent years, development of less invasive techniques and management strategies fortunately diminished the need for open surgical intervention; however, some cases are best managed with open operative repair.

DIAGNOSIS

In general, ureteric complications following transplantation present as ureteral obstruction, urinary leaks/fistulae, or ureteral reflux; however, the underlying etiologies and time of presentation vary greatly (Table 14.1). Timely identifying the cause of the complication will lead to successful treatment in most cases.

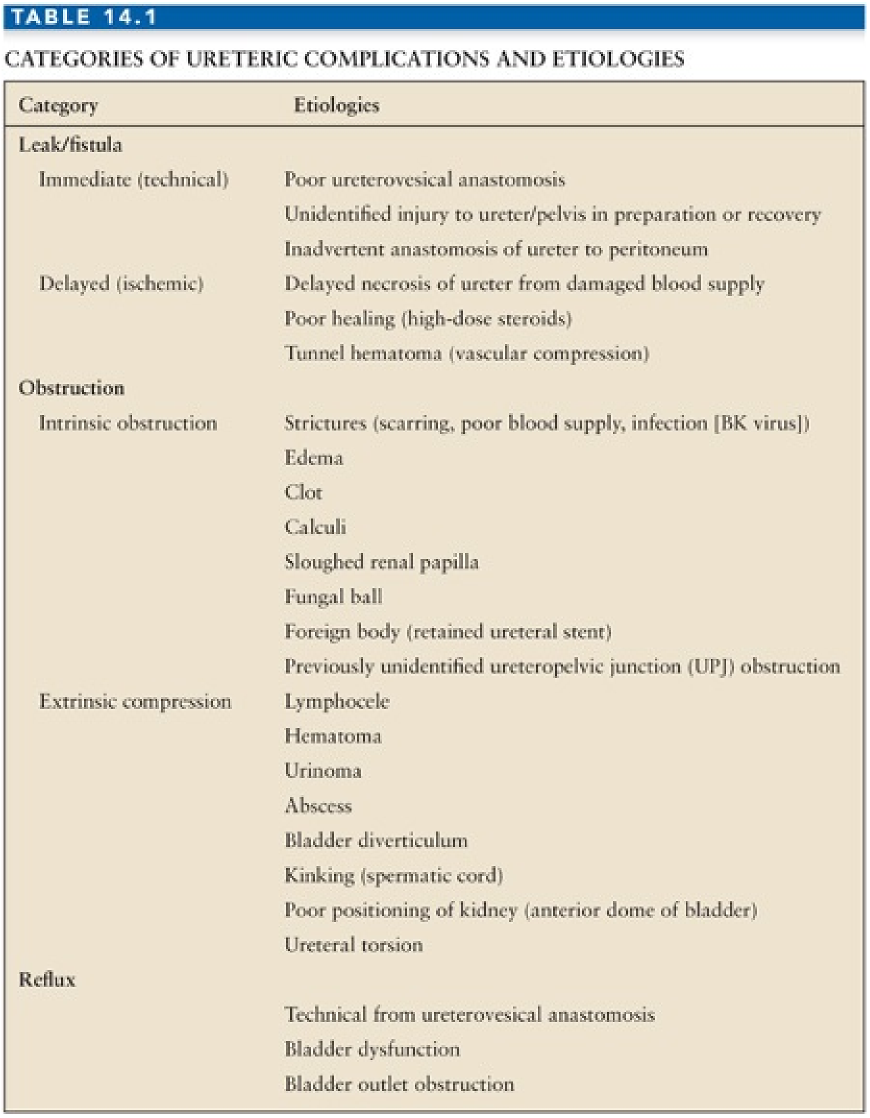

TABLE 14.1

CATEGORIES OF URETERIC COMPLICATIONS AND ETIOLOGIES

Category	Etiologies
Leak/fistula	
Immediate (technical)	Poor ureterovesical anastomosis
	Unidentified injury to ureter/pelvis in preparation or recovery
	Inadvertent anastomosis of ureter to peritoneum
Delayed (ischemic)	Delayed necrosis of ureter from damaged blood supply
	Poor healing (high-dose steroids)
	Tunnel hematoma (vascular compression)
Obstruction	
Intrinsic obstruction	Strictures (scarring, poor blood supply, infection [BK virus])
	Edema
	Clot
	Calculi
	Sloughed renal papilla
	Fungal ball
	Foreign body (retained ureteral stent)
	Previously unidentified ureteropelvic junction (UPJ) obstruction
Extrinsic compression	Lymphocele
	Hematoma
	Urinoma
	Abscess
	Bladder diverticulum
	Kinking (spermatic cord)
	Poor positioning of kidney (anterior dome of bladder)
	Ureteral torsion
Reflux	
	Technical from ureterovesical anastomosis
	Bladder dysfunction
	Bladder outlet obstruction

Ureteral Leak/Fistula

Urinary leaks generally present early after transplantation however can present after removal of a ureteral stent or later occasionally. Leaks are the most common ureteral complication occurring in up to 1% to 5% of transplants (4,5). Presenting signs and symptoms include urine leaking from wound, increased surgical drain output (fluid creatinine levels twofold serum creatinine levels indicates urine), decreased urine output (in patients anuric prior to transplantation), pelvic fluid collections, pain, or unexplained graft dysfunction. Suspicion of a urinary leak should be promptly evaluated. If the diagnosis is obvious, then further testing may be unnecessary. Imaging studies such as abdominal/transplant renal ultrasound or nuclear renogram may aid in the diagnosis. A renal scan demonstrating extravasation is the most sensitive imaging to differentiate a urine leak from other fluid collections such as lymphoceles or hematomas. Differentiating fluid collections as a urine leak from a lymphocele or hematoma is critical because their management is very different. Occasionally, fine needle aspiration and laboratory analysis of a fluid sample may be needed to confirm a urine leak. Voiding cystourethrogram or cystogram may help delineate bladder leaks however are limited in demonstrating leaks at the ureteroneocystostomy site where urine leaks most commonly occur following transplantation. Proximal leaks occur in the ureteropelvicalyceal system when there is concurrent obstruction or infarction. Leakage may also result from injury during recovery, transplantation, or renal biopsy. Bladder leaks are rare because contemporary surgical techniques almost exclusively perform extravesical ureteroneocystostomies. Of note, if a urine leak is detected in the first 4 days following transplant, the cause is most likely technical with the reimplantation. If a leak develops 5 to 10 days posttransplant, the cause is often necrosis from poor ureteral blood supply.

Ureteral Obstruction

Ureteral obstruction typically presents as graft dysfunction. This ureteral complication occurs in 1% to 3% of all transplants (4,5). Patients might develop signs and symptoms around the time of surgery or many years after transplantation. The onset can be sudden or gradual depending on the underlying etiologies (Table 1). Commonly, the onset is gradual and asymptomatic with steadily increasing serum creatinine levels prompting an ultrasound or computerized tomography scan demonstrating hydronephrosis. Pain is rare unless the obstruction is sudden. Again, prompt diagnosis is mandatory in order to undertake the appropriate management. Urinary retention and ureteral reflux must be excluded. A full bladder encountered on examination or imaging warrants decompression with a Foley catheter and careful assessment of postvoiding residuals and serum creatinine monitoring to exclude urinary retention. In some cases of ureteral obstruction, hydronephrosis is minimal. A diuretic nuclear renogram may be useful to reveal ureteral obstruction. When hydronephrosis is present, we prefer to proceed directly to immediate placement of a nephrostomy tube if obstruction is diagnosed. This provides the most definitive diagnosis and allows for relief of the obstruction in a timely manner. Antegrade nephrostogram can more accurately determine the location of obstruction.

Ureteral Reflux

Vesicoureteral reflux (VUR) of urine is common and seen in up to 79% of transplanted kidneys (6). Development of febrile urinary tract illness by reflux of infected urine into the allograft kidney eventually leads to scarring and potential graft loss particularly in pediatric patients (7,8). VUR can be clinically silent; however, worrisome presentation would be in the setting of allograft pyelonephritis (fever, chills, graft tenderness with or without dysfunction along with pyuria, and positive urine cultures). Diagnosis of VUR usually depends on identifying reflux on voiding cystourethrogram. In particular, underlying bladder and voiding dysfunction should be carefully evaluated and addressed. Treatment of any infection should be completed prior to any surgical reconstruction of the refluxing ureter.

INDICATIONS FOR SURGERY

The primary indication for operative management is renal allograft dysfunction caused by underlying anatomic pathology (obstruction, leak, reflux) amendable to surgical correction. Rejection, infection, or other nonanatomic causes of allograft dysfunction need to be carefully excluded and treated prior to definitive operative management of an identified physical abnormality. Rapid placement of a percutaneous nephrostomy tube is indicated to relieve obstruction until more definitive treatment can be undertaken.

ALTERNATIVE THERAPY

Recent technologic advances and improved endourologic techniques make allowance for less invasive approaches to ureteral complications (9). Placement of percutaneous nephrostomy tubes allows for quick diagnosis and temporary treatment of ureteral obstruction or diversion of a significant urinary leak. Maximal diversion with nephrostomy drainage, ureteral stenting, and Foley catheter drainage reportedly resolves urinary leaks in up to 63% of cases (10). For ureteral obstruction from strictures antegrade or retrograde balloon dilation or incision may resolve the blockage. Incisional techniques (even after failed balloon dilation) have reported greater success rates, up to 79% (10). Long-term success when strictures are longer than 1 cm is unlikely. In rare circumstances, prolonged or permanent ureteral stenting or nephrostomy drainage may suffice if open operative repair is inappropriate or contraindicated. For ureteral reflux, endoscopic injection of biomaterial (copolymer of dextranomer and hyaluronic acid) or Deflux (Salix Pharmceuticals, Inc. Raleigh, NC) has shown durable successful outcomes (11). Endourologic interventions prove most successful in carefully selected patients; however, open surgical interventions may be required for definitive treatment.

SURGICAL TECHNIQUE

General Considerations

A variety of surgical procedures exist to address complications of ureteral obstruction, leak, or reflux after kidney transplantation. The choice of which procedure to use depends on the nature of the complication and presentation. In our experience, for distal ureteral obstruction, caused by stricture or tight ureterovesical anastomosis, ureterovesical reanastomosis or “redo” commonly suffices to restore normal continuity of the urinary system. Alternatives include end-to-side or end-to-end ipsilateral native to allograft ureteroureterostomy, ureteropyelostomy, and vesicopyelostomy. These may be necessary if a long stricture or poor ureteral blood supply is encountered. With careful preoperative imaging and planning, the required technique can be anticipated; however, intraoperative findings may call for an alternative approach. Adjunct procedures such as mobilization of the bladder, psoas hitch, or Boari flap techniques may also aid in making a tension-free anastomosis. In our experience, for distal ureteral leaks and fistula, the majority of which emanate from the ureterovesical anastomosis, ureterovesical reanastomosis typically suffices to resolve the leak. For ureteral reflux, a redo anastomosis with attention to a nonrefluxing reimplant resolves most reflux. Again, the aforementioned alternative approaches may aid to create the optimal repair requiring intraoperative flexibility. In general, a well-vascularized, tension-free anastomosis must be created to avoid potential further complications or failure of the repair. A description of all the aforementioned techniques is beyond the scope of this chapter and can be found in other sections of the book, so herein, the redo ureterovesical reanastomosis and ipsilateral ureteroureterostomy will be described in detail.

The patient’s medical and urologic history, previous operations, and anatomy need to be clearly understood with particular attention to bladder capacity, compliance, function, or presence of any voiding dysfunction. Furthermore, native kidney or ureteral pathology needs to be considered especially if use of the native ureter is anticipated. Review all available imaging prior to the procedure, and sometimes an operative imaging study, such as a cystogram or retrograde pyelogram, or rarely cystoscopy with or without ureteroscopy may be warranted. A thorough knowledge of the prior transplant surgery and operative techniques will aid in the surgical repair. Consider the laterality of the allograft (right versus left) and positioning in the recipients pelvis, whether or not the renal pelvis lies anterior or posterior to the renal vessels. Understand the type of vascular anastomosis such as end-to-side or end-to-end and to which target vessels; common, external, or internal iliac; occasionally aorta; or vena cava and whether or not patch grafts, donor vena cava, or other vascular reconstructions were employed. Importantly, knowledge of the type of ureterovesical anastomosis used, such as extra- or intravesical, Lich-Gregoir, or Politano-Leadbetter, will also facilitate and guide dissection and repair and maximize the likelihood of a successful outcome. Prior to operating, assessment of graft function and treatment of rejection or infection need to be stabilized before undertaking operative repair.

Patient Preparation and Exposure

After obtaining surgical consent, the patient is brought back to the operating suite, placed in a supine position on the operating table, given preoperative antibiotic prophylaxis, and has sequential compression devices placed on the lower extremities to prevent deep vein thrombosis. Blood for transfusion should be available. General anesthesia is administered. A urethral catheter is placed. For adults, usually a 16Fr latex catheter suffices. We place a Y connector to the catheter and use a bacitracin saline irrigation solution hanging from an intravenous pole and clamp the urinary drainage bag tube to allow the bladder to fill with gravity. After about 150 mL (approximating the bladder capacity) of irrigation into the bladder, we clamp the irrigation tubing and allow the solution to sit in the bladder for a few minutes. Then by releasing the clamps on the drainage bag, the bladder empties. We keep this setup to allow us to fill or drain the bladder during the procedure when needed. An alternative would be to place the urethral catheter once the sterile field is established and manually irrigate during the case or place a three-way catheter with a similar irrigation setup. The lower abdomen and pubic hair is removed with clippers, and the patient is then prepped and draped.

The prior transplant incision typically suffices to gain surgical access to the transplanted kidney, ureter, and native bladder. If access to the contralateral ureter or extensive mobilization and dissection is anticipated, a midline incision is another option. If a prior midline incision was used (e.g., a kidney-pancreas transplant, or pediatric transplant), the prior midline incision can be used in most cases; however, a new ipsilateral Gibson incision could alternatively be used. Expect a dense fibrosis and inflammatory response 3 weeks after the initial transplant operation. This can last for months. The desmoplastic reaction can make the dissection quite difficult, and if possible, reoperation should be pursued sooner rather than delayed to avoid this inflamed, dense, and tricky dissection. Reoperation soon (within a few days) after the initial transplant requires little redissection in order to establish exposure.

Once the skin is incised, the subcutaneous fat and fascial layers are opened. Generally, through a Gibson incision, the external and internal oblique fascia are divided in an oblique fashion moving laterally from caudal to cranial. If recently transplanted, simply removing the closing sutures suffices to reopen the fascial layers. The allograft kidney lies directly posterior to the fascial layer. The rectus muscle is retracted medially and left intact. Identify the spermatic cord or round ligament and inferior epigastric vessels (often divided in the initial transplant procedure). The peritoneum rests medial to the allograft and should be carefully swept away medial and cranially. We routinely place a Bookwalter retractor to aid in maintaining exposure. Sometimes, a self-retaining retractor or Weitlaner retractor will work. In many cases where only a reimplantation is anticipated and the allograft has been functioning well, we avoid mobilizing the graft and only focus on exposing the ureter and bladder. Minimizing dissection helps prevent unnecessary injury or tissue manipulation. If a hematoma is located lateral to the bladder, the clots should be carefully swept toward the bladder to avoid injury to the ureterovesical anastomosis. However, if needed, the iliac vessels and allograft can be completely mobilized and freed. Figure 14.1 illustrates a left renal allograft placed in the right iliac fossa and the relationship of the recipient's iliac vessels, ureter, and the allograft vessels and ureter.

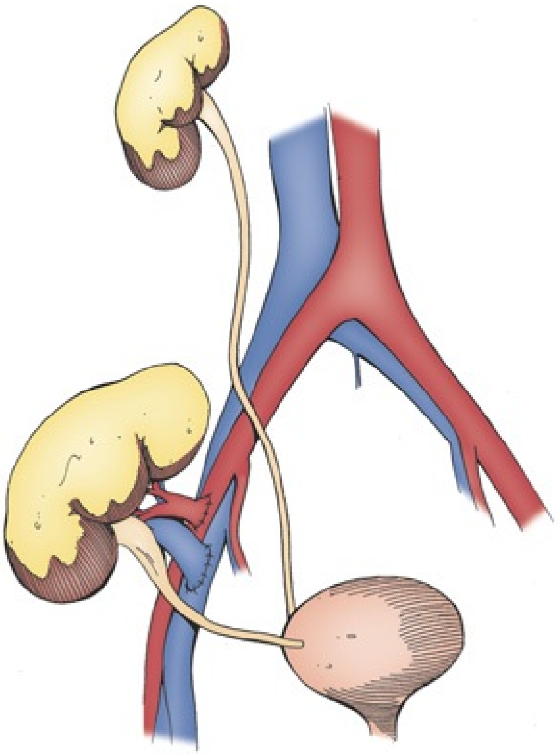

FIGURE 14.1 Relationship of the transplanted kidney and its vasculature to the recipient's iliac vessels and ureter.

Ureterovesical Reanastomosis (Redo) Procedure

Using the pubic symphysis as a bony landmark, the anterior bladder can be identified. Filling the bladder with irrigation solution can help delineate surrounding anatomic structures, and if there is a leak at the original ureterovesical anastomosis, the irrigation can demonstrate the leak and focus the surgical dissection. Adding an ampule of indigo carmine to the irrigation is sometimes helpful to distinguish the leak from either lymphatic or peritoneal fluid. If the complication being addressed is a stricture or ureteral reflux leaking irrigation will not be seen, however, distension of the bladder helps to show where the transplant ureter enters the bladder. Usually, the transplant ureter is found on the anterolateral aspect of the bladder. We prefer to locate the ureter near the bladder rather than the allograft. Because the transplant ureter usually crosses the external iliac vessels below the renal vessels, one should take care to avoid these structures when identifying the ureter. Exact visualization of the renal or iliac vessels is difficult, and many times, one is dissecting based on the expected, not visualized, location of these structures. A Doppler probe and placing a stent within the transplant ureter can facilitate the dissection. Once the ureter is identified, it is carefully dissected free and mobilized proximally with great care to not disturb the blood supply. The ureter should be disconnected from the bladder with effort to maintain as much viable, healthy ureteral length as possible. Sharp transection near the prior anastomosis is preferred. Vascular sutures and clamps should be readily available. A small vascular injury can usually be closed with a simple nonabsorbable monofilament suture. Closure of the distal stump or defect is sometimes not necessary; however, if needed, preferably an absorbable, monofilament suture, 4-0 or 5-0 polydioxanone (PDS, Ethicon, Somerville, New Jersey) may be placed in the detrusor muscle and perivesical fat to seal the bladder leak. The proximal allograft ureter should be inspected for viable tissue. If urothelial mucosal bleeding is observed, this usually indicates viable tissue. If uncertain, a Wood's lamp along with administering an ampule of fluorescein may be used to inspect the tissue for a healthy blood supply.

With the bladder slightly distended, assessment of a new ureterovesical anastomotic site can be made, usually more superior and slightly medial from the prior site with little to no tension. If there is not enough length of the allograft ureter to provide a tension-free anastomosis, several options may provide an adequate solution. Often, mobilization of the bladder on the contralateral side aids enough to allow a reanastomosis. Addition of a psoas hitch can help stabilize the reanastomosis. This might require more mobilization of the allograft to ensure exposure for good psoas fascial suture placement. We prefer two figure-of-eight sutures with 2-0 PDS for the psoas hitch, placed with care in the tendon to avoid entrapment of femoral, ilioinguinal, or genitofemoral nerves coursing along the psoas muscle. Again, use of adjunct procedures or more aggressive techniques (Boari flaps, vesicopyelostomy, bowel interpositions) are seldom needed. End-to-side or end-to-end ipsilateral allograft to native ureteroureterostomy (discussed later), if necessary, can reasonably provide an alternative repair at this point if a tension-free anastomosis cannot be achieved.

Once a location on the bladder is determined and adequate, viable allograft ureter is obtained, we perform a reanastomosis using the Lich-Gregoir technique. With the bladder distended, the perivesical fat is divided by electrocautery in an oblique angle with the proximal aspect being more cranial and lateral. A ratio of 4:1 or 5:1 (tunnel length:ureteral diameter) determines the length of the tunnel, which often amounts to 3 or 4 cm. The detrusor is likewise carefully divided using electrocautery (decreased energy setting to avoid accidental mucosal puncture). The bladder mucosa tends to expand and has a "robin's egg" appearance once the muscle is divided. Detrusor muscle flaps are carefully made, by undermining the detrusor on the lateral aspects of the incision to provide a space for ureteral swelling in the detrusor tunnel upon closure. The allograft ureter is prepared for anastomosis by careful spatulation and placement of a 5-0 PDS from outside to inside (ureteral mucosa) on the most distal apex. A 12-cm 4.5Fr double-J ureteral stent is placed in the ureter. A small mucosal vesicostomy is made using tenotomy scissors at the most caudal and medial aspect of the bladder mucosa. The size of the mucosal puncture should match the spatulated ureter. Having the suction handy aids in removing the irrigation that quickly empties through the mucosal puncture. The ureteral stent is placed inside the bladder and the previous set 5-0 PDS in the ureter is then thrown by starting inside the bladder through the mucosa and small amount of detrusor muscle to bring the apex of the ureter to the apex of the vesicostomy and tunnel and tied. A second 5-0 PDS is placed in the other ureteral apex (crotch) starting outside in and then inside to out on the corresponding bladder mucosa apex and tied. Note this apex does not have any detrusor to anchor the suture. The two apical sutures are used to sew the bladder mucosa to the ureter in a running fashion and loosely tied to each other to complete the anastomosis. At this point, the bladder can be irrigated gently to check for a watertight anastomosis. If satisfactory, then the detrusor tunnel is created. A 5-0 PDS is secured at the caudal-medial end of the tunnel approximating the two detrusor tunnel flaps (created earlier). This is then run the length of the tunnel over the ureter and tied to itself once an adequate tunnel is created. The end of tunnel should be inspected to ensure it is not too tight (leading to obstruction) or too loose (leading to possible bladder diverticulum or reflux). We usually pass a right angle alongside the ureter into the tunnel. It should pass snug but without difficulty. A surgical drain (19Fr round Blake) is placed near but not on the anastomosis and brought out through a separate stab incision and secured with a 2-0 silk drain stitch. We close the fascia in one layer; running 0 PDS from each apex to the middle of the incision and bury the knots. The subcutaneous tissue is closed running a 3-0 polyglactin (Vicryl, Ethicon, Somerville, New Jersey). The skin is closed using a 4-0 absorbable monofilament subcuticular stitch (or staples).

Ipsilateral Native to Allograft Ureteroureterostomy or Ureteropyelostomy

A similar surgical approach as described earlier for ureterovesical reanastomosis is used for identifying the transplant ureter. The incision is extended cranially to identify the native ureter above the allograft in order to avoid the adhesions and difficult dissection planes around the transplanted kidney. An alternative approach is to open the peritoneum to identify the ureter; however, we prefer to avoid entering another anatomic space if possible. Once the native ureter is identified (typically around the crossing of the iliac vessels), careful dissection to mobilize the ureter cranially will allow for a tension-free anastomosis. Great care is given to preserving the periureteral blood supply. Figure 14.2 shows the native ureter mobilized distally and doubly ligated proximally in preparation for ureteropyelostomy.

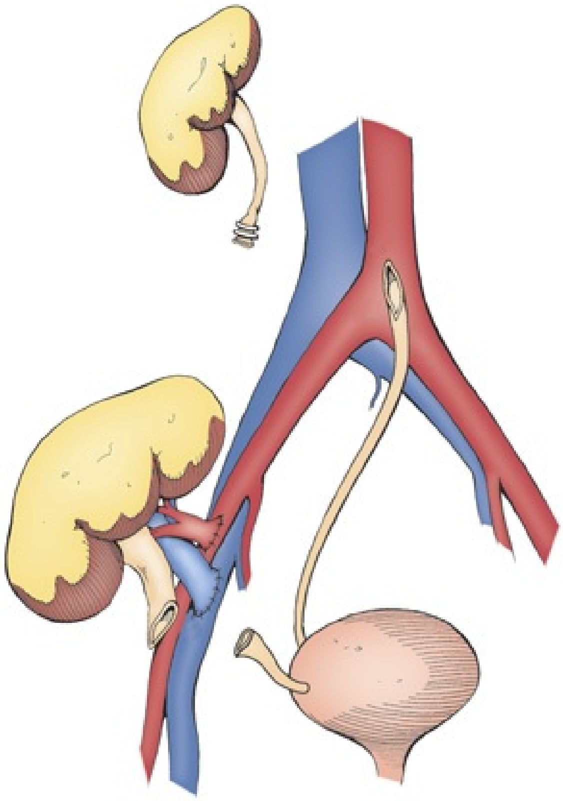

FIGURE 14.2 Mobilization of the native ureter with the proximal segment ligated.

The positioning of the native ureter depends on the relationship to the transplant ureter and/or pelvis. In addition, whether a side-to-side ureteral anastomosis or a ureteropyelostomy is to be performed may make a difference in the exact positioning of the native ureter. All of these factors relate to the extent of fibrosis and the appearance of the transplant ureter. To prevent any additional future problems, a tension-free, widely spatulated anastomosis of well-vascularized ureter to either the transplant ureter or renal pelvis is critical (Fig. 14.3). The anastomosis is performed using 5-0 PDS in a watertight single layer. The critical aspect is to obtain a mucosa-to-mucosa approximation to avoid tension, devascularization, and urinary leak. As shown in the Fig. 14.3 the superior (A’) or inferior (B’) apices can be rotated, and the length of the ureter trimmed to establish an optimal position to avoid kinking of the ureter. A 12-cm 4.7Fr double-J stent is routinely used on all anastomoses. The anastomosis may in addition be wrapped in omentum or peritoneal flap, if available, to decrease further the risk of leak. The wound is well irrigated with antibiotic solution. A closed suction surgical drain is also placed. The closure is the same as described earlier.

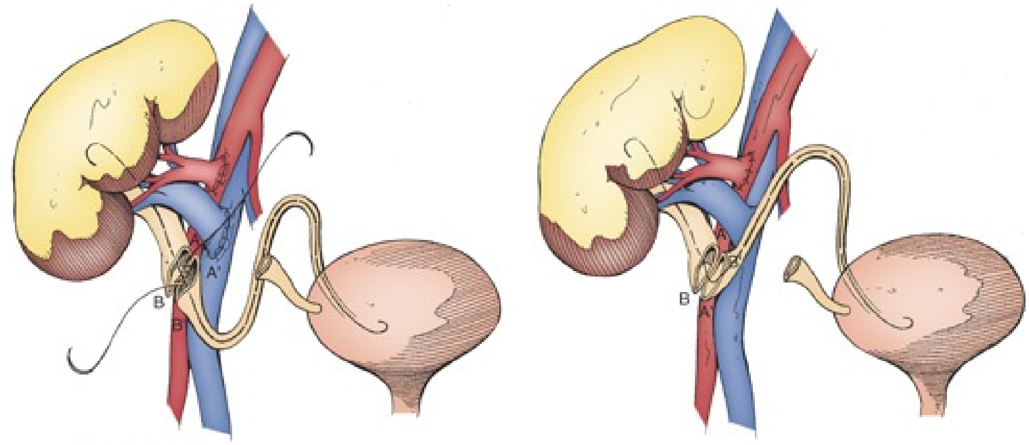

FIGURE 14.3 Anastomosis of spatulated native ureter to (A) transplant ureter and (B) with rotation to prevent kinking.

Typically, for redo operations, a conservative approach is taken with drainage. The Foley catheter is left in place for 3 to 10 days, depending on the extent of repair and condition of the bladder/anastomosis. We remove the surgical drain only if the output is minimal after removal of the Foley catheter. We leave the ureteral stents in place for 3 to 6 weeks.

OUTCOMES

Complications

Immediate postsurgical complications specific to reimplantation include bleeding, urine leak, ureteral obstruction (rare with stenting), and graft failure or loss. Long-term complications include ureteral stricture and scarring, ureteral reflux, urinary fistula, and graft failure or loss.

Results

Rarely will careful reimplantation lead to further ureteral complications or graft loss. In our experience, most ureteral complications have been managed successfully with reimplantation as described earlier. We prefer to avoid using ureteroureterostomy techniques because they are more likely to develop strictures and lead to failure and need for further intervention. Occasionally, we do perform these procedures as secondary or tertiary repairs. In cases of native to transplant ureteroureterostomy or ureteropyelostomy, we tie off the proximal native ureter. We have rarely needed to perform native nephrectomy or have had patient’s develop significant complications from doing so. Sometimes, we have managed significant leaks or strictures with chronic indwelling ureteral stents (with routine exchange) or nephrostomy tubes with reasonable patient comfort and long-term success. However, infectious complications are common with foreign bodies in the transplant urinary collecting system.

CHAPTER 15 RENAL AUTOTRANSPLANTATION

VENKATESH KRISHNAMURTHI AND DAVID A. GOLDFARB

Having been first performed by Ullman over 110 years ago, renal autotransplantation is now considered a last resort in the spectrum of surgical treatment for upper urinary tract disorders (1). Renal autotransplantation serves to maintain urinary tract integrity in cases of extensive ureteral tissue loss. This operation is also valuable for any disease where intervention on the kidney would expose it to prolonged warm ischemia resulting in permanent renal damage, such as is the case for complex distal renal arterial disease and large kidney tumors where renal preservation is imperative. The basic techniques have evolved as a consequence of developments in the field of renal allotransplantation, particularly an improved understanding of renal preservation. The advantages of back-table reconstruction include optimal exposure, use of optical magnification (loupes), a bloodless surgical field, and incorporation of renal preservation techniques (intracellular flush solutions and hypothermia) (2).

DIAGNOSIS

Because there are varied indications for renal autotransplantation, the diagnostic evaluation will vary depending on the indication. Proximal ureteral obstruction and extensive ureteral loss are usually documented by contrast-based imaging studies, such as computerized tomography (CT) scan, intravenous urography, retrograde or antegrade ureteropyelography, or a combination of these imaging modalities. Complex renal vascular diseases are typically identified on CT or magnetic resonance (MR) angiography. Due to the distal nature of renal vascular disease (branch disease) amenable to autotransplant, almost all candidates also have catheter-based arteriographic studies. Renal tumors are assessed by CT or MR imaging. Extensive investigation is typical for the loin-pain hematuria syndrome. Patients have usually had the full spectrum of radiographic testing to assess the renal vasculature, parenchyma, and collecting system. They have also had diagnostic ureteroscopy. Most have had visceral pain blocks that have failed to provide durable pain relief.

INDICATIONS FOR SURGERY

Autotransplantation of the kidney is an acceptable treatment option for patients with impassable proximal ureteral obstruction and extensive ureteral loss (3). Complex renal vascular lesions requiring ex vivo repair can also be successfully managed with renal autotransplantation (2). Lastly, complex intrarenal or central renal tumors may be successfully treated with ex vivo resection and autotransplantation.

Urinary tract disorders that necessitate consideration for autotransplantation include proximal ureteral obstruction that cannot be managed with bladder-based methods of repair (Boari flap, with or without psoas hitch). These bladder-based repairs require the presence of a large capacity bladder and, notwithstanding this prerequisite, these repairs can rarely extend beyond the pelvic ureter. Moreover, even if bladder-based flaps can reach beyond the area of obstruction, successful reconstitution of the urinary tract may be compromised by excessive tension at the site of reconstruction.

Common etiologies of proximal ureteral obstruction include multiple failed repairs of ureteropelvic junction (UPJ) obstruction (failed pyeloplasty or endoscopic repair), desmoid tumor (with or without Gardner syndrome) obstructing the proximal ureter, and extensive ureteral stricture. Prior to pursuing autotransplantation, these patients have generally been managed with indwelling ureteral stents and/or percutaneous nephrostomy tubes. They are completely stent-dependent and often have developed recurrent episodes of pyelonephritis.

An uncommon condition that is amenable to autotransplant would be the loin-pain hematuria syndrome (4). This is characterized by flank pain with gross or microscopic hematuria for which exhaustive diagnostic testing has failed to disclose a specific etiology. Aggressive treatment is driven by the chronic pain that accompanies the syndrome.

Finally, some centers have used ex vivo back-table excision, reconstruction, and autotransplantation for large renal cancers that are not felt to be amenable to in situ repair (5,6).

ALTERNATIVE THERAPY

An alternative to renal autotransplantation in patients with proximal ureteral obstruction is ileal ureteral substitution; however, ileal substitution may not be possible in patients with a history of extensive intestinal surgery, such as those patients with the Gardner syndrome who have undergone total proctocolectomy with ileostomy or ileal pouch creation. Additionally, the long-term consequences of intestinal interposition within the urinary tract are not completely known and must be considered when utilized in younger patients. Therefore, for patients in whom an ileal substitution does not seem favorable, autotransplantation may be the only option.

Complex renal vascular disorders are also an indication for renal autotransplantation. These are most often arterial disorders such as stenoses or aneurysms involving the segmental renal arteries and are difficult to treat with in situ methods. As an extension of the techniques routinely applied in renal allotransplantation, the renal hilum can be readily accessed while the kidney is on the “back table.” Revascularization to branch vessels or excision of aneurysms deep in the hilum is much easier on the back table and thus can be accomplished satisfactorily prior to autotransplantation.

TECHNIQUE OF RENAL AUTOTRANSPLANTATION

Surgical Instrumentation

Autotransplantation of the kidney combines the techniques of living donor nephrectomy and standard renal transplantation within the same patient. Successful performance of these operations requires instrumentation to facilitate fine vascular repairs. Although the specific instrumentation is a matter of individual preference, instrumentation for vascular surgical procedures should include (a) noncrushing vascular clamps designed for blood vessel occlusion, (b) forceps with fine tips designed for handling both small suture needles and the walls of small blood vessels in an atraumatic manner, (c) needle holders with fine tips to grasp small needles yet prevent unwanted needle movement, and (d) an assortment of silastic vessel loops and umbilical tapes for atraumatic vessel manipulation.

Given the variety of sizes and shapes of vascular clamps, appropriate selection depends on the size of the vessel to be occluded and the desired direction of vessel wall occlusion (longitudinal, transverse, or oblique). The jaws of vascular clamps should have rows of interdigitating teeth that allow vessel wall apposition without endothelial damage. Vascular clamps should be applied by compressing the jaws only to the point necessary for blood flow cessation. Excessive or forceful application can result in endothelial damage and subsequent vessel dissection.

For small, delicate blood vessels or relatively inaccessible areas, spring-loaded (bulldog) clamps are useful devices for vascular occlusion. Bulldog clamps also come in a variety of sizes, strengths, and shapes. Additionally, plastic varieties with soft padded jaws may be useful for extremely delicate vessels.

Vascular forceps must have tines that are in direct apposition, and the tips should be precise enough to grasp the vascular adventitia as well as a suture needle. Forceps with rows of interdigitating teeth serve to accomplish both of these purposes. Alternatively, forceps designed for stable needle grasp, such as diamond jaw forceps, do not allow for reliable manipulation of tissue.

Vascular needle holders should also have fine tips to stabilize small suture needles. The two common choices in vascular needle holders are a ring-handled needle holder and the spring-loaded type. Needle holder selection is a matter of individual preference; however, spring-loaded needle holders generally enable precise needle placement without large degrees of wrist rotation. Ring-handled needle holders permit a more stable needle grasp and facilitate accurate needle placement in deep structures or through densely-calcified vessels.

As with surgical instruments, the selection of vascular suture is also a matter of individual preference. The caliber of the suture should be as fine enough to minimize bleeding through suture holes but strong enough to avoid suture line disruption. In most cases, suture sizes between 2-0 and 7-0 will be applicable for vascular procedures in the abdomen and pelvis. At the level of the aorta, a 2-0 or 3-0 suture should suffice, and 4-0 is almost always suitable for the inferior vena cava. As one progresses to smaller vessels, including the common and external iliac arteries and veins, a 5-0 and 6-0 suture is suitable. Repair of small vessels, such as segmental renal arteries, may require a 7-0 or 8-0 suture.

Nonabsorbable sutures should be selected for vascular procedures. Although silk suture has favorable handling and tying characteristics, its popularity has waned with the development of synthetic, nonabsorbable sutures such as polypropylene. In comparison to silk, synthetic monofilament sutures are relatively inert in tissue, have a low coefficient of friction and thereby result in less tissue drag, and tend to retain a greater amount of tensile strength over time. Vascular sutures are swaged onto fine, one-half-circle or three-eighths-circle needles. The vascular needle should be large enough to penetrate tissue yet small enough so as not to cause hemorrhage from the needle holes. A common practice in vascular repair is to use a continuous suture with needles swaged onto both ends. This construction allows for greater flexibility in accomplishing the repair (e.g., closure from both directions). In select instances, specifically that of pediatric vascular surgery, absorbable monofilament suture with a long half-life (e.g., polydioxanone suture) can be used to allow anastomotic growth.

As with all operative procedures, an essential requirement for renal autotransplantation is optimal retraction and exposure of the operative field. We prefer to use a self-retaining, ring-based retractor system that is fixed to the table. For flank exposure, the Bookwalter retractor (Codman & Shurtleff, Inc, Raynham, Massachusetts) provides for excellent exposure of the kidney and renal hilum. We have modified the medium-sized Bookwalter oval by creating a modest angle (20 to 30 degrees) along the two ends of the ring. This enables the ring to better “fit” the patient’s flank during the operative procedure. A standard oval ring works very well in the iliac fossa. Lastly, for midline intraperitoneal abdominal incisions, we have utilized both the Bookwalter retractor system and the Thompson retractor (Thompson Surgical Instruments, Inc, Traverse City, Michigan). In our opinion, the Thompson retractor provides better exposure in more obese patients as the side bars of the retractor can be placed further from the incision. One disadvantage of this feature, however, is that the side bars tend to be closer to the operating surgeon and can be difficult to work around.

Renal Autotransplantation: Operative Approaches

The selection of the incision for renal autotransplantation depends on (a) the patient’s prior surgical history and (b) the indication for autotransplantation. When the autotransplant is being performed to treat conditions affecting the proximal ureter (as opposed to the renal vasculature), we favor placing the kidney into the contralateral iliac fossa. This enables the renal pelvis and ureter to be the most superficial structures such that if repeat procedures are required on the urinary tract, these structures can be accessed without dissecting or retracting the main renal vessels. Although the kidney can be removed and placed in either iliac fossa through a midline intraperitoneal incision, we often prefer a retroperitoneal flank approach for “donor nephrectomy,” when the kidney is being removed for conditions affecting the proximal urinary tract (7). Following completion of the flank approach for the “donor” nephrectomy, the patient is placed back in the supine position, the contralateral iliac fossa is reprepped and draped, and exposure of the iliac vessels is conducted in a standard manner. In theory, combining two separate procedures may result in a longer total operative time; however, this must be balanced against the benefit of extraperitoneal procedures and improved exposure along both the flank and iliac operative fields.

A midline intraperitoneal approach functions very suitably for renal autotransplantation. We prefer to use this technique when the autotransplant is being performed for vascular conditions, since the midline approach enables dissection of any abdominal structure. During repair of vascular disorders, arterial conduits (e.g., hypogastric artery) are often necessary for reconstruction, and these vessels can be easily exposed through a midline intraperitoneal approach. In contrast to two retroperitoneal procedures, the midline approach does require mobilization and retraction of the small bowel and colon, which may add to postoperative ileus. An upper abdominal transverse intraperitoneal approach is not recommended because it is very difficult to expose structures caudal to the aortic bifurcation, such as the iliac vessels.

Lastly, a laparoscopic approach has also been successfully utilized for the donor nephrectomy portion (8,9). In order to effectively utilize the laparoscopic approach, however, the kidney extraction incision should be made over the iliac vessels for subsequent implantation of the autograft. As mentioned previously, when autotransplantation is performed for urinary tract disorders, placement of the kidney in the ipsilateral iliac fossa puts the urinary tract structures in the most posterior location, which is suboptimal should further procedures become necessary.

Technique of Flank Donor Nephrectomy

Following satisfactory induction of general endotracheal anesthesia and placement of the necessary arterial and central venous monitoring lines, a Foley catheter is placed in the bladder. The patient is then placed on his or her side with the kidney that will be operated on facing “up.” The “down” leg is then bent and the “up” leg is maintained in a straight position. Pillows are placed between the legs, and the greater trochanter along the table surface is padded with egg crate mattresses. The kidney rest is maximally elevated and the operating table is placed in a fully flexed position. This enables a maximum distance between the lower ribs and the iliac crest. An axillary roll is placed, and the arms are padded and secured to a double arm board. The patient is then secured to the table prior to preparation and drape of the operative field.

Our preference, in general, is an incision over the course of the 11th rib. Although selection of the 12th rib may be suitable in many instances, the exposure of the kidney through the bed of the 11th rib essentially always provides for adequate exposure of the kidney and renal hilum. The approach through the 11th rib bed has a slightly greater chance of pleural entry, which is easily managed by evacuation of the entrained air or by placement of a thoracostomy tube. The most important aspect of flank donor nephrectomy is exposure of the renal hilum, and the disadvantage of approaching this through the 12th rib is that the hilum may be at the most superior portion of the operative field. Additionally, exposure through the 12th rib bed may require significant caudal retraction on the kidney during mobilization, potentially traumatizing the kidney.

Following incision of the skin, subcutaneous tissue, and superficial flank musculature, the anterior surface of the 11th rib is exposed, and the rib is then dissected in a subperiosteal plane. Once the rib is mobilized to a suitable posterior location, it is transected. It is sometimes necessary to cauterize the cut end of the rib or obtain hemostasis with bone wax. The retroperitoneal space is then entered along the tip of the removed rib, and, once retroperitoneal entry is verified, the abdominal contents are swept off the undersurface of the deeper flank musculature. These muscles are then further opened in the direction of the incision.

The next step in flank exposure of the kidney is diaphragmatic and pleural mobilization. The neurovascular bundle associated with the removed rib is identified, protected and is swept inferiorly and laterally. Care should be taken with the neurovascular bundle in order to avoid denervation injury to the flank musculature. The attachments of the periosteum and diaphragm against the adjacent lower rib are then divided sharply with the electrocautery. We prefer to continue this division all the way back to the insertion of the diaphragm on the psoas muscle, or lumbocostal arch. This allows for excellent exposure, and, by completely mobilizing the pleura and diaphragm, retraction-related tears on the pleura are avoided. Finally, the kidney can be mobilized within Gerota fascia since the procedure is being done for benign conditions. Once the kidney is suitably mobilized, the self-retaining retractor can be positioned to retract all adjacent structures but the kidney.

At the time of kidney mobilization, intravenous mannitol (12.5 g) is given to promote diuresis. A second 12.5-g dose is usually given just prior to renal artery clamping. The perinephric fat is then completely removed. The renal artery and vein are skeletonized to as proximal a level as possible. The renal artery should be dissected so that an adequate length is maintained for the implantation and the diseased portion can be reconstructed; however, it is extremely important not to dissect the artery too close to the aorta, since a minimal amount of artery must be maintained for suitable control. Too short of a stump on the aorta can lead to significant hemorrhagic complications; however, too short of an artery on the kidney can be reconstructed through a variety of techniques. One must differentiate the dissection of the renal artery during an autotransplant from that of in situ revascularization procedures. In revascularization procedures, the aorta is more accessible and may be more readily controlled, in contrast to flank exposures.

On the right side, the renal vein should be dissected all the way to the inferior vena cava (IVC), and the juxtarenal IVC must also be exposed. It is essential to mobilize the IVC posterior to the insertion of the renal vein, as the posterior wall of the IVC must be satisfactorily clamped during extraction of the kidney. On the left side, the adrenal, gonadal, and lumbar venous branches should be divided.

The ureter is dissected typically to the level of its crossing over the iliac vessel. Ureteral length at this level is essentially always suitable when the kidney is implanted in the iliac fossa. In cases of proximal ureteral obstruction, the ureter should be dissected approximately to the level of obstruction, but more importantly, it must be dissected to only a length suitable for reimplantation. A generous amount of periureteral tissue should be maintained with the ureteral dissection. We prefer to include the gonadal vein and intervening tissue along with the ureter. In cases where the ureter is dilated due to chronic obstruction, the need to maintain an adequate amount of periureteral tissue is less important due to the development of neovascularity. The ureter is then divided above the level of the obstruction (if present), and a satisfactory diuresis is verified by observing urine flow from the cut end of the ureter.

The kidney should be palpated to ensure a turgid feel. A soft kidney with no urine production should raise concern for arterial spasm. In these situations, the kidney should not be handled, and warm saline can be placed as an initial maneuver. If the kidney turgor has not improved and the spasm has not abated after a period of several minutes, papaverine can be applied topically along the renal artery adventitia.

When the kidney is firm and there is an adequate diuresis of urine, it is acceptable to proceed with removal. Mannitol (12.5 g) is given intravenously. The renal artery is then clamped and transected and the kidney mobilized so that the renal vein is stretched to maximize length. The renal vein, or IVC, is then clamped, and the vein is divided sharply at a suitable location. The kidney is then passed off to a separate team, who will commence with both surface hypothermia and in situ cold perfusion.

Attention is directed toward securing the renal vessels. The renal vessels can be secured with any combination of ties, clips, or suture ligatures. The renal artery should be controlled in a transfixing manner because non transfixing methods have been associated with hemorrhagic complications. Our practice is to oversew the renal artery stump with a 5-0 polypropylene suture or with a transfixing 3-0 polypropylene suture. The left renal vein can be similarly controlled (Figs. 15.1 and 15.2). On the right side, however, it is essential to remove the kidney with a small (few millimeters) margin of IVC (Figs. 15.3 and 15.4). In this situation, the vena cava is closed with a 4-0 polypropylene suture. We generally place one suture at each apex and run toward the midpoint. It is not essential to run this closure in an over-and-back manner as the low-pressure venous system is unlikely to leak between the suture lines. It is also important to leave a suitable margin of vein above the clamp so the cavotomy can be safely closed. If the renal vein is transected directly on the clamp, either of two approaches can still be employed to ensure a hemostatic closure. One option is to place a larger clamp below the existing clamp and to remove the first clamp. If this option is pursued, it is imperative to make sure that the second clamp is properly placed and that the walls of the vena cava are in proper apposition. Another, potentially safer option is to reapproximate the IVC walls in a horizontal mattress fashion by sewing "under" the clamp. In all cases, we recommend that the vena caval clamp be slowly released so that it can be immediately reapplied should there be unexpected, significant bleeding from the vena caval closure.

Once the renal vessels are secured, the operative field is irrigated and inspected for hemostasis. The retractor is then removed and the adjacent structures are inspected. If necessary, pleural entry is closed at this time, and the flank musculature and fascia are closed in two layers. Following completion of the flank procedure, general anesthesia is maintained and the patient is repositioned for the renal transplant procedure.

Donor Nephrectomy via a Midline Intraperitoneal Approach

The patient is placed in the supine position with both arms abducted. After satisfactory induction of general endotracheal anesthesia, appropriate arterial and central venous monitoring lines are placed. A Foley catheter is placed in the bladder in a sterile manner. Surgical preparation should include the field from the upper chest to the lower thighs. The genitalia should be shaved and prepped and covered with a sterile surgical towel. Both groins should be available for access should there be a need for saphenous vein procurement.

For renal autotransplantation, a midline incision from xiphoid to pubic symphysis should be employed. After dividing the subcutaneous tissues and linea alba, the abdomen is entered and the abdominal wall can be retracted with a self-retaining retractor. It is important to ensure complete neuromuscular blockade so that the maximal retraction of the abdominal wall can be accomplished. For right-sided autotransplantation, we mobilize the right colon and duodenum medially to expose the entire infrarenal vena cava, left renal vein, and abdominal aorta. For left renal autotransplantation, the left colon should be mobilized medially so that the left renal vein can be accessed as it crosses over the aorta. Following mobilization, the viscera are padded and retracted with the self-retaining retractor. The kidney can be mobilized within Gerota fascia, as mentioned previously. The ureter should be mobilized with a generous amount of periureteral tissue to either the point of obstruction or to a level where it crosses the iliac vessels. When autotransplantation is being performed for vascular conditions, the ureter does not always need to be divided as the renal vascular reconstruction can be performed in a basin containing iced slush placed on the patient’s abdomen. We typically divide the ureter so that the kidney can be taken off the operative field and exposed maximally on the back table, during which time the iliac fossa can be prepared by a separate surgical team.

With the kidney fully mobilized and the ureter divided, the renal vessels are dissected. Because cases of renal autotransplantation for vascular diseases often involve arterial disorders, we feel it is important to completely skeletonize the renal vein so that it can be mobilized away from the posterior renal artery. Accurate preoperative judgment is essential to determine the feasibility of in situ repair. However, even in cases in which in situ repair is thought to be unfeasible, intraoperative findings may dictate otherwise, and the surgeon should be prepared to reconstruct the kidney in situ. However, in cases of proximal ureteral obstruction and in cases of vascular disease requiring ex vivo repair, the kidney has to be removed and reconstructed on the back table. As previously described, the vessels are dissected as proximally as is necessary to correct the lesion. Intravenous mannitol (12.5 g) is administered. After an adequate diuresis and a firm kidney are verified, the renal artery is clamped and divided, the renal vein or IVC is clamped, and the vein is divided. The kidney is passed off to a separate team, who will commence surface hypothermia and in situ cooling. The main renal vessels are secured, and the field is inspected. As the kidney is being perfused, the iliac fossa can be prepared by a separate surgical team.

Back-Table Preparation of the Renal Autograft

Once the kidney is removed, it should be placed in a basin containing ice slush. The renal artery is carefully cannulated and in situ perfusion with cold preservation solution started. Cannulation may be achieved with a large-gauge angiocatheter (14-gauge) or a metal-tipped cannulation device. Arterial cannulation must be performed in a manner that avoids damage to the arterial intima and/or arterial dissection.

Because there is minimal ischemic time during renal autotransplantation, nearly any cold intracellular electrolyte solution can be used to provide in situ cooling for the kidney. In our center, we routinely use a modified Euro-Collins solution. We prefer to perfuse the kidney with an entire volume of perfusate (approximately 1,000 mL); however, it is necessary to perfuse a kidney only until the entire parenchymal surface is blanched and the venous effluent is clear. In cases of multiple arteries, all arterial branches need to be separately perfused as these represent end vessels to the kidney. Very small vessels may require manual perfusion with a syringe and a small-caliber (22-gauge) angiocatheter tip. Once the kidney has been perfused, the renal vasculature can be prepared. The renal vein should be dissected back to its segmental branches. Small venous tributaries are ligated with silk ties and divided. Large segmental branches should be preserved, and it is imperative to maintain at least 50% of the total venous drainage of the kidney. Once the vein is skeletonized back to its segmental branches, it can be retracted away from the artery, which can then be similarly dissected. The lymphatic tissue surrounding the artery is sharply excised and secured along the segmental arterial branches. Large lymphatic trunks in this location should be secured with silk ties in order to prevent a lymph leak, particularly if the implantation of the kidney is going to be placed in a retroperitoneal location. Once the artery has been mobilized to its segmental branches, it should be ready for implantation. Any remaining perinephric fat should be removed, and, if indicated for additional histologic information, a needle biopsy of the kidney is performed at this time.

In cases of renal vascular disease, the renal artery should be dissected distally, beyond the level of the disease. The diseased segment of the artery or arteries should be excised, and the remaining normal artery or branch artery can be reconstructed in a variety of techniques (Fig. 15.5).

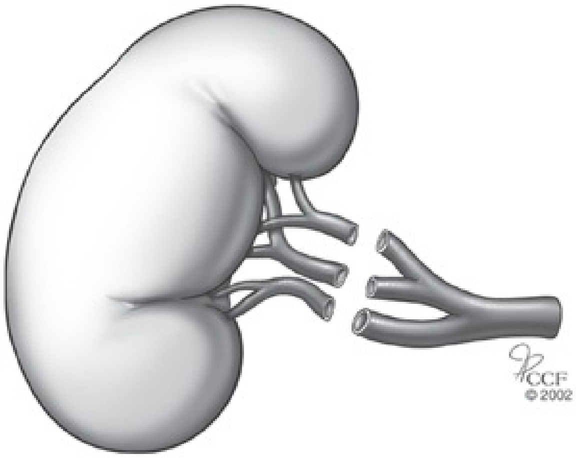

FIGURE 15.5 The native hypogastric artery can often be used as an interposition graft in complex branch renal artery repair. The hypogastric artery must be free of significant vascular disease to be useful. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2002–2014. All rights reserved.)

Implantation of the Renal Autograft

Exposure of the Iliac Vessels

As mentioned previously, the site for renal autograft implantation can be exposed by a second surgical team while the kidney is being prepared on the back table. A standard lower quadrant oblique (Gibson) incision can be used to enter the retroperitoneum when two separate incisions are utilized for autotransplantation. Of particular importance with the retroperitoneal approach, large lymphatic trunks should be ligated prior to division to prevent postoperative lymphocele. We typically expose the full length of the external iliac artery, specifically from the common iliac bifurcation to the inguinal ligament. The external iliac vein is similarly exposed from the inguinal ligament to the first major posterior branch. The external iliac artery is almost always free of branches until the most distal aspect, where the epigastric vessels arise. The external iliac vein can often have posterior tributaries (e.g., obturator vein), and division of these vessels lends significant mobility to the external iliac vein. The internal iliac or hypogastric vein is a large trunk, often composed of three veins, entering along the posterior aspect. Division of this vessel must be approached with care as the hypogastric vein is very short and very wide and loss of control of this vein can lead to significant hemorrhage. We prefer to divide this vein only when the iliac vein needs to be mobilized lateral to the external iliac artery due to a short renal vein. Our approach to dividing the hypogastric vein(s) is to (a) medially mobilize the external, internal, and common iliac arteries and (b) obtain circumferential control of the external iliac vein and common iliac vein (we prefer to encircle these vessels with silastic loops). This approach works well with a short hypogastric vein(s) as it can be difficult to obtain enough distance between two ties. Accordingly, we have found that titanium clips provide satisfactory occlusion along the proximal aspect. If another tie cannot be placed on the distal aspect (insertion into the external iliac vein), this orifice can be suture-ligated after occluding flow in the external and common iliac veins.

In contrast to an extraperitoneal approach, the iliac vessels can be exposed directly when using an intraperitoneal approach. Lymphatic trunks are simply cauterized, and similar exposure of the iliac vessels is obtained. Another advantage of an intraperitoneal approach is that it is often easier to expose larger vessels for implantation, specifically the common iliac artery and infrarenal vena cava. These vessels are more accessible and larger caliber, features that may facilitate renal vascular anastomoses.

Important points in selecting the target for renal autograft implantation are that (a) the vessels should be adequately mobile to allow for tension-free anastomoses to the renal artery and vein and (b) the inflow artery should be sufficiently free of atherosclerotic disease. The second point deserves further elaboration in that, not only should the anastomotic site be acceptable, but the location for clamp placement should also be "soft." If there is concern over the suitability of the artery, a "softer" location should be explored both proximally and distally.

Renal Autograft Revascularization

Revascularization of the kidney is commenced by anastomosis of the renal vein to the iliac vein (or vena cava) (Fig. 15.6). We typically occlude the iliac vein with a tangentially occluding or Satinsky-type clamp. An appropriate-length venotomy is made on the anterior wall, and the lumen is irrigated with heparinized saline. The kidney is brought into the operative field, and a continuous anastomosis is completed by first placing sutures at both apices of the venotomy and then running around each "side." For anastomosis to the iliac vein, both 5-0 and 6-0 polypropylene sutures are acceptable, and when the vena cava is used for outflow, 5-0 polypropylene is suitable.

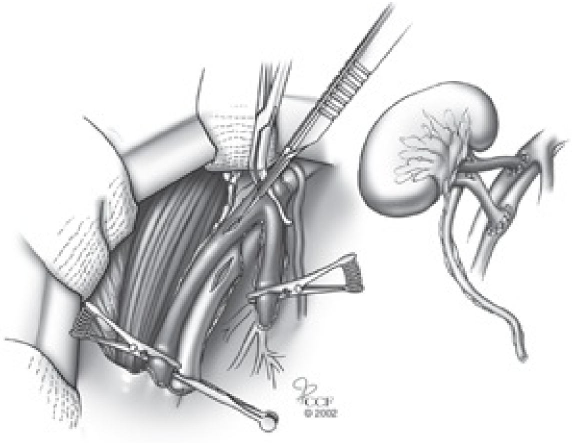

FIGURE 15.6 This figure demonstrates regional control of the external iliac artery and vein. It also shows the final appearance of the transplanted kidney. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2002–2014. All rights reserved.)

In the majority of cases, we perform the arterial anastomosis following completion of the venous anastomosis. The iliac artery (common or external) is occluded with vascular clamps both proximally and distally. Alternatively, a single clamp (Satinsky type) can be used for arterial occlusion as well, but the disadvantage to this approach is that the artery cannot be unclamped without restoring the high-pressure antegrade flow. Following clamp control, the periadventitial tissue at the proposed site of anastomosis is sharply excised, an arteriotomy is made with a no. 11 blade, which is then further fashioned to match the caliber of the renal artery, and the lumen is irrigated with heparinized saline. We commonly use a continuous 6-0 or 7-0 polypropylene suture to complete the end-to-side anastomosis to the iliac artery.

Following completion of the vascular anastomoses, we release the venous clamp first, then the distal arterial clamp, and last the proximal arterial clamp. This allows the anastomoses to be "tested" in a low- to high-pressure direction. Once hemostasis is ensured, the operative field and kidney are bathed in warm saline solution, after which the kidney is inspected for uniform perfusion. The renal cortex may take several minutes to become homogenously perfused (pink-appearing), and soon after this occurs, urine production should be seen from the distal end of the ureter.

Ureteroneocystostomy

In general, we prefer to reimplant the autograft ureter in an extravesical full-thickness manner (Fig. 15.7). We do not feel that creation of an antireflux tunnel is essential and direct anastomosis solely between the ureteral and bladder mucosa may have a higher incidence of anastomotic urinary leaks (10).

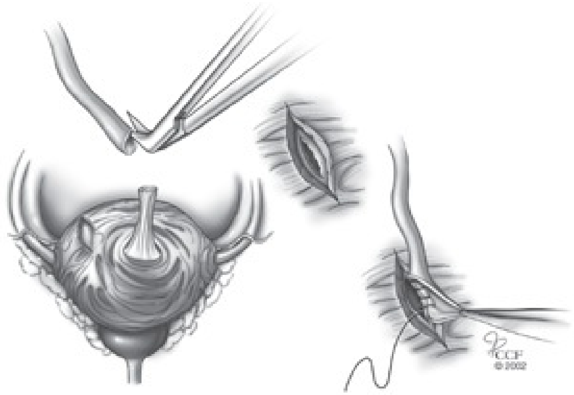

FIGURE 15.7 The location and creation of the extravesical ureteroneocystostomy is demonstrated. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2002–2014. All rights reserved.)

Unlike dialysis-dependent patients who are undergoing renal allotransplantation, nearly all patients who are undergoing autotransplantation have “normal” urine volumes and “normal” bladder capacities. The bladder, which is readily distensible in autotransplant patients, is filled by instillation of saline solution, and the perivesical fat over the intended site of ureteral reimplantation is removed with electrocautery dissection. Occasionally, large veins in the perivesical fat must be ligated, and in these instances, absorbable suture should be used to avoid potential migration into the anastomosis.

We then trim and spatulate the ureter at an appropriate length. For renal autotransplantation, the ureter is not excessively long and does not need to be trimmed to any significant degree (1 to 2 cm at most). Additionally, unlike the ureter received with a deceased donor renal allograft, the viability of the autograft ureter can be ensured during the nephrectomy. Periureteral vessels are ligated with absorbable ties, and the ureter is spatulated for a distance of approximately 1 cm. The detrusor musculature is then divided with the electrocautery, with care taken to avoid entering the bladder mucosa. The bladder mucosa is entered sharply, and the ureter is anchored at this site with one or two absorbable sutures placed at the “heel” and “toe” of the anastomosis, respectively. We prefer to complete the typical extravesical ureteroneocystostomy with a continuous 5-0 polydioxanone suture. Routine use of an indwelling double-J stent is dependent on surgeon preference; however, if there are concerns over the integrity of the anastomosis or the viability of the ureteral end, use of a stent is recommended.

Alternative urinary tract reconstructive approaches should be considered in cases of renal autotransplantation for urinary tract obstruction and/or intractable stone disease. In these situations, the proximal ureter and renal pelvis are often markedly dilated, and direct anastomosis to the bladder provides unobstructed urine drainage and stone passage. The optimal position for the kidney should be determined prior to revascularization. Following this, urinary tract continuity can be reestablished either directly or through bladder- and/or ureteral-based flaps (11).

Closure of Incision

Prior to closing the incision, we ensure an appropriate position for the kidney. In most cases, the kidney can be placed on the psoas muscle, with the lateral aspect of the kidney directed laterally and the hilum directed medially. This position places the urinary tract in a medial position, should later access be necessary. Once the kidney is positioned, cortical perfusion should be verified and the hilum should be palpated to ensure a strong arterial pulse. Additionally, satisfactory drainage from the renal vein can be ensured by the palpation of a soft, easily compressible renal vein.

We reapproximate the abdominal wall musculature most often in a single layer. We typically close a midline incision with a single layer of no. 1 polydioxanone or no. 1 polypropylene. For most retroperitoneal incisions, one layer is satisfactory. In cases where the abdominal wall is thin and the musculature is attenuated, closure in two layers can provide adequate reapproximation.

OUTCOMES

The end points for outcomes vary according to the indication for the procedure (ureteral obstruction, renal vascular disease, loin-pain hematuria syndrome). Preservation of the affected kidney is very high. Several reports have demonstrated >90% technical success rates for renal autotransplantation that seem durable. Understand that autotransplantation for a diseased kidney is a more complicated endeavor than renal allotransplantation. Simultaneous donor and transplantation procedures are performed on the same individual, which is an enormous physiologic burden. The kidney being autotransplanted is often anatomically compromised. This is in contrast to the donor kidneys in standard allotransplantation, which are normal, and for which the reported technical loss rates are <5%.

COMPLICATIONS

Complications of using autotransplantation may derive from the procurement of the kidney or may be related to the implantation of the kidney. The main complications arising from procurement would be bleeding and injury to adjacent viscera (colon, pancreas, spleen, liver). From the implantation portion of the procedure, there may be vascular problems. The biggest concern is the potential for arterial or venous thrombosis. Attending to proper vascular technique and ensuring appropriate geometric alignment of the kidney in its final location will help prevent vessel kinking. Recipient vessel dissection or embolization is rare; nonetheless, early recognition and repair are required to avoid catastrophic limb-threatening problems. With respect to the ureter, there is potential for urine leak or obstruction. Attention to creating a tension-free anastomosis by using a ureter with a well-preserved blood supply is important. Given the diseased status of the vessels or ureter, a ureteral stent is recommended. Finally, when kidneys are autotransplanted into a retroperitoneal position, lymphocele is possible. Meticulous ligation of perivascular lymphatics will help to prevent this complication. A retroperitoneal drain for a brief period may also help avoid this complication. If a lymphocele is causing graft dysfunction, it can be drained percutaneously or surgically.

CHAPTER 16 ■ MISCELLANEOUS LAPAROSCOPIC UROLOGIC PROCEDURES: LYMPHOCELES, CALCULUS, VARICOCELE, URETEROLYSIS

SRI SIVALINGAM, SEAN P. HEDICAN, AND STEPHEN Y. NAKADA

The evolution of laparoscopic surgery permits it to be a viable alternative to less commonly used miscellaneous procedures such as lymphocele repair, urinary calculi, ureterolysis, and variocele ligations. Ongoing refinements and advancements continue to evolve with the use of laparoendoscopic single-site surgery (LESS) and robot-assisted approaches for these specialized procedures.

LYMPHOCELE REPAIR

Lymphoceles are localized encapsulated collections of lymphatic fluid created by disruption of lymphatic vessels that can occur following renal transplantation or other procedures during which lymphatic channels are transected in the pelvis or retroperitoneum. The incidence of asymptomatic lymphoceles following renal transplantation or combined kidney pancreas transplantation has been reported to be as high as 20% (1). Contributing factors in transplant patients include episodes of rejection, cytomegalovirus infections, and posttransplantation reoperations (2,3).

Disruption of the lymphatics during pelvic lymphadenectomy for prostate cancer has also led to localized lymphoceles, with a reported incidence of 0.5% to 10% (2,4,5). Significant contributing factors to the formation of the lymphoceles include the administration of low-dose heparin (6), prior radiation, presence of metastases, surgical technique, and the extent of the dissection (5). Fortunately, the majority of these pelvic lymphoceles remain clinically asymptomatic. Lymphoceles have also been described following retroperitoneal procedures including nephrectomies, retroperitoneal lymph node dissections for testis cancer, or aortic surgery.

Diagnosis

Asymptomatic lymphoceles are usually discovered incidentally at the time of renal allograft ultrasound (Fig. 16.1) or computerized tomographic (CT) imaging of the abdomen and pelvis (Fig. 16.2) performed for unrelated indications. They appear as a single or septated chamber with Hounsfield unit characteristics and echotexture consistent with fluid located in the region of the renal allograft or adjacent to the iliac vessels. Lymphoceles related to radical prostatectomy occur primarily in the pelvic cavity, and a recent series that evaluated 105 symptomatic lymphoceles following radical prostatectomy requiring intervention reported that the most characteristic locations are paravesical (69.5%), lateral pelvic wall (16.5%), deep pelvic (6.7%), prevesical (4%), and pelvic with retroperitoneal extension (2%) (7).

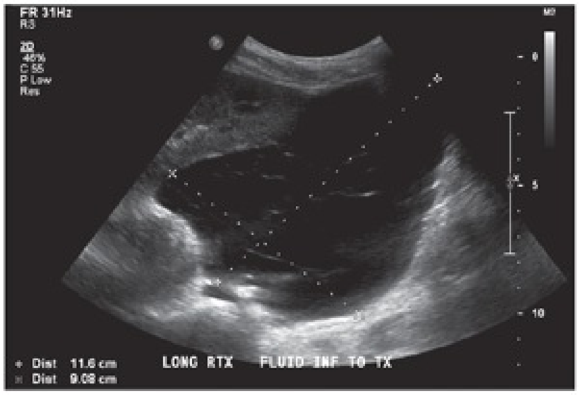

FIGURE 16.1 Ultrasound images of a large lymphocele containing low echogenic fluid extending below and medial to the transplant kidney.

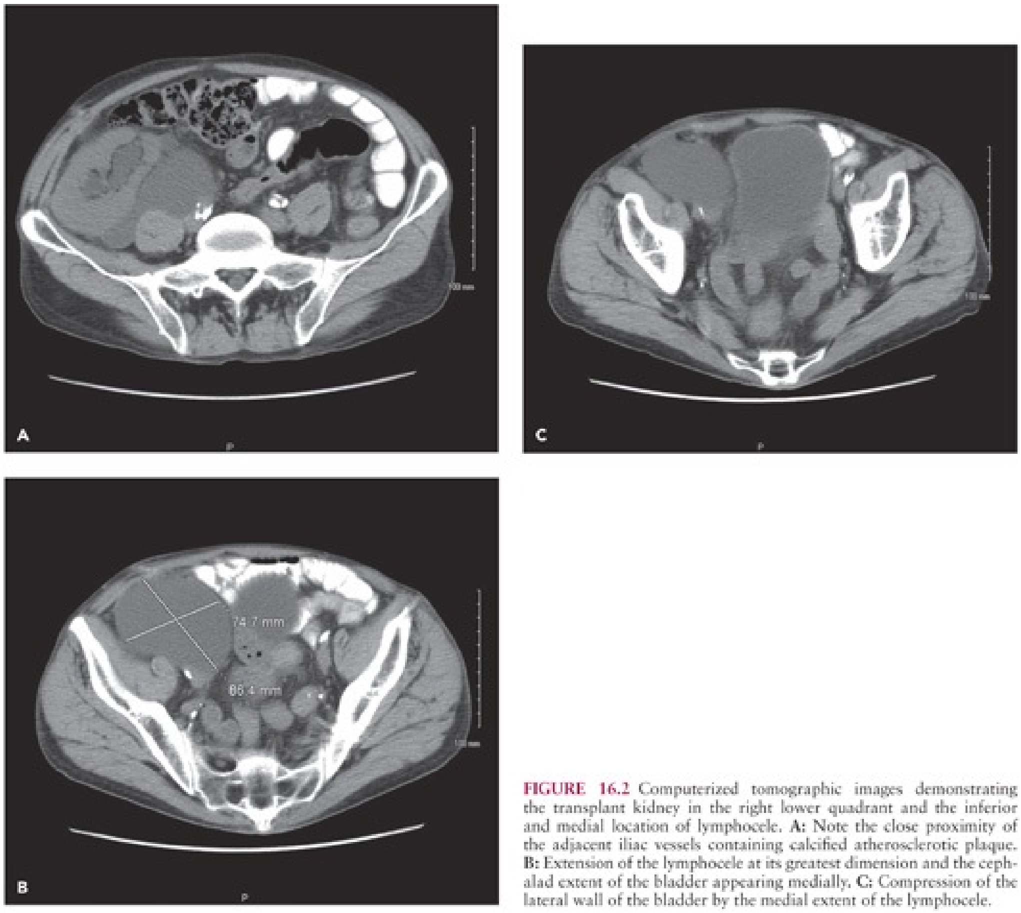

FIGURE 16.2 Computerized tomographic images demonstrating the transplant kidney in the right lower quadrant and the inferior and medial location of lymphocele. **A:** Note the close proximity of the adjacent iliac vessels containing calcified atherosclerotic plaque. **B:** Extension of the lymphocele at its greatest dimension and the cephalad extent of the bladder appearing medially. **C:** Compression of the lateral wall of the bladder by the medial extent of the lymphocele.

Lymphocele collections can be difficult to differentiate from a urinoma unless an ongoing urine leak can be documented via contrast or radionuclide imaging. In the case of a urinoma, aspiration and analysis of the fluid will demonstrate a creatinine value elevated above corresponding serum values

(8). The creatinine value on the fluid aspirated from a lymphocele will be equivalent to serum. Hematomas and abscesses usually contain fluid with a higher echogenicity on ultrasound examination, with an increased nonenhanced density on CT imaging (9). The presence of signs and symptoms of an infection in association with a high-density fluid collection, often with mild enhancement of thickened walls or surrounding tissue stranding, usually denotes an abscess. The diagnosis is confirmed and therapeutic intervention often begins with percutaneous drainage or aspiration of purulent material (2).

Indications for Surgery

The primary indication for a lymphocelectomy (surgical unroofing or marsupialization of a lymphocele) is symptoms related to its mass effect. The reported incidence of symptomatic lymphoceles following renal transplantation ranges from 3% to 7% (10,11). Symptomatic lymphoceles after pelvic lymphadenectomy following radical retropubic prostatectomy are relatively rare, but some series have reported the prevalence of lymphoceles following prostatectomy as high as 10% (12). Fortunately, the majority remains asymptomatic and resolves spontaneously. One study showed that only 2.4% of lymphoceles following radical prostatectomy were symptomatic and 2% required intervention (13). Symptoms necessitating surgical drainage and unroofing include labial, scrotal, or lower extremity swelling; deep venous thrombosis with or without pulmonary embolism; a sensation of pelvic fullness; and irritative voiding complaints due to compressive effects on the bladder or rectum (5). Renal transplant dysfunction secondary to ureteral obstruction with associated hydronephrosis versus direct compressive effects on the allograft has also been reported. A review of indications for surgery in transplant recipients demonstrated that 69% were performed for local symptoms, 14% for graft dysfunction, and 17% for both (10). Ureteral obstruction following pelvic lymphadenectomy for prostate cancer is extremely rare (5).

Alternative Therapy

Prior to the first reported case of laparoscopic lymphocelectomy in 1991 by McCullough et al. (14), the treatment of choice for a symptomatic lymphocele was open transperitoneal marsupialization, with a reported complication rate of 4% and a recurrence rate of 15% on review of 129 patients undergoing open lymphocelectomy (11). This method is still used for complex lymphoceles that are multiseptated and lying in a difficult-to-access posterolateral or inferolateral position relative to the allograft. Lymphoceles located in these locations have also been shown to be associated with a higher incidence of conversion from a laparoscopic to open surgery as a result (15). Infected lymphoceles requiring extensive evacuation and washout of purulent debris, excision of all septations, and drain placement also support the use of an open extraperitoneal approach (2,3).

Similar to symptomatic renal cysts, aspiration of lymph fluid alone via a percutaneous approach is associated with a 75% to 100% incidence of lymphocele recurrence. These results are not significantly improved by insertion of a percutaneous drain. The use of sclerosing agents instilled into the lymphocele cavity has been reported to increase the likelihood of successful ablation to approximately 85% to 90% (3). Sclerosing agents vary depending upon the series, but the use of alcohol, tetra- or doxycycline, povidone-iodine, and fibrin sealant have all been reported (3,16). It should be noted that this treatment usually requires multiple instillations that can last as long as 45 days (3). The use of this approach is contraindicated for complex multiseptated lymphoceles due to incomplete drainage and inability to introduce sclerotic agent into all chambers (16). Sclerotic agents are also best avoided when the ureter contacts one of the walls of the lymphocele due to the concern that the inflammatory response induced could result in periureteral fibrosis and ultimate transplant ureteral obstruction. Infected lymphoceles likewise should not be treated with aspiration and sclerosis even when utilizing antibiotic agents, as this can lead to persistence and even aggravation of the infection.

Surgical Technique

Preoperative Preparation

Patients are placed on a clear liquid diet beginning at noon the day prior to their procedure and are also instructed to drink a bottle of magnesium citrate in an effort to cleanse the bowel. Decompression of the bowel aids in visualization during the operation and improves the speed of bowel recovery. On call to the operating room, the patient is administered a single dose of an appropriate intravenous broad-spectrum antibiotic. Patients on long-term steroid immunosuppressive therapy may require supplemental stress dosing per the anesthesia team. Compressive knee or thigh-high stockings (T.E.D.) and sequential compression devices are applied to the lower extremities to reduce the risk of deep venous thrombosis formation. Hair is removed from the area of the operative field, including the pubic region and lower abdomen, using electric clippers.

Patient Positioning

The operating table should be equipped with a kidney rest and allow flexion/deflection and full Trendelenburg positioning. A 3-inch foam pad mattress is placed on the operating table, followed by a full-size gel pad to aid in securing the patient. Prior to transferring the patient from the transport bed to the operating table, 70% isopropyl alcohol can be used to cleanse the back to remove body oils and debris to establish secure traction between the patient and the gel pad without the use of shoulder bars, chest tape, or straps. Alternatively, any of the other aforementioned securing methods can be utilized. Following intubation of the patient, an orogastric tube is inserted to decompress the stomach, and nitrous oxide should be avoided to prevent bowel distention and to reduce the risk of creating a combustible environment when electrocautery is being utilized. The patient should be positioned with the umbilicus at the region of the kidney rest to allow flexion of the table with slight kidney rest elevation to increase the distance between the umbilicus and the pubic symphysis, assisting in spacing of the trocars.

The Foley catheter should be inserted on the operative field after preparing and draping to allow access for filling and decompressing the bladder, which may assist in localization of the lymphocele. Male patients are placed supine on the operating table. Female patients should be positioned in low lithotomy using Allen stirrups to allow adequate access to the urethral meatus. Alternatively, slight frog-leg positioning can be utilized in nonobese female patients. If the legs are not secured in stirrups, tape can be placed across the upper thighs and a strap across the lower legs to secure them in position.

The arms are protected in eggcrate foam and tucked at the sides. When arm sleds are utilized, care must be taken to avoid disruption of the securing Velcro on their insertion, as this holds the 3-inch foam mattress in place and can lead to its dislodgement and inadvertent patient movement on deep Trendelenburg positioning. Although it is rarely required, the security of the patient’s position should be tested in full Trendelenburg tilt prior to preparation and draping. A wide surgical skin preparation should be performed to include the genitals for sterile Foley catheter insertion and adequate exposure to allow adequate trocar spacing and conversion to an open operation if necessary.

A standard wide-aperture laparoscopic drape can be utilized when patients are not placed in stirrups; otherwise, standard cystoscopy legging and aperture drapes are utilized after four-towel draping of the abdominoperineal region. The aperture can be enlarged to give adequate exposure to the lower abdomen.

Establishing Peritoneal Access and Trocar Configuration

Access to the peritoneum can be obtained utilizing a closed needle (Veress) puncture technique or an open direct vision (i.e., Hasson cannula) method. If the lymphocele is extremely large, extending to or above the level of the umbilicus, this centrally located port can be moved in a cephalad direction to ensure that the port enters approximately a handsbreadth above the upper extent of the lymphocele. Transabdominal ultrasound can be used to assist in port placement or the extent of the lymphocele estimated by counting CT scan slices above and below the umbilicus to predict its location. The underlying soft tissues are bluntly dissected down to fascia using a sharp clamp.

Pneumoperitoneum is established using standard technique. The insufflation pressure set point should be placed at 15 mm Hg, and once this pressure level is obtained, a visual introducing trocar (e.g., Optiview, Ethicon Endo-Surgery, Cincinnati, Ohio) is used to insert a 10/12-mm port via the previously made periumbilical incision. The 0-degree 10-mm laparoscope is inserted into the Optiview and can be used to visualize each layer of the abdominal wall as it is traversed using a back-and-forth twisting motion until full entry into the peritoneal cavity is confirmed. Once the visual introducing port has been inserted, the 0-degree lens is exchanged for a 30-degree lens to allow a greater range of visualization angles.

Two additional working ports are then placed, adjusting their position depending on the location of the lymphocele. In general, a 5-mm working port is inserted a handsbreadth down from the supraumbilical port just lateral to the midline on the side contralateral to the lymphocele. If the distance between the umbilicus and the pubic symphysis is sufficient to allow placement of two ports separated by a handsbreadth without entry into the bladder, the third port (5 mm) can be placed below the second port in the midline. This also requires that the lymphocele is not exceptionally large and that the patient is not morbidly obese (body mass index <35). In general, placement of this port a handsbreadth lateral to the midline just below the level of the umbilicus on the side ipsilateral to the lymphocele is preferred. In the standard trocar arrangement, a 10-mm port can be utilized to allow lateral camera positioning if desired during the case (Fig. 16.3). Alternatively, a 5-mm port can be utilized if a 5-mm laparoscope is available.

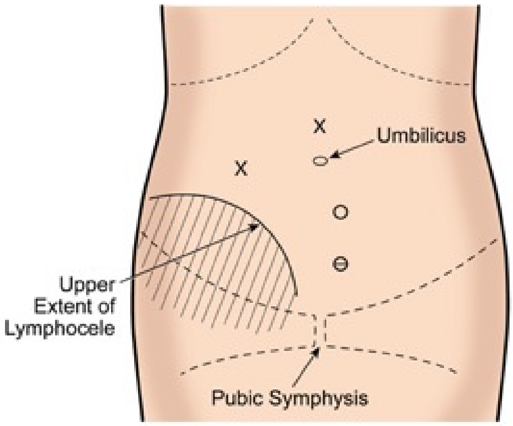

FIGURE 16.3 Recommended port configuration for right laparoscopic lymphocelectomy. X, 10/12-mm port; O, 5-mm port; Θ, alternative 5-mm port.

The surgeon stands on the side opposite the lymphocele and the assistant and scrub personnel stand on the ipsilateral side across from the primary surgeon. The monitor and tower or boom arm containing the insufflation unit, light, and camera source are positioned at the foot of the patient. The patient is placed in Trendelenburg positioning to the extent necessary to liberate the bowel off the area of dissection, and the table is airplaned slightly toward the operating surgeon.

Identification of the Lymphocele

After release of any overlying bowel or omental adhesions to the lower quadrant of interest, the lymphocele can be identified as a bluish-black pelvic structure if thin-walled. The overall appearance can vary significantly, and when the wall is thickened, differentiation from the bladder can be difficult (Fig. 16.4A). Depending upon its location, other surrounding vital structures, such as the transplant or native ureter or iliac vessels, can also be incorporated into one or more of the walls of the lymphocele. Methods to assist in identification and differentiation from the bladder have been described, including distention followed by decompression of the bladder with sterile saline. The bladder can also be filled with indigo carmine or methylene blue–stained saline and a laparoscopic aspirating needle can be inserted into the identified structure presumed to be the lymphocele (Fig. 16.4B). This is confirmed to be the lymphocele if the aspirated fluid does not contain blue-tinged fluid (17).

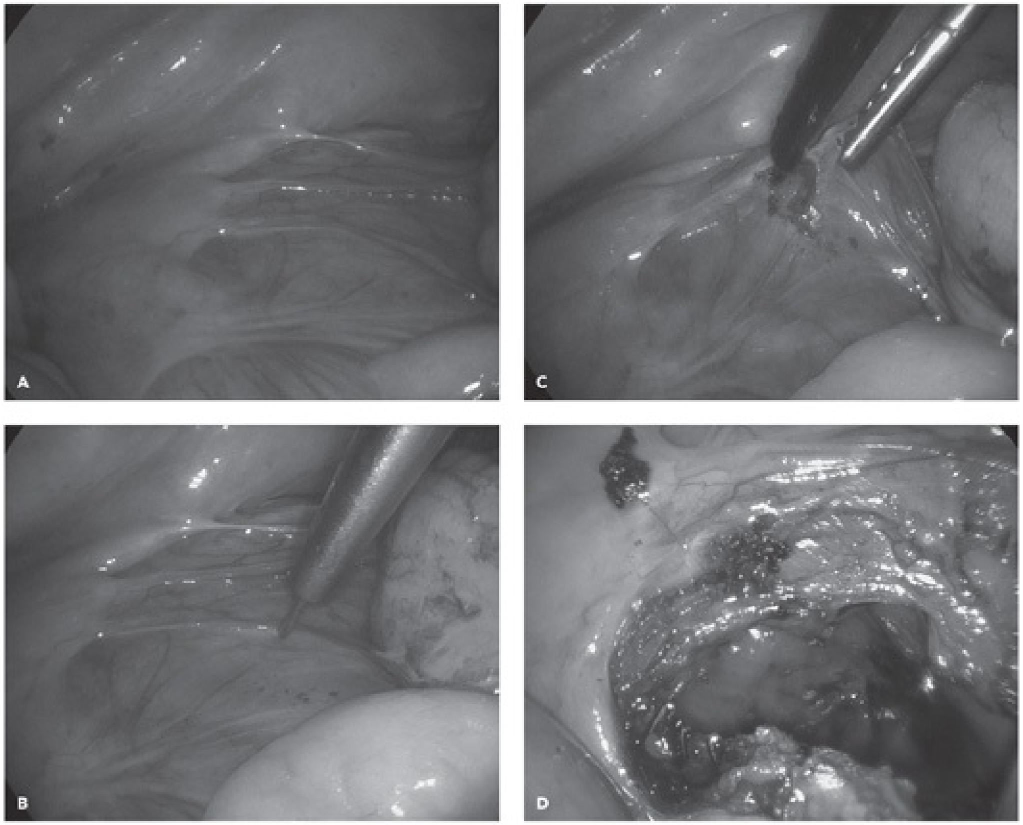

FIGURE 16.4 Laparoscopic view of right lower quadrant lymphocele adjacent to a renal transplant. **A:** Thick-walled appearance making differentiation between the indigo carmine–containing bladder and lymphocele difficult. **B:** Laparoscopic aspiration needle inserted into the lymphocele, yielding clear fluid. **C:** Lymphocele unroofing begins utilizing an electrocautery hook. **D:** Final appearance of wide-mouthed peritoneal aperture created in the lymphocele.

Alternatively, outlining the lymphocele using transabdominal ultrasound and percutaneous needle puncture with aspiration followed by injection of the lymphocele with dilute methylene blue–tinged saline results in staining of the walls of the lymphocele, allowing confirmation of the structure prior to unroofing by laparoscopic needle aspiration with return of blue-tinged fluid (2,17). Once the lymphocele is entered, the blue staining of the chamber assists in identification of its extent and the amount of unroofing required.

Excision of the Lymphocele

Laparoscopic shears (Fig. 16.4C) or a harmonic scalpel can be used to unroof the lymphocele, incising through the area of the wall that appears to be the thinnest portion of the structure in a direction parallel to the presumed course of the transplant ureter. After the initial incision, care should be taken to inspect the wall to make sure that structures such as the renal allograft ureter or pelvis, native ureter, or bladder are not injured in the process. In general, only the portion of the wall in contact with the peritoneum is excised, and any of the contained loculations are disrupted bluntly and the walls excised. Although stenting of the transplant ureter can be performed to help in its identification, this can be technically challenging. In a large multi-institutional retrospective study, 81 patients underwent laparoscopic marsupialization, and none of the ureters were stented prior to the laparoscopic surgery, yet no ureteral injuries occurred (3). The wall of the lymphocele can then be excised from the central incision to the edge of the thin region of the wall using the laparoscopic instruments to ballot the area to help judge its thickness and the likely involvement of surrounding structures. The excision is then carried out circumferentially until the entire exposed region of the lymphocele is excised (Fig. 16.4D). Once the segments are excised, they can be removed via the 10/12-mm port or cut into strips prior to removal if they are too large to fit through the port. The specimen is visually inspected, and if any concerning elements are identified, such as portions of ureter, these can be confirmed via frozen section analysis, allowing intraoperative management. If the excised region of the lymphocele is small (<4 cm) and this results in a deep-chambered cavity with a narrow aperture, consideration should be given for placement of an omental wick.

Placement of Omental Wick

Hsu et al. (3), reported that omental interposition was used in only 14% of the 81 reported cases and “was not considered to be an essential prerequisite for long-term success.” Use of an omental tag was recommended only if it could be “readily transposed and affixed to the lymphocele window.” In theory, use of native vascularized tissues to maintain patency of the unroofed portion of the lymphocele will facilitate continued patency and peritoneal drainage of the lymphatic fluids.

The omental interposition graft is usually established using the most distal tip of the omentum, which is isolated; if necessary, the omentum can be divided in a craniocaudad direction to facilitate mobilization. Major vasculature should be left in place, and typically extensive dissection to the margin of the stomach is not required. Once the omentum can be readily affixed to one of the internal walls of the fenestrated lymphocele, several sutures on a small (e.g., RB-1) needle or tacking titanium clips are placed to secure the tip of the mobilized omentum near the base of the lymphocele. Needles for laparoscopic suturing should be introduced and removed via one of the 10/12-mm trocars to prevent their entrapment in the valve mechanism of the port. If the camera port is the only 10/12-mm trocar being utilized for the procedure, this may require switching to a 5-mm laparoscope to use via one of the working ports to allow needles to be introduced into the peritoneal cavity.

In more complex cases of difficult-to-reach lymphoceles, where an omental wick may not be expected to maintain durable patency, laparoscopic marsupialization with placement of peritoneal dialysis catheters cabled together has been utilized to maintain continued lymphoperitoneal flow (18).

Postoperative Care

The patient’s postoperative diet is advanced as tolerated and the Foley catheter is removed once the patient is able to ambulate. In male patients with a history of voiding dysfunction, the Foley catheter is left indwelling until the first postoperative day, and several scanned postvoid residual volumes are evaluated following its removal to ensure adequate bladder emptying. Intravenous pain medication is transitioned rapidly to oral analgesics once the patient is tolerating clear liquids. Laboratory studies are kept to a minimum and individualized depending upon the patient’s clinical condition.

Discharge criteria include toleration of a regular diet, passage of flatus, and pain adequately controlled on oral analgesics. Typically, patients are ready for discharge the same day, or within 24 hours of the procedure; however, the mean hospital stay in a large reported review series was 1.5 days (3).

Outcomes

Hsu et al. (3) noted a lymphocele recurrence rate of 6% over an average of 27 months of follow-up after laparoscopic marsupialization. This compares favorably to the 0% to 15% recurrence rate following open lymphocelectomy reported in the literature (11,17). In a comparison of a group of patients treated with laparoscopic lymphocelectomy to a contemporary group of patients treated via an open approach, Gill et al. (2) reported a statistically significant reduction in blood loss (34.6 versus 117.3 mL), more rapid resumption of oral intake (0.9 versus 2.5 days), shorter hospital stay (2 versus 6.1 days), and more rapid convalescence (2.2 versus 6.9 weeks), respectively. A $7,400 reduction in total hospital costs has also been reported for laparoscopic versus open lymphocelectomy, largely due to the significant reduction in hospital stay (15). It is important to note that more contemporary case series would likely reflect trends toward shorter hospital stays for both of these approaches.

Complications

The reported incidence of complications in one of the largest series of laparoscopic lymphocelectomy was 5% intraoperatively and 4% postoperatively (3). This compares favorably to the 0% to 12% complication rate reported following open lymphocelectomy (2,15,17). One of the most frequently occurring intraoperative complications noted by Melvin et al. (17) was division of the transplanted ureter, which occurred in 7% of their cases. Several methods have been employed to prevent this complication, including ureteral stent placement and insertion of a lighted fiberoptic stent.

The reported incidence of open conversion was shown to be 0% to 36% (15,17). Risk factors for conversion of a laparoscopic to an open approach include prior operations, multiple fluid collections, and unfavorable location of the lymphocele.

CALCULUS DISEASE

U.S. Food and Drug Administration approval of extracorporeal shock wave lithotripsy (ESWL) in 1984 marked a significant paradigm shift in the treatment of urinary tract calculus disease, moving away from open surgery to less invasive techniques. In modern urologic practice, open stone surgery now accounts for <5% of all procedures performed to treat urolithiasis (19,20).

Diagnosis

Imaging with computerized tomography (CT) is the standard today for the identification of urolithiasis. Less commonly, excretory urography, retrograde pyelography, or ureteroscopy is the diagnostic method.

Indications

Technologic advances in the design of endourologic instruments, including ureteroscopes, nephroscopes, baskets, and lithotriptors, including the holmium laser, have all contributed to the great success of minimally invasive stone therapy. Yet infrequent cases exist in which endoscopic or ESWL treatment either has failed or has low expectations for success, and in such cases, surgical stone removal remains a viable option.

Since the introduction of laparoscopic surgery in the early 1990s, urologists have recreated virtually every open stone surgical procedure using laparoscopic techniques. Appropriate patient selection is crucial to ensure that a given patient is amenable to laparoscopic management of such calculi. Some of the indications for laparoscopic stone removal include severely impacted stones (21,22), very large stones >3 cm (23), or complete staghorn stones (24). Although laparoscopy is infrequently utilized for management of urolithiasis, this technique is invaluable when truly indicated, providing a minimally invasive approach to managing select cases of urolithiasis (20,21,25). Laparoscopic stone removal is also often combined with pyeloplasty when concurrent stones are present with ureteropelvic junction obstruction (26).

Alternative Therapy

As noted, ESWL, ureteroscopic, or percutaneous techniques are the preferred standard for the management of urolithiasis. Open ureterolithotomy is another alternative to the laparoscopic approach. Robotic surgery, particularly due to reconstructive capabilities, has been reported for large renal stones, with and without concomitant ureteropelvic junction repair (27,28).

Surgical Technique

The precise location of the stone must be identified with preoperative imaging. Noncontrast CT provides detailed anatomic information. The planned approach for appropriate trocar placement will depend on the location of the stone and can be categorized as either *upper*, which includes calculi in the renal pelvis and the upper ureter (above the pelvic brim) (Fig. 16.5), or *lower*, for calculi in the ureter distal to the pelvic brim.

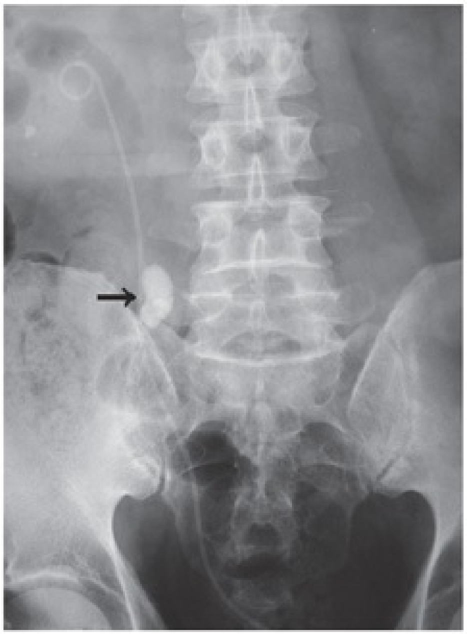

FIGURE 16.5 X-ray shows a very large calculus (*arrow*) impacted in the upper portion of the right ureter.

Placement of a ureteral stent is often required to manage large or impacted stones. To facilitate intraoperative placement of a ureteral stent, cystoscopy with ureteral catheterization should be performed at the onset of the case. If a guide wire can be manipulated past the stone, this will aid the stent placement; if a wire cannot bypass the stone, an open-ended ureteral catheter is advanced up to the level of the stone. This provides a conduit for passing a wire after the stone is removed and may help identify the ureter during the laparoscopic dissection portion of the procedure. A urethral Foley catheter is placed to drain the bladder and a suture used to secure the ureteral catheter, both of which are prepared into the operative field during laparoscopy.

Upper Stones

The patient is placed in a modified lateral recumbent position with the ipsilateral side elevated with a beanbag or kidney rest. The patient is secured to the operating room table with 3-inch silk tape across the chest, waist, and legs. The abdomen is entered with either the Veress needle or the Hasson method, at the surgeon's discretion. Port placement is similar to that used for pyeloplasty, with the camera port placed at the umbilicus. The two operating ports can be placed either in the midline, superior and inferior to the umbilical port, or lateral to the midline and 45 degrees to either side of a "line" from the camera port toward the renal pelvis or ureteral stone location (19). The axis of balance is a line joining the camera trocar to the location of the calculus. The accessory or working trocars are placed with this axis in mind (Fig. 16.6).

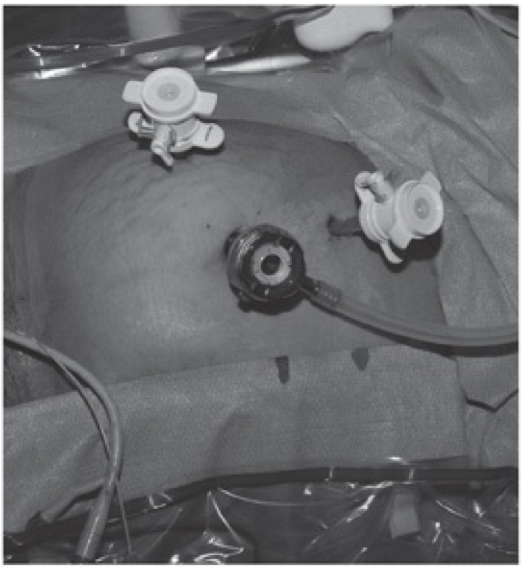

FIGURE 16.6 Patient positioned for right laparoscopic ureterolithotomy. The camera is placed in the umbilical trocar. This configuration can also be used for laparoscopic right ureterolysis, also described in this chapter.

The colon is reflected along the white line of Toldt and is allowed to fall medially, aided by airplane rolling the bed, if needed. The ureter is identified and traced to the renal pelvis or until the stone is encountered. For a ureteral stone, since the proximal ureter is usually dilated or tortuous, placement of vascular tape or a vessel loop around the ureter proximal to the stone can help prevent proximal stone migration. The ureter or renal pelvis is opened with either shears or a laparoscopic scalpel handle (Aesculap, Center Valley, Pennsylvania). The stone should be removed in one piece when possible and may have to be extracted with the use of an Endo Catch bag at the end of the procedure. A guide wire can be placed retrograde through the preplaced ureteral 5Fr open-ended catheter, followed by placement of a double-pigtail ureteral stent. The incision in the ureter or pelvis is closed laparoscopically with a 4-0 polyglactin suture (continuous or interrupted) and a closed suction drain is left in place until output subsides.

Lower Stones

For stones in the lower portions of the ureter, the patient may be left in a supine position. The peritoneum is again entered at the choice of the surgeon with the camera port placed at the umbilicus. The axis between the camera trocar and the stone is marked, and the two operating ports are then placed under direct vision on either side of the body just lateral to the rectus muscles. The surgeon stands on the contralateral side of the patient and begins the dissection at the level of the bifurcation of the common iliac vessels. The ureter is followed proximally or distally until the stone is located. The surgical procedure proceeds in a similar fashion as described earlier. For stones located in the midureter, the colon may need to be mobilized for exposure, which may be assisted by a gentle airplaning of the table to the contralateral side.

Postoperative Management

The Foley catheter is left in place for 48 hours to maintain a low-pressure drainage of the urinary tract. This will expedite removal of the peri-incisional drain. The ureteral stent can be removed with the use of a cystoscope in 2 to 4 weeks.

Outcomes

This procedure is not commonly performed and is practiced more commonly outside the United States. Success rates of over 94% are reported (29).

Complications

All standard laparoscopic surgical complications are possible, including infection, bleeding, and conversion to an open surgical procedure. Prolonged urinary leakage and urinary stricture are possible.

LAPAROSCOPIC VARICOCELE LIGATION

Dilation of the pampiniform plexus of veins draining from the testicles is encountered in up to 15% of the general male population and in 40% to 70% of men undergoing evaluation for infertility. Laparoscopic varicocele ligation closely resembles the retroperitoneal approach first described by Palomo in 1948 (30). More recently, LESS laparoscopic varicocelectomy has been applied with a tendency toward improved cosmesis and postoperative pain (31).

Indications for Surgery

Indications for surgical correction include infertility with poor-quality semen, decrease in testicular size, and chronic pain or discomfort from a large varicocele. A failed previous attempt at retroperitoneal repair is a contraindication to laparoscopic varicocele ligation. The ultimate choice of varicocele ligation method is determined by surgeon preference and experience as well as patient-specific factors.

Alternative Therapy

Several different surgical techniques have been described with inguinal (Ivanissevitch), subinguinal microscopic (Marmar–Goldstein), and open retroperitoneal or high ligation techniques (Palomo) approaches. Microscopic techniques are becoming more commonly used to reap the benefits of a less invasive procedure and reduced incidence of hydrocele. Embolization may also be used.

Surgical Technique

Most surgeons utilize the transperitoneal approach, with some reports of successful laparoscopic extraperitoneal varix ligation. The patient is placed in a supine position and the peritoneum entered at the umbilicus with either the Veress needle or Hasson technique. After creation of pneumoperitoneum, the table is rotated, and the additional operative trocars are placed under direct vision.

Two separate trocar templates exist. The first places one port just inferior to the umbilicus and lateral to the rectus muscle on the ipsilateral side, with the second port infraumbilical in the midline. The second template places both operative trocars just lateral to either edge of the rectus muscle and slightly inferior to the umbilicus. The latter allows for bilateral procedures to be performed if necessary (Fig. 16.7).

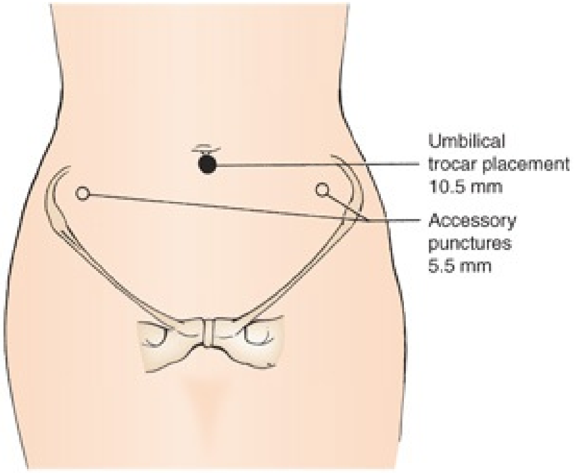

FIGURE 16.7 Appropriate position of trocars for varix ligation. The array of trocars is used in either left or bilateral varix ligation. The subumbilical trocar is either a Hasson cannula for open laparoscopy or a standard trocar inserted following Veress needle insufflation. The operating trocars are 5.5 mm when a 5-mm clip applier is available or 10 mm when one must rely upon a 10.5-mm hemoclip applier.

Once the ports are placed, attention is turned to the internal inguinal ring, and the nearby iliac vessels, vas deferens, and medial umbilical ligament are all identified (Fig. 16.8). If the colon obscures the internal ring, it should be mobilized by incising the line of Toldt or placing the patient in slight Trendelenburg position. The magnification afforded by the laparoscope aids in the visualization of the spermatic vessels running beneath the peritoneum.

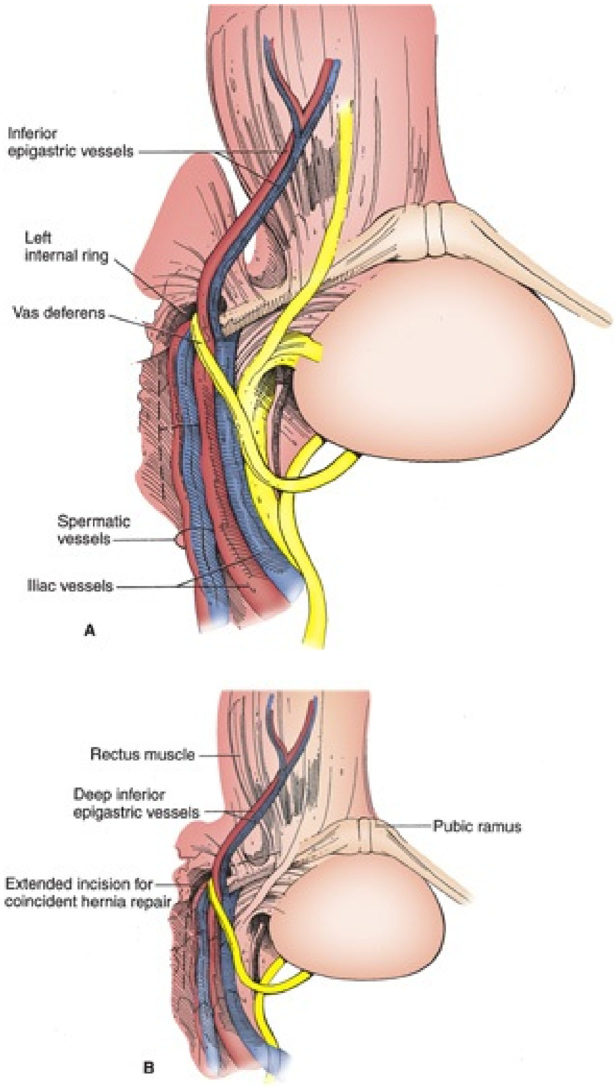

FIGURE 16.8 A 3- to 5-cm incision through the peritoneum is made lateral to the spermatic vascular bundle; it extends cephalad from a point 3 to 5 cm above the internal ring.

The peritoneum is incised lateral to the spermatic cord (see Fig. 16.8) and the testicular artery and veins are dissected free. If identified, the testicular artery should be preserved. Use of electrocautery should be restricted so as not to cause thermal injury to the artery. The use of papaverine liquid over the vessels will assist in dilation of the artery, subsequent pulsations, and easier identification of the artery. The intraoperative laparoscopic Doppler probe is helpful to identify the artery. Arterial preservation is not a requirement. The cremasteric and deferential collateral circulations are not jeopardized by the laparoscopic approach and are usually sufficient to maintain the viability of the testicle. The dissection and ligation is described in Figures 16.9 to 16.11. The vessels may be ligated with titanium clips, the endovascular stapler, or intracorporeal knot tying. After ligation, they are transected, completing the procedure. Alternatively, a bulk ligation of the cord with a 2-0 silk or stapler can be performed without regard to preserving the artery. It may be useful to divide the cord into smaller packets without regard to the spermatic artery preservation.

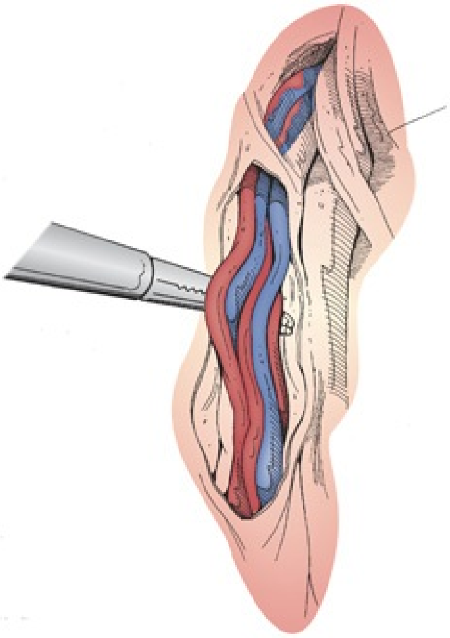

FIGURE 16.9 The entire spermatic vascular bundle is mobilized from the underlying psoas muscle. A combination of sharp and blunt dissection facilitates separation of the spermatic vessels from surrounding tissues. One should avoid deep dissection in order to spare the underlying genitofemoral nerve crossing anterior to the psoas muscle.

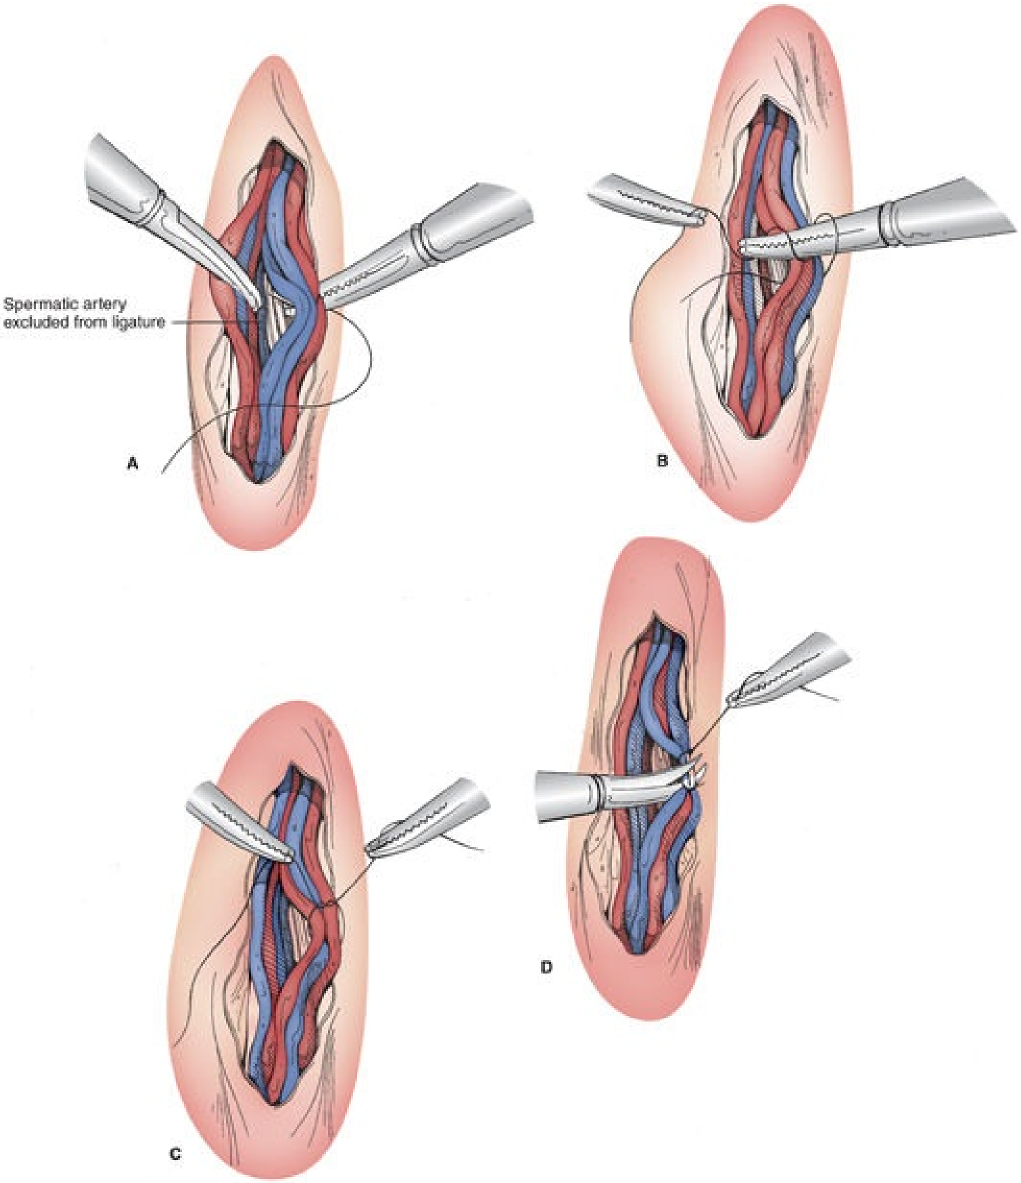

FIGURE 16.10 **A:** When performing an artery-sparing varix ligation, the vascular bundle that does not contain the spermatic artery is ligated and then divided. For small venous aggregates or single spermatic veins, the 5-mm reusable clip or suture ligature is utilized based on surgeon preference. A 5- to 10-cm ligature is passed into the abdominal cavity. One end is passed from right to left under the vessels to be ligated, extending only 1 cm beyond the vessels. The other end is long to facilitate instrument tie. **B:** The long end is grasped by the left-hand instrument, allowing sufficient slack to permit easy wrapping around the tip of the right-hand instrument. The instrument tie can be accomplished with two curved dissectors with tips rotated up. Alternatively, instruments specifically designed for laparoscopic suture and ligation may be used. **C:** The nonarterial vascular bundle is ligated. **D:** The spermatic veins are divided between ligatures.

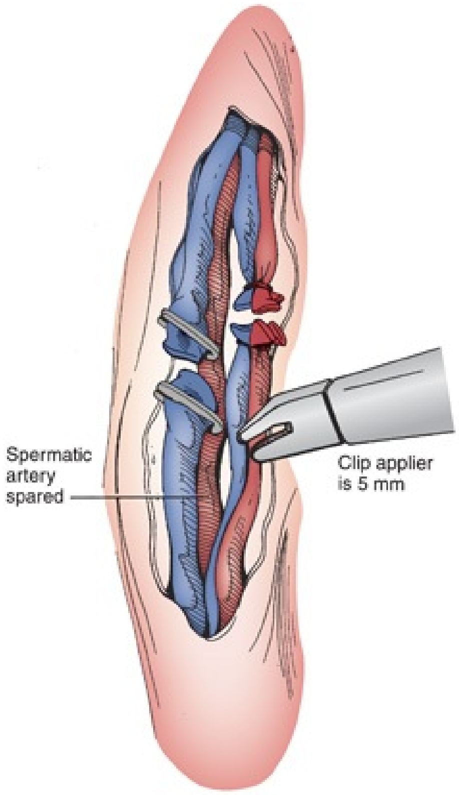

FIGURE 16.11 Upon completion of the procedure, all spermatic veins have been ligated and divided by either clip or suture. Only the spermatic artery or arteries remain, and arterial patency is documented by Doppler.

If scrotal emphysema is present, we eliminate it with brief compression before final port removal. Standard laparoscopic closure techniques are followed. Patients are discharged on the day of surgery without restrictions in physical activity.

Outcomes

Operative times vary based upon extent of operation (unilateral or bilateral), complexity of repair (artery sparing takes longer than artery sacrifice), and laparoscopic experience (novice takes longer than expert). With experience, non–artery-sparing procedures will last 15 to 30 minutes and artery-sparing procedures will last 45 to 60 minutes. A randomized trial comparing open to laparoscopic varix ligation revealed similar outcomes in terms of efficacy and complications, but advantages in terms of pain and recovery time (32). Results indicate that spermatic arterial ligation did not influence response and did not result in testicular atrophy.

Complications

Due to the age group involved, perioperative complications are very rare. Potential complications include bleeding, a need to convert to an open procedure, infection, testis atrophy or loss, and failure to correct the varicocele. Even with successful correction of the varicocele (i.e., absence of a palpable varix at 6 months following surgery), signs and/or symptoms that prompted the operation (orchalgia, oligoasthenospermia) may persist.

LAPAROSCOPIC URETEROLYSIS

Ureteral stenosis or strictures can be caused by a variety of intrinsic as well as extrinsic causes. Thus, ureteral strictures can be caused iatrogenically, such as post-ureteroscopy or following other surgical procedures in close proximity to the ureter. Stenosis may also be secondary to conditions such as retroperitoneal fibrosis (RPF) or extrinsic tumors. The clinical features include flank pain, abdominal pain, renal failure, as well as signs and symptoms of urinary tract obstruction, bacteremia, etc.

RPF is an inflammatory process involving the retroperitoneum that results in excessive fibrosis and often causes ureteral entrapment, compression, and obstruction leading to hydronephrosis. The primary, idiopathic etiology accounts for 70% of the cases, with the remainder of cases occurring secondarily in response to numerous conditions, including vascular aneurysm with or without grafting; radiation exposure; inflammatory bowel disease; malignancy; or drug exposure, including use of beta-adrenergic blockers or ergot alkaloids.

The most common presentation is colicky flank pain from ureteral obstruction; however, the fibrosis may be so extreme as to entrap the great vessels or renal vasculature, so that lower extremity edema, hypertension, or hematuria may also occur. On the other hand, ureteral strictures may be asymptomatic and can present with painless hydronephrosis (29,33,34).

Diagnosis

Preoperative imaging may consist of intravenous pyelography or CT scans, typically demonstrating hydronephrosis and medial deviation of the course of the ureter, either unilaterally or bilaterally. Retrograde pyelograms performed just prior to ureterolysis may provide updated information regarding the course of the ureter and help identify the extent (length) of ureteral entrapment.

Indications for Surgery

Ureterolysis can be both diagnostic, allowing for biopsy of the retroperitoneal mass, and therapeutic, allowing release of the ureters.

Alternative Therapy

Traditionally, ureterolysis is performed by the open surgical approach, often with a large midline incision. Many centers will attempt a trial of steroids or selective estrogen modulator such as tamoxifen empirically before surgical correction. Malignant RPF can sometimes be managed primarily by chemotherapy without the need for ureterolysis (29,33). Laparoscopic ureterolysis has the obvious cosmetic advantages compared to the open approach, and some studies suggest the added benefits of a shorter hospital stay, decreased analgesic use, and decreased transfusion rates (35,36). Recently, robot-assisted laparoscopic ureterolysis with omental wrap has been described (37,38).

Surgical Technique

Ureterolysis

Laparoscopic ureterolysis begins with cystoscopy and retrograde placement of either a double-pigtail stent or a ureteral catheter to aid in identification of the ureter during laparoscopy. Either a regular 5Fr open-ended or lighted catheter may be used. To further aid ureteral delineation from the surrounding dense fibrotic tissue, a super-stiff guide wire may also be placed inside a ureteral catheter (34). Similar to laparoscopic pyeloplasty positioning, the patient is placed in a lateral decubitus position with the ipsilateral side elevated to allow gravity retraction of the bowels. If a bilateral ureterolysis (29,33,34) is planned, the patient may either be left supine or repositioned (this is recommended) after completion of the first side.

The template for port placement will vary depending on the extent of fibrosis and the levels of the ureter involved. A standard pyeloplasty template (see earlier under calculus management) may be sufficient for isolated upper ureteral involvement, but additional ports may be necessary to free the entire ureter.

After creating pneumoperitoneum and rotating the patient, the colon is mobilized along the white line of Toldt and allowed to fall medially. When necessary, this incision is extended over the iliac vessels to allow exposure of the full course of the ureter. Depending on the extent of RPF, the ureters are often retracted medially and may be overlying the great vessels entrapped in dense fibrous scars, making localization difficult.

If a ureteral catheter was placed, gentle manipulation may help locate the ureter. Alternatively, the distal ureter may be encountered medial to the medial umbilical ligament and traced proximally, or the proximal ureter may be isolated at the ureteropelvic junction and dissected distally. Once positively identified, a window is created around the ureter and vascular tape or a vessel loop is placed around to allow retraction without undue manipulation of the ureter. Combinations of blunt, sharp, and electrocautery dissection are necessary to liberate the ureter from surrounding fibrosis, although the latter should be used sparingly to avoid vascular compromise. For patients with RPF, after the ureter is mobilized, it should be intraperitonealized, and after this is accomplished, the posterior peritoneum is closed with clips or preferably with sutures. Laparoscopic omental wrap can be performed to further isolate the ureter using a variety of techniques as described by Stein et al. (39). If a ureteral catheter was placed at the onset, it should be exchanged for an indwelling self-retaining ureteral stent at this time. Special efforts must be made to rule out malignancy as the underlying cause of the fibrosis, and multiple biopsies are taken from periureteral tissues and sent for both frozen and permanent analysis.

Laparoscopic ureterolysis is also amenable to hand-assisted laparoscopic approaches and has also been reported using robotic techniques. The principles of ureterolysis can be followed with the use of the intra-abdominal hand to assist in identification and dissection of the ureter (33). Robot-assisted laparoscopic ureterolysis has been shown to compare favorably with the pure laparoscopic technique, with the theoretical advantages inherent to robotic surgery (37,38).

Management of Ureteral Strictures

For benign, iatrogenic or idiopathic ureteral strictures, the strictured ureteral segment is excised. Caution should be exercised around the iliac vessels and the inferior vena cava so as to prevent vascular injury. The ureteral ends are then spatulated. The posterior walls of the ureteral ends are anastomosed using 4-0 polyglactin sutures. A ureteral stent is then placed in a retrograde fashion utilizing the 5Fr open-ended ureteral catheter, which is removed after a guide wire is placed through it. The anterior end-to-end anastomosis of the ureteral ends is now completed. A closed-suction drain is placed. A Foley catheter drains the bladder postoperatively to maintain a low-pressure urinary drainage system.

If the ureteral stricture is long, and if the anastomosis is under tension, then the management strategy may involve further laparoscopic ureterolysis to ensure a tension-free anastomosis. Rarely, one may have to utilize procedures such as nephropexy to enable a tension-free end-to-end ureteroureterostomy.

Postoperative Management

The Foley catheter is usually left indwelling for 48 hours. The drain is kept in place for another day or two, then removed. The indwelling stent is removed using a flexible cystoscope 4 to 6 weeks postoperatively. Postoperative imaging is recommended to evaluate for any residual or silent recurrence of the hydronephrosis.

Outcomes

A recent multicenter review indicated overall success rates of 83% per renal unit (29). This was confirmed by follow-up imaging in these cases. Other institutional series are also favorable (29,33,35).

Complications

Any complication that can be associated with laparoscopy, including conversion to an open procedure, has been reported. One series reported a conversion rate to open of 17.6% (35).

SECTION II ■ BLADDER

Section Editor: STEPHEN J. SAVAGE

CHAPTER 17 ■ ANATOMY OF THE BLADDER

CLINTON W. COLLINS AND ADAM P. KLAUSNER

GENERAL DESCRIPTION

The bladder is a hollow, muscular retroperitoneal organ with a capacity of 400 to 500 mL in the normal adult. The bladder is a pelvic organ when empty, lying behind the pubic symphysis. However, when distended, it can be palpated above the pubic symphysis and can protrude well into the abdomen during an episode of severe urinary retention.

PERITONEAL RELATIONSHIPS

The peritoneum covers the superior and a portion of the posterior bladder. In females, the peritoneum continues posteriorly onto the surface of the uterus and rectum, establishing the vesicouterine and rectouterine pouches, respectively (Fig. 17.1) (1). In the male, the peritoneum continues along the surface of the rectum, establishing the rectovesical pouch of Douglas. The two leaves of the peritoneum embryologically coalesce to form the anterior and posterior layers of Denonvilliers fascia (rectovesical fascia), a critical landmark in the performance of a radical retropubic prostatectomy (Fig. 17.2) (2).

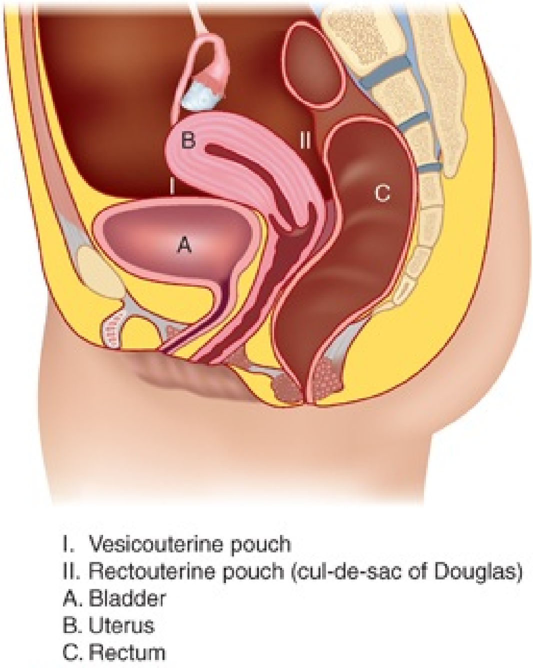

FIGURE 17.1 Sagittal view of female pouches.

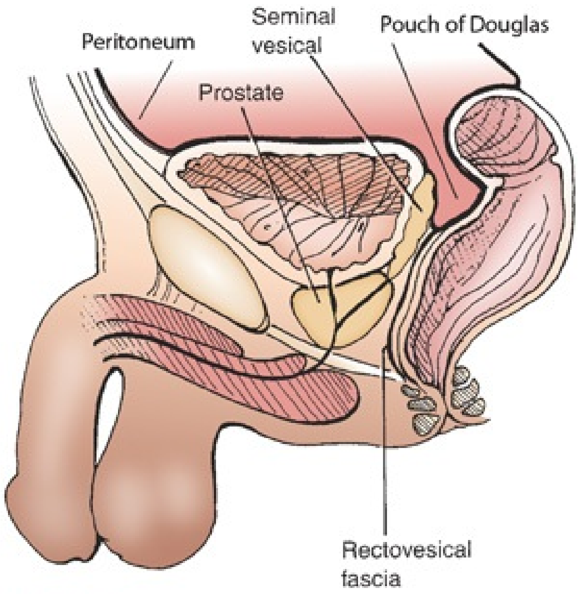

FIGURE 17.2 Lateral view of the male pelvis showing the peritoneal reflection and the pouch of Douglas.

PERITONEAL FOLDS

As seen from a typical laparoscopic approach to the abdominal cavity, the anterior surface of the peritoneum has three characteristic deflections, also called folds. The midline fold is called the *median umbilical ligament* and the paired paramedian folds are called the *medial umbilical ligaments*. Fortunately, the anatomy itself is less confusing than the terminology. In relation to the bladder, the median umbilical fold is the most important of these structures as it contains the urachal ligament. Attaching to the bladder anteriorly at its dome, this ligamentous structure, containing fatty and vascular tissue, tethers the bladder to the umbilicus. This structure, which represents the obliterated urachus, contains paraumbilical veins and must be ligated when divided during surgical exposure of the bladder. The bladder muscle, also called the detrusor, is attenuated where the urachal ligament attaches, predisposing this area to the formation of diverticula. Retropubic and perivesical fat is present anteroinferior and lateral to the bladder.

LIGAMENTOUS ATTACHMENTS

In the pelvis, the bladder is supported anatomically by two types of ligaments: fibroareolar (true) ligaments and peritoneal folds. True ligaments provide support for the bladder laterally via the lateral ligament of the bladder and posteriorly via the vesicovenous plexus. The lateral ligament derives from the transversalis (endopelvic) fascia as it courses over the levators and attaches the bladder to the tendinous arch of the endopelvic fascia. This ligament contains the inferior vesical and vesicodeferential arteries in the lateral extensions as well as the pudendal plexuses of nerves and vessels. In addition, in males, this ligament contains the vasa deferentia. The posterior ligaments provide posterolateral support to the bladder. These ligaments are connective tissue condensations in which the vesical venous plexus drains into the internal iliac veins. Peritoneal folds also connect the bladder to the pelvic sidewalls and consist of the median, medial, and lateral umbilical folds as well as the sacrogenital folds. The median umbilical fold and medial umbilical folds originate at the bladder and terminate at the umbilicus. They contain the urachus and the obliterated umbilical arteries, respectively. The lateral umbilical folds attach the bladder to the pelvic sidewalls and contain the inferior epigastric arteries. The sacrogenital folds connect the bladder to the sacrum (Fig. 17.3)

The bladder is also fixed to the symphysis pubis by the pubovesical ligaments in females and the puboprostatic ligaments in males. The dorsal vein of the clitoris or penis passes between these paired ligaments. These ligaments represent an important surgical landmark as they form the anteromedial portion of the retropubic space, also called the space of Retzius. The space of Retzius is bound anteriorly by the transversalis fascia, inferiorly by the puboprostatic (pubovesical) ligaments, and infralaterally by the lateral ligaments of the bladder (Fig. 17.4).

HISTOLOGIC STRUCTURE

The lumen of the bladder is lined by transitional epithelium, also called urothelium. This unique epithelium is characterized by its outer layer of umbrella cells, which are sealed closely together and communicate via tight junctions. The term *transitional* denotes the ability of these outer cells to undergo significant transitions in shape depending on the state of bladder filling. Thus, the cells are puffy and cuboidal when the bladder is empty and become flat and elongated when the bladder is distended (4). Beneath these umbrella cells, the transitional epithelium contains additional layers of cells (usually about seven) and a distinct layer of basal cells. Deep to the transitional epithelium lies the lamina propria, composed of fibroelastic connective tissue through which vessels course. Wisps of smooth muscle also course within the lamina propria, and this portion of the lamina propria is sometimes referred to as the muscularis mucosa (Fig. 17.5).

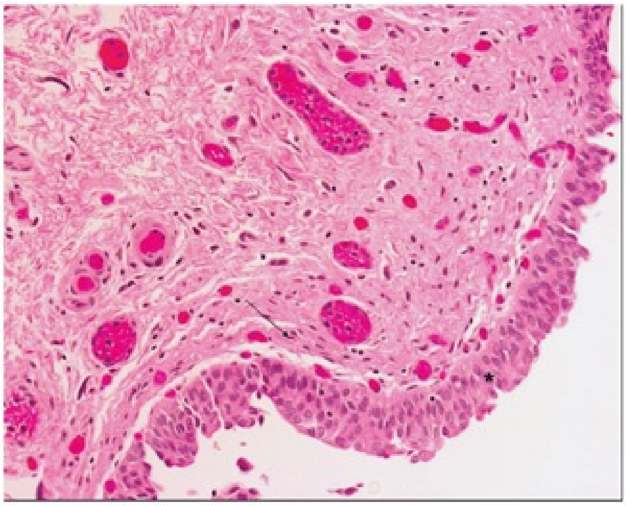

FIGURE 17.5 Microscopic image of normal bladder. Note wisps of smooth muscle (*arrow*) within the lamina propria (*asterisk*).

The distinction between the muscularis mucosa and muscularis propria or true muscular layer of the bladder that lies deep to the lamina propria is critical in the staging and prognosis of urothelial cancer. Cancer that is confined to the urothelium or lamina propria, even when surrounded by wisps of muscularis mucosa, is considered superficial disease and is mainly treated via local resection or with intravesical immuno- or chemotherapeutic agents. However, cancer that penetrates into the muscularis propria, characterized histologically by large, distinct detrusor smooth muscle bundles (Fig. 17.6), is considered invasive cancer and is treated more aggressively, usually requiring surgical removal of the entire bladder or bladder-preserving chemoradiation. Within the muscularis propria, detrusor smooth muscle bundles course in inner longitudinal, middle circular, and outer longitudinal orientations. In addition, interstitial cells surround and percolate within the muscle bundles and may be important in maintenance or modulation of bladder muscle tone (5). These muscle layers are less distinct in the upper aspect of the bladder. However, they become quite prominent at the bladder neck, although composed of finer fibers. In males, the middle layer of circular detrusor smooth muscle forms a preprostatic layer that has robust expression of alpha receptors (mainly alpha 1a) and contributes to continence at the bladder neck. Furthermore, the success in treatment of benign prostatic hyperplasia with alpha blockers stems, in part, from a pharmacologic reduction in tone in the smooth muscle surrounding the prostate and bladder neck (6). In females, the bladder neck differs dramatically, with a less distinct middle layer of smooth muscle (1,7).

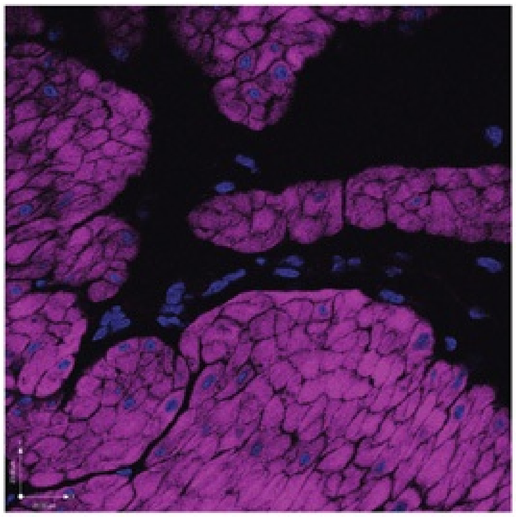

FIGURE 17.6 Confocal immunohistochemical imaging showing detrusor bundle. Detrusor bundle is stained purple with phalloidin, which binds actin in detrusor smooth muscle cells. Nuclei within detrusor smooth muscle bundles and nuclei within interstitial cells are stained blue with DAPI, which binds strongly to DNA.

URETERAL VESICAL JUNCTION AND TRIGONE

The spiral fibers of the ureter become more longitudinally oriented near the bladder and are encased in the fibromuscular Waldeyer sheath from a distance just proximal to its entrance into the bladder wall through its course to the trigone (1,8). Obliquely, the ureters enter the bladder posteroinferiorly and course approximately 2 cm toward the ureteral orifice, narrowing as the intramural ureter is compressed by the detrusor of the bladder surrounding it. The ureter lies just beneath the bladder mucosa with a muscular layer backing (1).

A distinct landmark is formed at a triangle located between the ureteral orifices and the bladder neck, referred to as the bladder trigone. Layers of ureteral and bladder smooth muscle coalesce here as a raised ridge of tissue between the two orifices referred to as the interureteric ridge. This ridge is helpful in identifying the ureteral orifices endoscopically (Fig. 17.7). The trigone is composed of three distinct layers: (a) a superficial layer derived from the longitudinal layer of ureteral smooth muscle; (b) a deep layer that is continuous from Waldeyer sheath, inserting at the bladder neck (Fig. 17.8); and (c) the detrusor layer, derived from the outer longitudinal and middle circular layers of smooth muscle (1). The unique anatomic structure of the intramural ureter and trigone contributes to the intrinsic antireflux mechanism, which prevents vesicoureteral reflux during bladder filling and voiding.

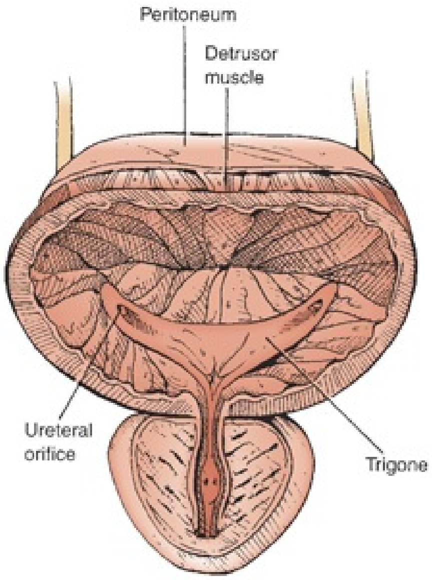

FIGURE 17.7 Anterior view of the bladder of a male opened and demonstrating intravesical anatomy. Note the trigone continues into the prostatic urethra.

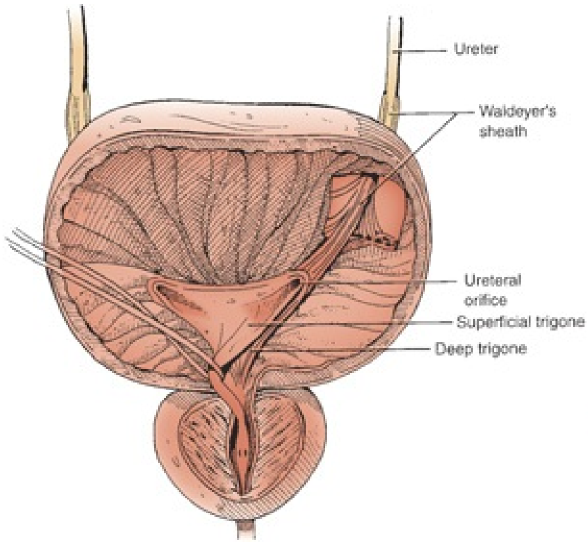

FIGURE 17.8 Lateral view of ureter as it enters the bladder via the intramural tunnel. Note Waldeyer sheath extends from the bladder to encase the distal ureter just proximal to the bladder and fuses to the ureteral musculature. Waldeyer sheath is a continuation of the deep trigone and connects by a few fibers to the detrusor muscle at the ureteral hiatus.

BLOOD SUPPLY

Multiple blood vessels supply the urinary bladder; however, the exact vascular anatomy can vary somewhat between individuals. Less variable is the presence of two more distinct collections of vessels referred to as the lateral and posterior pedicles (Fig. 17.9). In the male, the lateral and posterior pedicles are also called the lateral and posterior ligaments. In the female, these vascular pedicles are part of the cardinal and uterosacral ligaments. The blood vessels within these pedicles branch from the superior and inferior vesical arteries. The superior vesical artery arises from the internal iliac close to its origin from the common iliac. It can also arise as a branch from the umbilical artery, which branches off of the proximal internal iliac. The inferior vesical artery branches off of the internal iliac artery at a more distal location. However, it is important to recognize that the arterial supply to the bladder may arise from *any* portion of the internal iliac. In terms of venous drainage, veins from the bladder drain predominantly into lateral plexi and then empty into veins within the lateral prostatic ligaments and ultimately into the internal iliac veins (1).

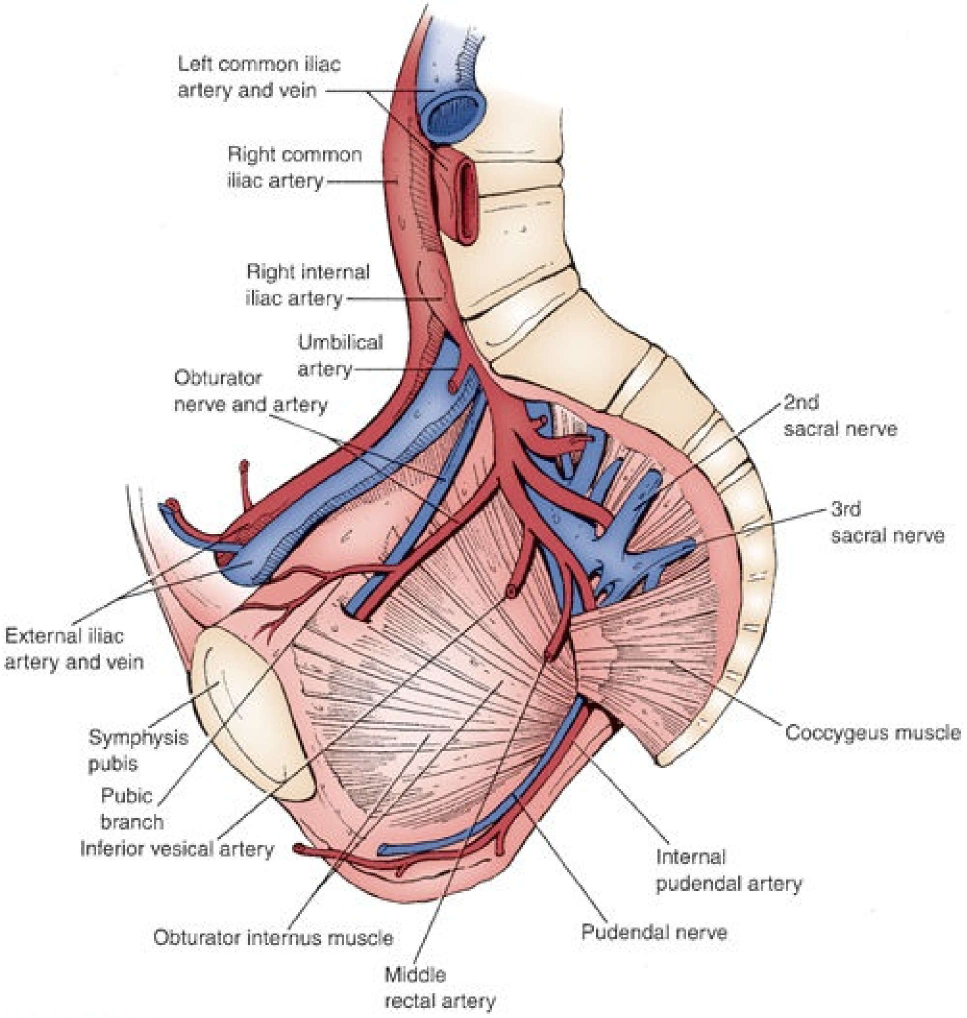

FIGURE 17.9 Lateral pelvic side wall demonstrating the vasculature and innervation of the deep pelvis. The arterial supply of the bladder is from the superior lateral vesical artery and the inferior vesical artery enclosed in the posterior pedicle.

INNERVATION

Sensory Innervation

In the bladder, there are two types of sensory (afferent) nerve fibers: alpha-delta and C fibers. Alpha-delta fibers are partially myelinated and carry information to the central nervous system regarding bladder fullness and wall tension. These sensory fibers are responsible for initiating the normal voiding reflex. On the other hand, C fibers are unmyelinated nociceptive fibers that mainly carry information to the central nervous system regarding noxious or painful stimuli. Although these C fibers comprise about 70% of the total afferent nerves supplying the bladder, they are generally silent and only become sensitive during inflammation, irritation, or suprasacral spinal cord injury. Prolonged activation of C fiber afferents may be responsible for the development of pathologic voiding reflexes associated with some forms of overactive bladder.

Sensory or “afferent” fibers from the bladder are contained in the pelvic, hypogastric, and pudendal nerves. Afferent fibers in the pelvic and pudendal nerves enter the sacral spinal cord via dorsal root ganglia, with the most prominent projection passing anterolateral toward the sacral parasympathetic nucleus. Afferent fibers in the hypogastric nerves also enter the spinal cord via dorsal root ganglia in the lumbar spinal cord. Afferent fibers from the external urethral sphincter pass through Onuf nucleus in the sacral spinal cord.

Motor Innervation

Motor innervation to the bladder arises from three sets of nerves: (9) the *parasympathetic* sacral (pelvic) nerve, arising from the sacral spinal cord between S2 and S4; (6) the *sympathetic* thoracolumbar (hypogastric) nerve, arising from the spinal cord between T10 and L2; and (10) the *somatic* pudendal nerve, which also arises between S2 and S4. In humans, parasympathetic preganglionic motoneurons reside in the sacral intermediolateral cell group in the sacral cord segments at S2–S4, and their axons reach the bladder via pelvic nerves (11,12). In the cat and human, the motoneurons to the external urethral sphincter (EUS) are located in Onuf nucleus in the ventral horn at the level S1–S2 of the spinal cord (13,14).

THE MICTURITION REFLEX

Pontine Micturition Center

Barrington (9) helped define a crucial structure of the micturition reflex located in the dorsolateral pons by showing that bilateral lesions in this area in the cat result in urinary retention. This area is known as the pontine micturition center (PMC), Barrington nucleus, or the M-region. The PMC projects to the sacral parasympathetic nucleus located in the sacral intermediolateral cell column and to the sacral intermediomedial cell column or dorsal grey commissure (DGC) (15).

Stimulation of the PMC causes detrusor contraction via synapses located in the aforementioned intermediolateral cell column from S2 to S4, and this signal travels to the bladder via pelvic nerves (16). Stimulation of the PMC also causes relaxation of EUS (15,17).

Damage to the spinal cord between the sacral motor outflow and the PMC leads to a characteristic pattern of neurogenic detrusor overactivity (involuntary contractions) and detrusor external sphincter dyssynergia (lack of coordination between the bladder and urethral sphincter) due to lack of the complex coordination of urine storage and voiding reflexes previously described. In this situation, the coordinated spinal→ bulbo→ spinal reflex is converted to an uncoordinated spinal→ spinal reflex. This is similar to the reflex present in the neonate prior to higher level brain development.

External Urethral Sphincter

The striated EUS is innervated by the pudendal nerve. The PMC stimulates GABA-ergic interneurons in the intermediomedial cell column (DGC), which subsequently inhibit the motoneurons located in Onuf nucleus. This leads to inhibition of the EUS via the pudendal nerve (18,19). Signals from the PMC also inhibit sympathetic outflow from the hypogastric nerve, leading to relaxation of the bladder neck, a process which facilitates emptying.

An Alternate Micturition Reflex

Projections from sensory neurons in the lumbosacrum only weakly communicate directly with PMC in humans, so there must be another pathway of communication from the bladder to the PMC (20). Projections between periaqueductal gray (PAG) in the caudal brainstem and the lumbosacrum appear to contain important sensory information from the bladder. This information then travels to the PMC so micturition can occur at an appropriate level of filling. Evidence for this includes observations that interruption of fibers between PAG and PMC result in a low capacity bladder, contracting at volumes of only a few milliliters (21). In addition, stimulation of PAG results in complete micturition (22).

Further support for the PAG's role in afferent input to the PMC is the interesting distinction between the sensory organization of humans and cats (higher mammals) and lower mammals (rodents). When rats are taken out of their cage, they urinate, but humans rarely urinate in stressful situations. An explanation may come from investigations revealing a more direct projection of sensory fibers in the lumbosacral cord to PMC in rats, perhaps reemphasizing the importance of the relay in humans between the lumbosacrum, PAG, and PMC (10,11).

Analyzing functional positron emission tomography (PET) and magnetic resonance imaging studies, Griffiths and Tadic (23) hypothesize a model (Fig. 17.10) in which secondary bladder afferents leaving the sacral and lumbar spinal cord synapse in the PAG and are relayed to the insula (right insula), forming the substrate for sensation. Insula representation may have slight right-sided predominance. The anterior cingulate gyrus (ACG) is responsible for monitoring, arousal, and efferent output to the PAG and PMC. The prefrontal cortex is involved in voluntary decision about voiding and generates efferent signals to control ACG and ultimately PMC. PMC provides motor output to cause voiding, as described earlier in this section (Fig. 17.11).

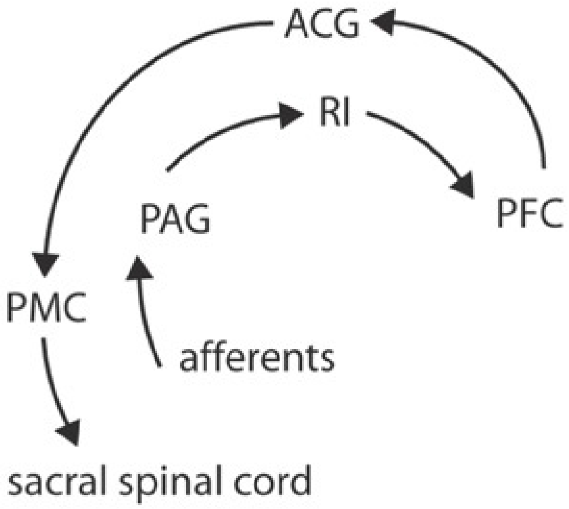

FIGURE 17.10 Griffiths and Tadic (23) hypothesis explaining a proposed periaqueductal gray (*PAG*) circuit and its connection to pontine micturition center (*PMC*). *ACG*, anterior cingulate gyrus; *PFC*, prefrontal cortex; *RI*, right insula.

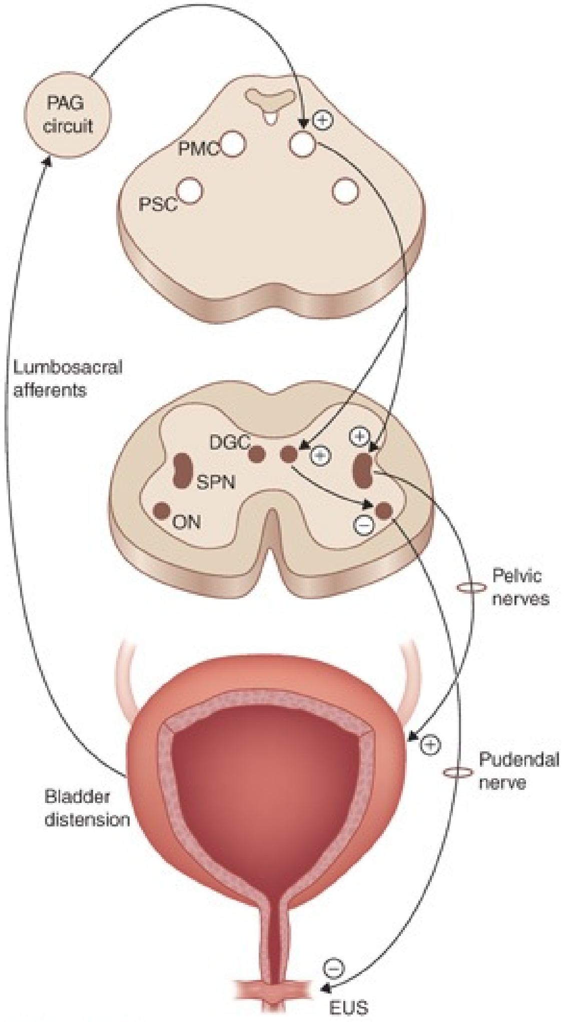

FIGURE 17.11 Micturition phase of bladder function. Micturition is stimulated by bladder distension. Sensory fibers carry information about bladder distension to the sacral spinal cord. Signals then ascend via pathways in the dorsal columns to the pontine micturition center (*PMC*). The *PMC* is the main center for coordination of lower urinary tract function. Information may pass through projections from the periaqueductal gray (*PAG*) (see Fig. 17.10) to the *PMC* (20). Motor responses then relay information back to the sacral parasympathetic nucleus (*SPN*), which ultimately triggers an excitatory stimulus for bladder contraction. Inhibitory signals to the dorsal grey commissure (*DGC*) leads to inhibition of Onuf nucleus (*ON*) and relaxation of the external urethral sphincter (*EUS*).

THE STORAGE REFLEX

Storage is facilitated by bladder afferent stimulation of Onuf nucleus, which increases tone of the EUS via the somatic pudendal nerve. A group of cells known as the pontine storage center (PSC) or L region is located more ventrally and laterally in the pons than the PMC. It projects to Onuf nucleus and is involved in the storage of urine during continence via a continuous excitatory effect during filling (11,15). Of note, the PMC and PSC are not interconnected at the level of the brainstem (24).

Simultaneously, the hypogastric (sympathetic) nerve, receiving input from pelvic afferents, inhibits detrusor muscle and bladder ganglia while stimulating the internal urethral sphincter (bladder neck), which has robust expression of alpha-1 receptors. As mentioned earlier, pharmacologic reduction in this bladder neck tone with alpha blockers is a mainstay for the treatment of benign prostatic hyperplasia as well as detrusor sphincter dyssynergia and other forms of voiding dysfunction (Fig. 17.12).

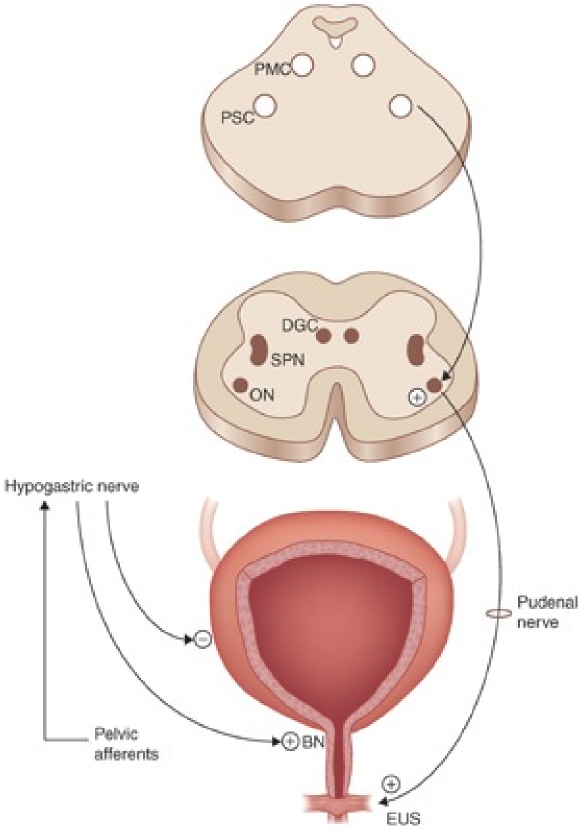

FIGURE 17.12 Storage phase of bladder function. Messages from the pontine storage center (*PSC*) stimulate Onuf nucleus (*ON*). Signals from *ON* travel via the pudendal nerve to stimulate the external urethral sphincter (*EUS*), resulting in continence. *DGC*, dorsal grey commissure; *PMC*, pontine micturition center; *SPN*, sacral parasympathetic nucleus.

ANATOMY OF SACRAL NEUROMODULATION

Sacral neuromodulation was largely pioneered by the work of Tanagho and Schmidt (25), whose studies focused on its use for the management of neurogenic bladder dysfunction, and by Shafik (26) whose studies revealed that stimulation of the EUS inhibits detrusor contraction.

It seems paradoxical that both detrusor overactivity and urinary retention can be improved with sacral neuromodulation, but there now exists decades of research to help explain why. Although the mechanism of action of sacral neuromodulation is not completely understood and is thought to be multifactorial, afferent pathways appear to play a crucial role as they modulate the activity in other neural pathways within the spinal cord and higher centers (27). One theory is that stimulating afferent pathways inhibits sacral interneuronal transmission, interrupting signals between the bladder and the pontine micturition center (28). This may explain why voluntary micturition is unaffected by sacral neuromodulation (29).

In studies of the latency of pelvic floor contraction during peripheral nerve evaluation, Fowler et al. (30) showed that the muscle response is reflexively mediated. These researchers measured latency of anal sphincter contraction in patients undergoing peripheral nerve evaluation of the S3 foramen, and based on longer latency between stimulation and contraction, they concluded that direct stimulation of the pudendal nerve could not be primarily involved. Instead, a more complex system than efferent stimulation must be involved. A study in patients with spinal cord injury concluded that although spinal pathways may be involved in the anal and pelvic floor response to S3 stimulation, supraspinal structures appear necessary for improvement in continence (31). Using stimulation of the dorsal penile nerve, a purely sensory nerve, the effect of pudendal afferent activity in sacral neuromodulation was demonstrated (32).

In separate studies using PET imaging during sacral neurostimulation, Blok et al. (33) and Dasgupta et al. (34) demonstrated that cortical and brainstem activity are affected by this therapy. Dasgupta's work suggests that brainstem activity can be improved with sacral neuromodulation, and this may help treat urinary retention in patients with external sphincter overactivity.

LYMPHATICS

The lymphatic drainage of the bladder is to the external iliac vein, the hypogastric nodes, or to the presacral promontory.

CONTIGUOUS STRUCTURES

In the male, the bladder joins the prostate and is anterior to the seminal vesicles and ampulla of the vas deferens. In the female, the bladder is in more direct contact with the pubococcygeus portion of the levator ani. Superiorly, the bladder is covered by peritoneum in both males and females. Posteriorly in females, the bladder is adjacent to the uterus and vagina. In males, the posterior bladder is adjacent to the seminal vesicles and rectum.

CHAPTER 18 SIMPLE AND PARTIAL CYSTECTOMY

RYAN S. LEVEY AND JONATHAN C. PICARD

SIMPLE CYSTECTOMY

Simple cystectomy is performed in the setting of benign disease requiring urinary diversion or locally invasive nongenitourinary malignancy. Simple cystectomy involves removal of the bladder without resection of adjacent structures or performance of a formal lymph node dissection. The other pelvic organs are also left intact; to preserve sexual function, the prostate, seminal vesicles, and urethra are spared in the male patient and the uterus, anterior vagina, adnexa, and urethra are spared in the female patient. Removal of a defunctionalized bladder is often very beneficial and can prevent many complications.

Diagnosis

Preoperative evaluation should include a complete history and physical examination. Specifically, a thorough investigation into the etiology of the voiding dysfunction, radiation treatments, prior pelvic surgeries, and all other interventions leading up to this evaluation should be performed. Biopsy should be undertaken if primary bladder malignancy is a consideration. Preoperative imaging of the abdomen and bladder are usually helpful, and we prefer both noncontrasted and contrasted computerized tomography (CT) scans of the abdomen and pelvis with delayed images to allow for visualization of the ureters and any abdominal or pelvic pathology that would preclude the procedure.

Indications for Surgery

Urinary diversion is indicated for patients who have refractory conditions such as severe radiation or chemical cystitis, intractable bladder pain from interstitial cystitis, severe urinary incontinence, neurogenic bladder, extensive trauma, large fistula formation involving the bladder, or recurrent pyocystis. Simple cystectomy can also be undertaken for invasive nongenitourinary cancers that are not amenable to resection with partial cystectomy.

Previous attempts at urinary diversion without concomitant simple cystectomy have led to complications in 54% to 80% of patients (1–3). Complications include pyocystis, intractable hemorrhage, severe pain or spasms, and the sensation of incomplete emptying. In these patients, the salvage cystectomy rate ranges from 20% to 30% (1–3). One recent series purports much lower rates of complications. They describe only 7% of their 60 cases as having complications (three pelvic pains and one pyocystis) with none requiring salvage cystectomy (4). Given the lack of quality data, we recommend concomitant simple cystectomy when permanent urinary diversion is undertaken.

Additionally, the risk of developing urothelial cancer of the bladder is significantly increased in patients who have received previous pelvic irradiation (relative risk = 4.6) (3). Some authors have even cited a risk for malignant degeneration in the setting of chronic irritation such as interstitial cystitis (3).

Alternative Therapy

Radical cystoprostatectomy in men and radical cystectomy in women should be considered as alternatives to simple cystectomy in the setting of possible prostate cancer or urothelial carcinoma (UCC) and can be considered as alternatives in nongenitourinary malignancies that are locally invasive into the bladder or in many benign diseases of the bladder. In the majority of patients, continued observation, hyperbaric oxygen, analgesic prescription, and other symptomatic treatments are the initial options, with simple cystectomy only being offered as a final intervention in patients with refractory nonmalignant disease.

In patients with nongenitourinary malignancies that are locally invasive into the bladder, simple cystectomy can be considered if the resection can be accomplished with negative margins. Laparoscopic and robotic-assisted laparoscopic techniques are also being refined and are certainly an option for appropriately trained surgeons, despite the fact that these procedures are often difficult due to the challenges of previously irradiated fields, previous surgery, and chronic infection or inflammation. Further, one group has developed a novel operative technique where the bladder is bivalved and resected, leaving a bladder base including the trigone and bladder neck. The remaining mucosa is then resected and fulgurated, with a small rim of detrusor muscle preserved (5). This technique may become another option with further validation over time.

Surgical Technique

Simple cystectomy can be undertaken extraperitoneally to avoid abdominal adhesions due to multiple previous surgeries or radiation; however, we prefer an intraperitoneal approach as these patients also frequently require concomitant urinary diversion. Antithrombotic medication, pneumatic compression cuffs, or compression stockings should be strongly considered prior to induction of anesthesia. The patient is positioned supine on the operating room table with the anterior superior iliac spines positioned over the inferior portion of the table break or kidney rest. The table is flexed to facilitate exposure, and the bed is slightly tilted in the Trendelenburg position until the abdomen is parallel to the floor. When urethrectomy is planned, a modified lithotomy position provides improved exposure to the perineum. The abdomen and pelvis are then prepped with an antimicrobial solution extending from the costal margin superiorly to the perineum, including the penis in men and the vagina in women. The patient is draped, and a Foley catheter is inserted following sterile procedures. The bladder is allowed to drain completely. Filling the bladder with 150 to 200 mL of sterile water may facilitate the dissection.

An intravenous antibiotic agent should be administered less than 1 hour prior to skin incision. A lower midline incision extending from the umbilicus to the pubic symphysis is made. The anterior rectus fascia should be opened sharply, and the rectus abdominis muscles in the midline should then be separated to facilitate entry into the space of Retzius.

The extraperitoneal space lateral to the bladder should be bluntly developed by extending the dissection from the bladder neck cranially to the dome of the bladder. In benign conditions, incising the anterior bladder wall may facilitate the dissection. The peritoneum should be incised lateral to the bladder in a posterior direction. The ureters can often be identified as the peritoneum is divided and reflected. They should then be dissected from their surrounding attachments, with care being taken to maintain a sufficient amount of periureteral tissue. The ureteral dissection should be continued proximally and distally. In women, care must be taken to avoid the uterine artery during the distal ureteral dissection. When the superior vesical arteries are encountered crossing anterior to the distal ureters, they should be ligated with 2-0 silk ties and divided (Fig. 18.1) to allow for improved exposure of the distal ureter and maximization of the ureteral length. The ureters are then clipped close to their insertion into the bladder and divided sharply. They can be packed away to prevent injury during the remainder of the bladder dissection.

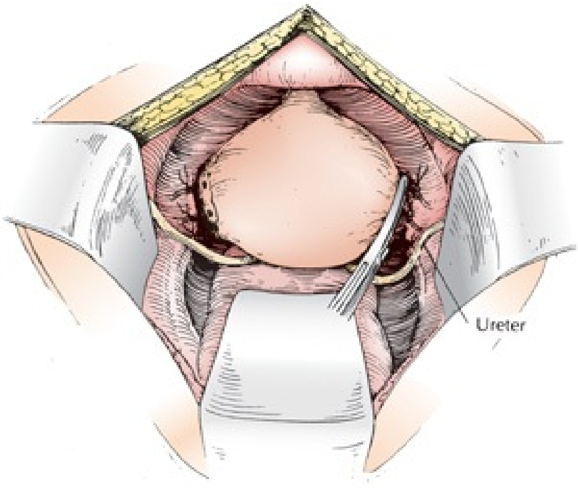

FIGURE 18.1 The vesical pedicles are clipped and divided.

In male patients, we begin our posterior dissection several centimeters anterior to the peritoneal reflection and enter the plane between the bladder (anterior) and the vasa deferentia and seminal vesicles (posterior) (Fig. 18.2). This dissection is continued to the prostatovesical junction using a combination of blunt and sharp dissection. Attention is then returned to the anterior dissection of the prostatovesical junction. The veins overlying the prostate and bladder can be ligated with 3-0 silk suture and divided. The bladder is then drained and the Foley catheter removed. Bovie cautery is used to transect the bladder in an anterolateral direction, and the posterior bladder wall is then divided to expose the previously exposed vasa deferentia and seminal vesicles (Fig. 18.3). The lateral vascular pedicles should be readily visible and can be ligated with 2-0 silk ties and divided. Instead of suture ligation, these pedicles can also be divided using an electrothermal bipolar sealing system such as a LigaSure device or using a linear cutting surgical stapler with the appropriate staple load. At this point, the bladder should be free and can be removed. The urethra is oversewn with 3-0 Vicryl suture, and the prostatic surgical capsule is oversewn with 0 Vicryl suture (Fig. 18.4). If significant prostatic hyperplasia prevents adequate closure of the capsule, a simple prostatectomy should be considered followed by closure of the prostatic surgical capsule as previously described.

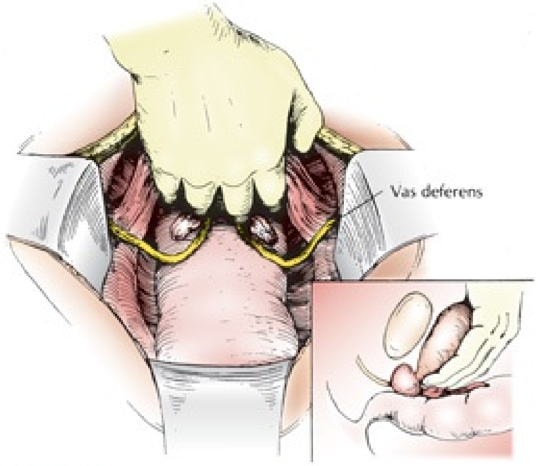

FIGURE 18.2 The plane between the bladder (anterior) and the vasa deferentia and seminal vesicles (posterior) is dissected.

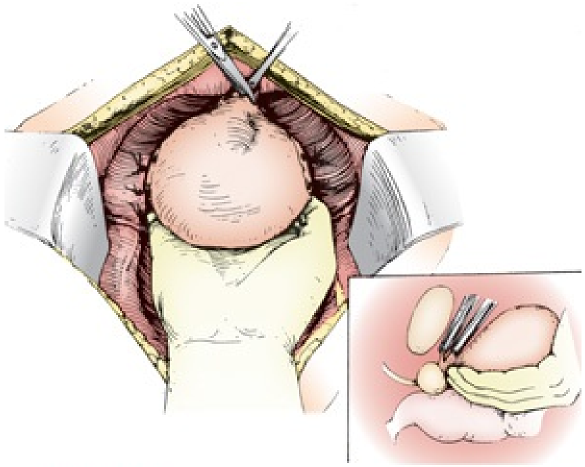

FIGURE 18.3 The bladder neck is incised anteriorly.

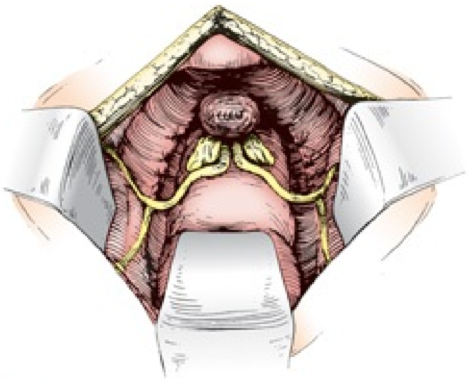

FIGURE 18.4 The bladder is removed. The urethra is oversewn. The prostatic surgical capsule is oversewn.

In female patients, the posterior dissection begins anterior to the peritoneal reflection. The plane between the bladder and the anterior vaginal wall is entered and is developed with sharp and blunt dissection. An intravaginal sponge stick is beneficial for traction and identification of the proper planes. During this dissection, the lateral pedicles are ligated with 2-0 silk ties and divided as they are encountered. Upon reaching the bladder neck, the Foley catheter is removed and Bovie cautery is used to transect the urethra. The urethral stump is then oversewn with 3-0 Vicryl sutures. Some authors advocate complete urethrectomy including the meatus in patients who have cystectomy performed for interstitial cystitis.

After the cystectomy is complete, the wound is copiously irrigated with sterile water. A closed drainage system, such as a Jackson-Pratt or Blake drain, is almost universally placed in the pelvis because this procedure is frequently performed in the setting of chronic inflammation or infection. Attention is next turned to creation of the urinary diversion of the surgeon's choice.

The abdominal wall is closed beginning with the rectus fascia. The edges of the rectus fascia are reapproximated using a 0 looped polydioxanone suture (PDS) in a running fashion. The wound is copiously irrigated with sterile water. If there is a large amount of subcutaneous tissue, the Scarpa fascia can be reapproximated using a 3-0 or 4-0 Vicryl suture to minimize the dead space. The skin is closed with a subcuticular 4-0 Monocryl suture or skin staples.

Outcomes

Surgical outcomes are generally very good, although the available literature is limited. One series suggested a mortality rate of 0% with no morbidities directly attributable to the cystectomy itself (2). Likely, the most important aspect of simple cystectomy is the morbidity that is prevented by removing the bladder at the time of urinary diversion. In patients not undergoing concomitant cystectomy with urinary diversion, major complications and hospitalization occur in >50% with >20% requiring a salvage operation, although one recent case series reports substantially lower complication rates of 7% and 0%, respectively (1–4).

Complications

For both partial cystectomy and simple cystectomy, the usual risks associated with urologic surgeries exist, including pulmonary embolus, myocardial infarction, bleeding that requires transfusion, ileus, and wound complications such as infections or seromas. The majority of complications are related to the urinary diversion rather than the simple cystectomy itself. Although there are no data directly related to simple cystectomy, the overall complication rate of partial cystectomy is classically reported as 11% to 29%, and the complication rate for simple cystectomy is likely similar.

PARTIAL CYSTECTOMY

Partial cystectomy is a full-thickness excision of abnormal bladder and a margin of adjacent normal bladder with the goal of preserving adequate bladder function and capacity. Traditionally, this surgery has been utilized in the management of localized urachal adenocarcinoma, an isolated UCC associated with a diverticulum, localized unifocal UCC in favorable locations, or in patients who are unable or unwilling to undergo radical cystectomy. This procedure offers the advantages of full-thickness resection of the diseased bladder in conjunction with a pelvic lymph node dissection for pathologic review while allowing for conservation of the native bladder and preservation of potency and continence.

Diagnosis

Preoperative evaluation before undertaking a partial cystectomy should include a thorough history and physical examination with a focus on prior pelvic surgeries or procedures and previous bladder pathology. Cystoscopy should be performed with biopsy of the lesion for histologic diagnosis. Additional mapping biopsies should be performed to confirm unifocality of the disease and to exclude carcinoma in situ. Both noncontrasted and contrasted CT scans of the abdomen and pelvis with delayed images of the urinary collecting system should be performed to assist with staging. Findings such as upper-urinary-tract involvement with disease, metastatic lesions, enlarged lymph nodes >1 cm, or other pelvic pathology may preclude utilizing this procedure.

Indications for Surgery

Partial cystectomy has emerged as the treatment of choice for localized urachal adenocarcinoma. The urachus is an embryologic remnant that persists in approximately 30% of the population and is capable of malignant transformation. In this setting, open partial cystectomy or laparoscopic partial cystectomy should be undertaken with en bloc resection of the involved bladder with a 2-cm margin of normal tissue, umbilicus, peritoneum, and posterior rectus fascia with concomitant pelvic lymphadenectomy. The 5-year survival rate in this setting is approximately 88% (6).

In the setting of UCC, partial cystectomy is indicated only in highly selected patients with limited disease, patients who are not candidates for radical cystectomy due to comorbid conditions, and patients who refuse radical cystectomy. Selection criteria should include no history of previous urothelial cancer, localized disease that is unifocal in nature without coexisting carcinoma in situ (CIS), and disease that is present in an area of the bladder that is amenable to complete resection with a negative margin. Patients must have a bladder volume that allows for resection of the diseased site with an adjacent 2-cm margin while still maintaining adequate functional capacity with normal compliance. We do not recommend partial cystectomy if resection of the bladder neck is required.

A special circumstance exists in the patient who presents with a bladder diverticulum containing a UCC. Because of the thin, amuscular walls of the diverticulum, these lesions are often at increased risk of higher stage disease. Additionally, attempted transurethral resection of a UCC within a diverticulum has a higher risk of perforation. For these reasons, this pathology is particularly amenable to partial cystectomy.

Other indications for partial cystectomy include resection of nonurologic cancers in the bladder, including pheochromocytoma, paraganglioma, rhabdomyosarcoma, osteosarcoma, lymphoma, and adjacent tumors that are locally invasive into the bladder, such as invasive colorectal cancer. Partial cystectomy may also be indicated in benign diseases such as a symptomatic diverticulum.

Alternative Therapy

Any malignant bladder tumor that is removable by partial cystectomy can also be removed by radical cystectomy, although morbidity may be increased. There have also been many advances in endoscopic tools and techniques. Some tumors may now be approached endoscopically via an aggressive transurethral approach or laparoscopically with a simple cystectomy. In regard to urothelial cancer, intravesical agents—including chemotherapy and bacille Calmette-Guérin (BCG) immunotherapeutic agents—have also been utilized to manage some of these patients. Radiotherapy and chemotherapy, alone or in combination, are also alternatives to cystectomy in the setting of muscle-invasive UCC. For many benign indications, simple cystectomy is an alternative.

Surgical Technique

Antithrombotic medication, pneumatic compression cuffs, or compression stockings should be strongly considered prior to induction of anesthesia. The patient is positioned supine on the operating room table with the anterior superior iliac spines positioned over the inferior portion of the table break or kidney rest. The table is flexed to facilitate exposure, and the bed is tilted slightly in the Trendelenburg position until the abdomen is parallel to the floor. The abdomen and pelvis are then prepped with an antibiotic solution extending from the costal margin superiorly to the perineum, including the penis in men and the vagina in women. After the patient is draped, a Foley catheter is inserted following sterile procedures. The bladder is then allowed to drain completely. At this point, filling the bladder with 150 to 200 mL of sterile water may facilitate the dissection.

An intravenous antibiotic agent should be administered prior to skin incision. A lower midline incision from just below the umbilicus (around and including the umbilicus if for urachal adenocarcinoma) to the pubic symphysis is made. The anterior rectus fascia should be opened sharply, followed by separation of the rectus abdominis muscles in the midline to facilitate entry into the space of Retzius.

Using blunt dissection, the tissues are dissected down to the level of the bladder dome at the reflection of the peritoneum. For dome or anterior tumors, it is possible to remain extraperitoneal; however, for posterior tumors, an intraperitoneal approach is recommended.

Extraperitoneal Partial Cystectomy

The extraperitoneal space lateral to the bladder is developed bluntly, extending from the bladder neck cranially to the dome of the bladder. The anterior aspect of the bladder is exposed to the peritoneal reflection, which is mobilized where it is readily separable. A bilateral pelvic lymph node dissection is undertaken using the bifurcation of the common iliac artery as the cranial limit, the pubic symphysis as the caudal limit, the genitofemoral nerve as the lateral limit, and the bladder as the medial limit of the dissection. All nodal tissue is dissected and sent for pathologic review. Prudent use of silk ties or titanium clips, especially at the cranial and caudal limits of the dissection, may limit the risk of lymphocele formation.

The bladder is freed from its surrounding attachments, with care being taken to preserve the perivesical fat overlying the region of interest. Blunt dissection is the primary approach, along with judicious use of cautery to minimize the risk to adjacent peritoneal contents. The superior vesical pedicle may be divided to provide adequate exposure of the resection site. This division may be performed with a LigaSure (Valleylab) device or in the traditional manner with hemostats and 2-0 silk ties. Once the bladder is freed, the area of the tumor should be localized with preoperative or intraoperative cystoscopy.

Several sutures are placed some distance from the known pathology. At this point, the bladder should be drained completely to prevent urinary spillage. The free wound edges can be covered with laparotomy pads moistened with sterile water. The bladder is incised using Bovie cautery in an area at least 2 cm away from the expected lesion. The incision is extended to allow for visualization of the pathology. The tumor is excised using Bovie cautery with a 2-cm margin on all sides, and the specimen is removed en bloc with the overlying perivesical fat and any adherent peritoneum (Fig. 18.5).

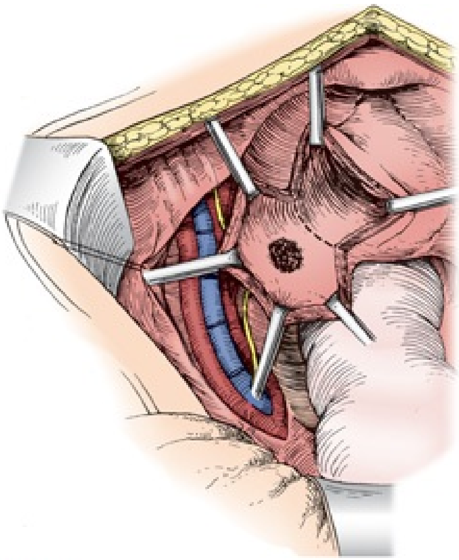

FIGURE 18.5 A 2-cm margin of normal bladder is taken around the tumor.

In general, we do not recommend this operation when ureteral reimplantation is necessary. However, in the event that a ureteral reimplantation is needed to complete the partial cystectomy, the ureter should be divided and the proximal ureter reimplanted into the bladder via the Politano-Leadbetter technique or the simple nipple reimplantation technique. A 4-0 Vicryl suture should be used for performing an interrupted ureterovesical anastomosis over a ureteral stent.

Once excision of the tumor is completed and adequate hemostasis is ensured, the bladder can be closed in two layers utilizing a running 4-0 Vicryl suture on the urothelium and a running, locking 2-0 Vicryl suture to close the muscularis layer (Fig. 18.6). Special consideration should be given to the apices of the closure because these are the most frequent sites of urinary leakage after closure. A suprapubic cystostomy is contraindicated in the setting of UCC; however, it can be considered for other pathologies. The wound is copiously irrigated with warm sterile water. A closed drainage system, such as a Jackson-Pratt drain or Blake drain, can be placed in a dependent position within the area of dissection. To minimize fistula formation, this drain should not be placed directly adjacent to the cystotomy closure. The anterior rectus fascia is reapproximated using a 0 looped PDS in a running fashion, and the wound is copiously irrigated with sterile water. The skin is closed with a subcuticular 4-0 Monocryl suture.

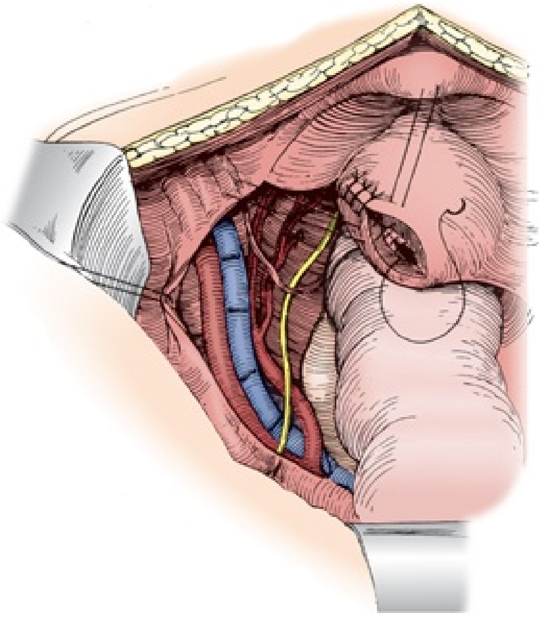

FIGURE 18.6 The bladder is closed in two layers.

The drain is removed on postoperative day 2 or 3 or when the output is <30 mL per shift. The catheter is removed on postoperative day 7. If complete bladder healing is a concern, a low-pressure cystogram can be performed.

Intraperitoneal Partial Cystectomy

Partial cystectomy through an intraperitoneal approach is often necessary with tumors on the posterior bladder wall. The extraperitoneal space lateral to the bladder is bluntly developed by extending the dissection from the bladder neck cranially to the dome of the bladder. The posterior rectus sheath and peritoneum just inferior and lateral to the umbilicus are divided sharply to enter the peritoneal cavity. The bowel is retracted into the upper abdomen using a retraction system such as the Bookwalter or Omni-Tract system. Trendelenburg can be steepened to assist in packing the bowel away. The peritoneum is incised over the iliac vessels, and the node dissection is undertaken using the same landmarks as described in the extraperitoneal approach. The procedure follows the steps previously described; the posterior aspect of the bladder is freed to allow adequate exposure, and the superior vesical artery is divided as needed. The lesion is located, and stay sutures are placed some distance away from the site of disease. After the bladder dissection is complete, the bladder is drained. The bladder is then incised, and the tumor is excised with a 2-cm margin followed by bladder closure and management of the Foley catheter and drains as previously described in the extraperitoneal approach.

Outcomes

In modern partial cystectomy series for the management of UCC, outcomes are good, with a 5-year overall survival rate of 64% to 70% and a 5-year disease-specific survival rate of 74% to 84% (7–9). However, UCC is well known for its high recurrence rates. In partial cystectomy series, recurrence rates range from 28% to 49%, with an approximate recurrence rate of 20% to 25% in locally advanced or metastatic disease. Because of this high recurrence rate, most authors agree that lifelong cystoscopy and repeat abdominal and pelvic imaging should be performed in these patients. Disease recurrence requires aggressive treatment similar to treatment for recurrence with other treatment modalities, including repeat transurethral resection, use of intravesical agents, chemotherapy and/or radiation protocols, and radical cystectomy with urinary diversion when indicated.

The success of partial cystectomy for urachal adenocarcinoma with en bloc resection of the urachus, umbilicus, and surrounding soft tissues with negative margins has resulted in an 88% 5-year disease-free survival rate (6). Local recurrence rates are approximately 18% with aggressive resection. Furthermore, a review of multiple small surgical series would suggest no survival benefit to radical cystectomy over extended partial cystectomy with en bloc resection, but a randomized trial has not been done.

Complications

For both partial cystectomy and simple cystectomy, the usual risks associated with urologic surgeries exist, including pulmonary embolus, myocardial infarction, bleeding that requires transfusion, ileus, and wound complications such as infections or seromas. Other more specific complications include reduction of bladder capacity, urinary leakage, fistula formation, and lymphocele formation. Recurrence is a concern and is discussed previously. The overall complication rate of partial cystectomy is classically reported as 11% to 29%. One retrospective review of 10,780 cases of partial cystectomy for bladder cancer reported a 15.8% complication rate and 1.8% mortality rate (10).

Of special consideration is the reduction in functional capacity during partial cystectomy. There are no good data to determine how much bladder capacity can be removed while still allowing good function. Preoperative urodynamic testing may be of some benefit in accurately assessing preoperative bladder capacity.

CHAPTER 19 RADICAL CYSTECTOMY IN MEN

MOHAMED A. GHONEIM AND AHMED M. HARRAZ

Although more complex urinary diversions are increasingly employed, contemporary cystectomy is associated with very low mortality. Furthermore, the advent of nerve-sparing cystectomy and orthotopic bladder substitution has significantly reduced functional losses and provided many patients with good locoregional control as well as a good quality of life. The technique, herein described, is based on cumulative experience of more than 30 years during which more than 2,000 cystectomies were carried out at the Department of Urology, Mansoura University, Egypt (1).

DIAGNOSIS

The diagnosis of transitional-cell carcinoma is generally made by transurethral resection of the tumor in the bladder. Once the diagnosis has been established, it is important to know the pathologic stage, particularly if the tumor invades the muscularis propria. Invasion of the muscularis mucosa is an important distinguishing factor and is not considered as constituting a muscle-invasive tumor. The clinical staging of transitional-cell carcinoma can generally be performed by abdominal and pelvic computerized tomographic (CT) scans and chest imaging. Occasionally, radionuclide bone scans are indicated if there is either symptomatic bone pain, abnormalities on the CT scan, or the patient has either an elevated serum calcium or alkaline phosphatase.

INDICATIONS FOR RADICAL CYSTECTOMY IN MEN

The major indication for cystectomy in men is carcinoma of the bladder. In general, the operation is carried out for the following:

1. Patients with superficial tumors in whom endoscopic control has failed in spite of adjuvant intravesical chemo- and/or immunotherapy. Although these measures have proven effective in the management of such cases (<T1), an important minority fail. High tumor grade, multifocal lesions, diffuse carcinoma in situ, and involvement of the prostatic urethra were all reported as high-risk factors.
2. Infiltrating tumor without evidence of distant metastasis. These include tumors infiltrating the muscle layers (P_2, P_{3a}) or the perivesical fat short of the pelvic wall (P_{3b}). Infiltration of adjacent organs (P_4) or involvement of the regional lymph nodes is not considered as a contraindication for the procedure.

The radical operation in men includes the removal of the bladder, its peritoneal covering, the perivesical fat, the lower ureters, the prostate, the seminal vesicles, and the vasa deferentia. In the standard procedure, as much as possible of the membranous urethra is also removed, and total urethrectomy is carried out only if there is involvement of the prostatic urethra (2).

ALTERNATIVE THERAPY

Alternatives to radical cystectomy include local therapy, partial cystectomy, intravenous chemotherapy, radiation therapy, or a combination of chemotherapy and radiation therapy. Local therapy in invasive disease generally results in progression of the disease and death of the patient within 5 years. Systemic chemotherapy or radiation therapy is associated with a 25% 5-year survival, although the combination of the two modalities can improve 5-year overall survival probability up to 48% (3).

SURGICAL TECHNIQUE

Preparation of the Patient

In view of the extent of surgery, the length of the operative time, and often advanced patient age, a thorough medical evaluation and anesthetic consultation are required.

Bowel preparation is necessary before surgery. If it is planned to use the small bowel, oral neomycin and a low-residue diet are all that are needed. More rigorous preparation with full bowel prep is required if the colon is utilized.

Patients with histories of thromboembolic disease or varicose veins should receive a prophylactic dose of heparin (5,000 U subcutaneously) the night before the operation and every 12 hours thereafter until ambulation. A parenteral broad-spectrum antibiotic is given just before induction of anesthesia and continued postoperatively for 3 days. The region extending from the midchest to the midthigh should be cleaned and prepared on the night before surgery.

Anesthesia and Instrumentation

Full relaxation of the abdominal muscles by an appropriate anesthetic is necessary throughout the entire procedure. Hypotensive anesthesia would provide an additional advantage and would reduce blood loss.

The choice of instruments depends mainly on the surgeon’s preference. Standard retractors of various sizes and curves as well as long curved and angled scissors are needed. Long curved clamps should also be available.

Position and Initial Exposure

The patient is put in the supine position with a Trendelenburg tilt. Slight bending of the knees would further help in the relaxation of the abdominal muscles, facilitate retraction, and provide a wider exposure. If a total urethrectomy is planned, the patient is put in a slight lithotomy position for access to the perineum.

The surgical area to be sterilized and draped extends from the lower chest down to the root of the penis. A self-retaining catheter is introduced into the bladder and kept indwelling for its evacuation throughout the procedure.

A long, vertical, right paramedian incision extending from the symphysis pubis inferiorly to a point halfway between the umbilicus and xiphoid process of the sternum superiorly is generally employed. Alternatively, a midline incision encircling the umbilicus can also be utilized. For obese patients, a lower abdominal muscle-cutting transverse incision is preferred. Under such circumstances, it provides a wide and direct exposure of the pelvis.

Initially, the abdominal and pelvic cavities are explored. The growth is palpated, its degree of mobility determined, and its relation to the adjacent structures assessed. The endopelvic and aortic lymph nodes are palpated and frozen sections are taken if necessary. The general peritoneal cavity, omentum, intestinal tract, kidney, spleen, and liver are thoroughly examined. If the decision is to proceed with the radical operation, the intestines are packed out of the pelvis, and the retropubic space is opened by blunt dissection. Any small bleeders are coagulated. This dissection is extended inferiorly and laterally until the ventral surface of the bladder and prostate are exposed. The peritoneal incision is extended inferiorly on either side of the urachal remnant. The urachal remnant is dissected off its attachment with the umbilicus and clamped. In this manner, a triangular peritoneal flap with its apex pointing superiorly is raised and will be removed later en bloc with the bladder.

Lymphadenectomy

The peritoneal incision, on either side, is extended posterolaterally along the lateral border of the external iliac and common iliac vessels up to the aortic bifurcation. The vas deferens is identified and ligated near the internal ring. The fascia on the iliopsoas is incised and reflected medially. The triangle of Marseille is exposed by retracting the common and external iliac arteries medially and dissecting the space between these vessels and the medial border of the psoas muscle (4). Dissection of the fibrolymphatic tissues in this space will expose the obturator nerve as it emerges from the medial border of the psoas muscle (Fig. 19.1). The fibrofascial sheath covering the distal half of the common iliac and the external iliac vessels is then opened and stripped medially to remove the perivascular lymphatics and lymph nodes (Fig. 19.2A). The vessels are gently retracted laterally and immediately below and medial to the cleaned external iliac vein, and the obturator space is entered (Fig. 19.2B). By working right on the psoas and obturator muscles, one can strip all the pelvic fascia medially without difficulty. The obturator neurovascular bundle is included in the stripped mass. The obturator nerve is identified and separated from its vessels, which are ligated and divided as they leave the pelvis through the obturator foramen. Dissection is facilitated and the operating time reduced by the use of electrocoagulation to control lymphatic and small blood vessels throughout the lymphadenectomy. The fibrolymphatic mass is now reflected medially, and the internal iliac artery and its branches are identified (Fig. 19.2C), and its anterior division is divided and ligated. This completes the lateral dissection (Fig. 19.3A and B).

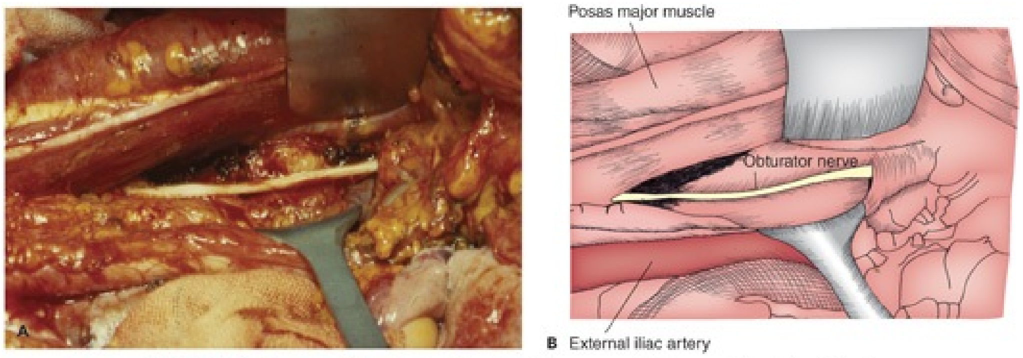

FIGURE 19.1 Dissection of the triangle of Marseille. The psoas muscle is retracted laterally and the iliac vessels medially. The obturator nerve is exposed in the floor of the triangle as it emerges from the medial border of the Psoas muscle. A: Operative photograph. B: Explanatory diagram.

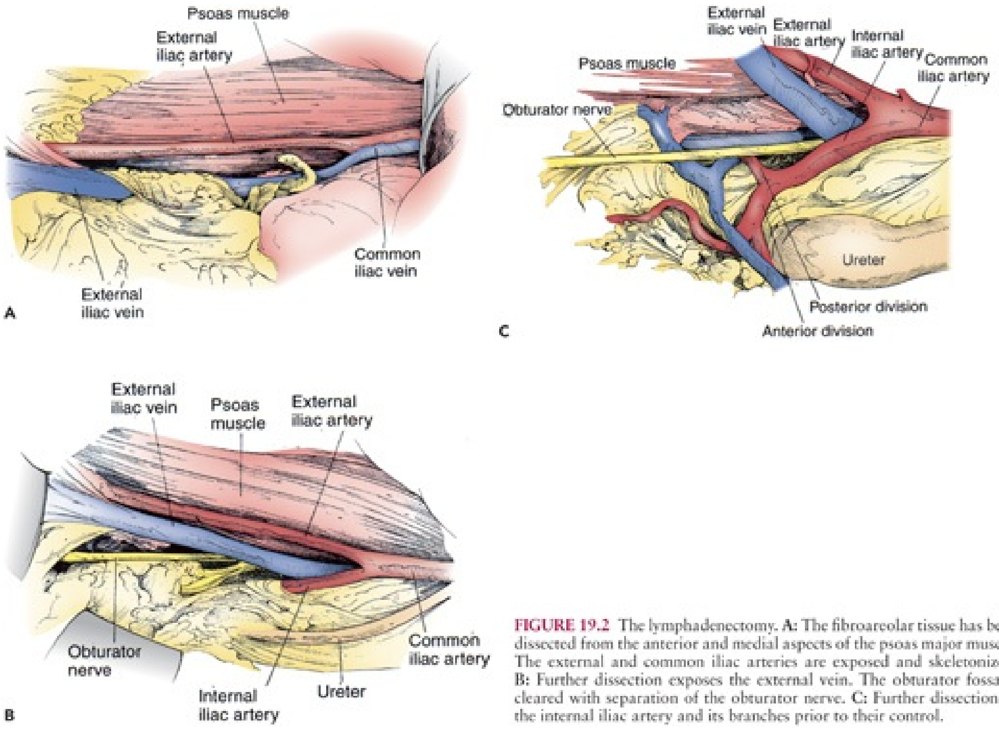

FIGURE 19.2 The lymphadenectomy. **A:** The fibroareolar tissue has been dissected from the anterior and medial aspects of the psoas major muscle. The external and common iliac arteries are exposed and skeletonized. **B:** Further dissection exposes the external vein. The obturator fossa is cleared with separation of the obturator nerve. **C:** Further dissection of the internal iliac artery and its branches prior to their control.

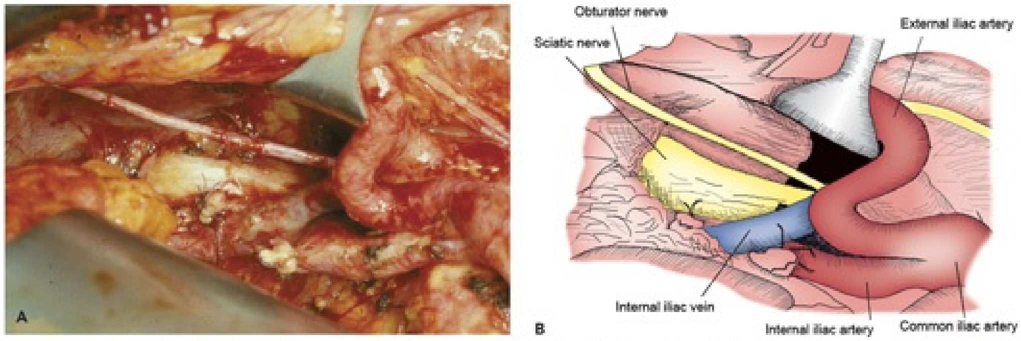

FIGURE 19.3 The lateral dissection is completed. The anterior division of internal iliac artery is divided with control of its parietal branches. **A:** Operative photograph. **B:** Explanatory diagram.

The ureter is identified where it crosses the common iliac bifurcation, dissected free for 3 to 4 cm, divided, and its distal end ligated. While traction is applied on the ligated ureteric stump of the ureter, finger dissection along its posteromedial border opens the space of Denonvilliers laterally. The step greatly helps in the definition of the plane between the bladder and rectum, which will be required at a later stage in the operation.

Cystoprostatectomy

The endopelvic fascia on either side on the prostate is then opened by the tip of a blunt pair of scissors (Fig. 19.4). The optimal site for the creation of this opening is a white line marking the fusion of the parietal fascia lining the pelvic surface of the levator ani with the visceral fascia covering the lateral surface of the prostate. A right-angle clamp is used to lift the fascia from the underlying venous plexus, and it is further incised medially until the prostatic ligaments are reached. By blunt dissection, this plane is further developed posteriorly on either side of the prostate. Further anterior dissection is deferred to the final stages of the procedure to minimize the possibility of sudden blood losses from inadvertent injury of the prostatic venous plexus.

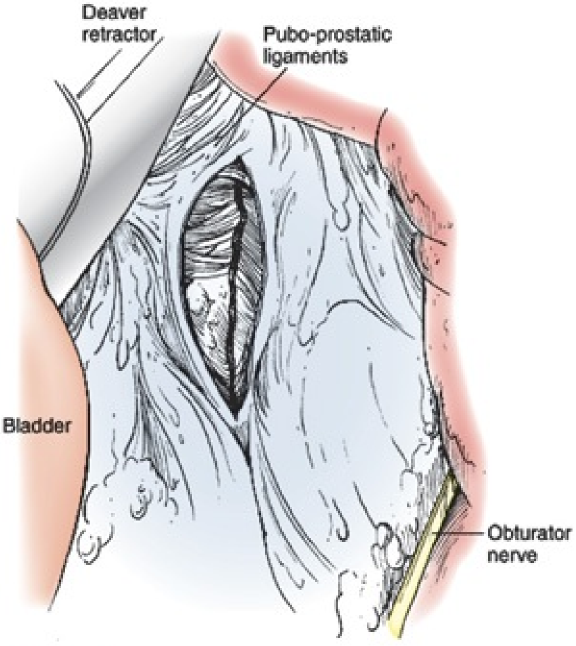

FIGURE 19.4 The bladder and prostate are retracted medially by a Deaver retractor. The reflection of the endopelvic fascia from the ventral surface of the levator ani to the prostate is opened. Blunt dissection would further develop this space and expose the lateral surface of the prostate.

The specimen is now lifted ventrally by applying traction on the median umbilical ligament (urachus). The two planes developed along the posteromedial borders of the ureter on either side are easily joined together by blunt dissection. As a result, the peritoneal reflection from the anterior surface of the rectum to the back of the bladder could be stretched and safely incised by diathermy. The potential space between the rectum posteriorly and the bladder, seminal vesicles, and prostate anteriorly is opened by blunt dissection (Fig. 19.5). As the prostatic apex is reached, this space becomes obliterated as a result of fusion of the two layers of the fascia of Denonvilliers. This cul-de-sac is opened by the blunt tip of long angled scissors. Once this is completed, the tip of the surgeon’s forefinger would readily feel the apex of the prostate as well as the catheter in the urethra in the midline. Alternatively, if it is directed laterally, it will appear through the previously created openings on either side of the prostate (Fig. 19.6).

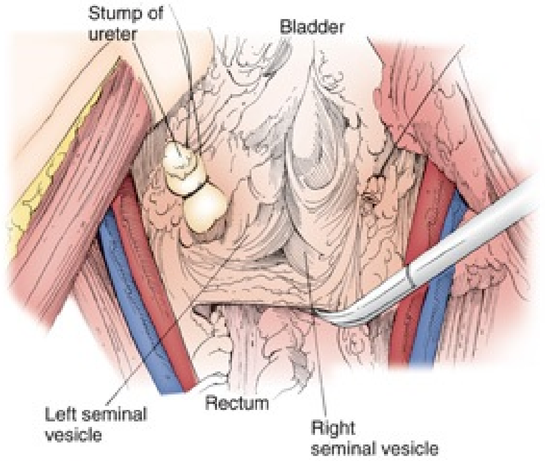

FIGURE 19.5 The peritoneum of the floor of Douglas pouch is incised by diathermy. The space between the rectum posteriorly and the bladder and seminal vesicles anteriorly is dissected and opened.

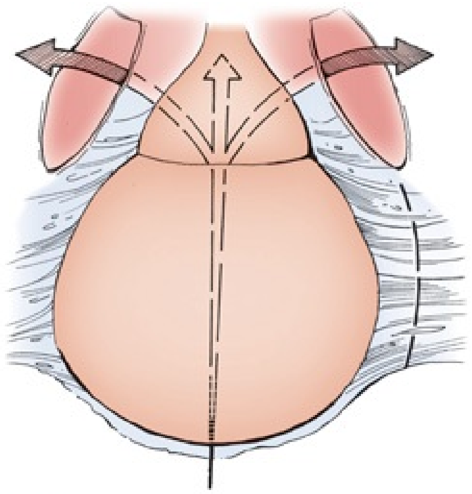

FIGURE 19.6 The cul-de-sac formed by the fusion of the two layers of the fascia of Denonvilliers is opened by the tip of a blunt pair of long scissors. Thereafter, the tip of the surgeon's forefinger would feel the apex of the prostate and the catheter in the urethra. If the forefinger is directed laterally, it would appear through the previously created openings on either side of the prostate. Thus, a thick, wide, fascial band is defined (the vesicoprostatic pelvic fascia). It is divided piecemeal between clamps (*arrows* and *interrupted line*).

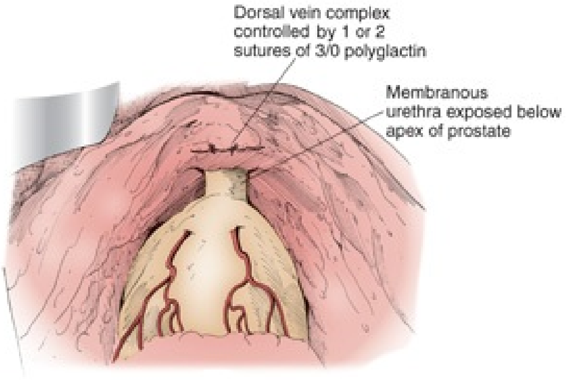
In this manner, a thick and wide fascial band is created on either side, connecting the bladder, vesicles, and prostate anteriorly with the pararectal fascia posteriorly (the vesicoprostatopelvic fascia). This is divided piecemeal between clamps, which are underrun by 2-0 polyglactin sutures.

The bladder is now free laterally and posteriorly, and the mass is left to drop in the pelvis. Attention is now focused on the anterior and final phase of the procedure. The puboprostatic ligaments are identified by applying traction on the prostate in a cephalad and posterior direction. These ligaments are carefully severed at the point of their insertion in the pubic bone. The prostatic venous plexus is controlled by one or two sutures of 3-0 polyglactin acid placed near the prostatic apex. A transverse incision is made proximal to these sutures with a long scalpel and extended with sharp dissection by scissors, exposing the urethra, within which the catheter can be palpated (Fig. 19.7). The catheter is then withdrawn; the urethra is clamped and transected; the distal end is ligated; and the specimen is removed. Final hemostasis is achieved by inserting deep 2-0 polyglactin sutures between the edges of the levator ani muscles on either side (Fig. 19.8). No attempt is made to reperitonealize the pelvis. Two tube drains are placed in the pelvic cavity and brought out through separate incisions in the abdominal wall. The wound is closed in layers with particular attention for careful closure of the anterior rectus sheath. This is closed with interrupted sutures of nylon with the knots tied to the inside.



Dorsal vein complex controlled by 1 or 2 sutures of 3/0 polyglactin
Membranous urethra exposed below apex of prostate

FIGURE 19.7 The puboprostatic ligament is incised and the prostatic venous complex controlled. The membranous urethra is thus exposed.

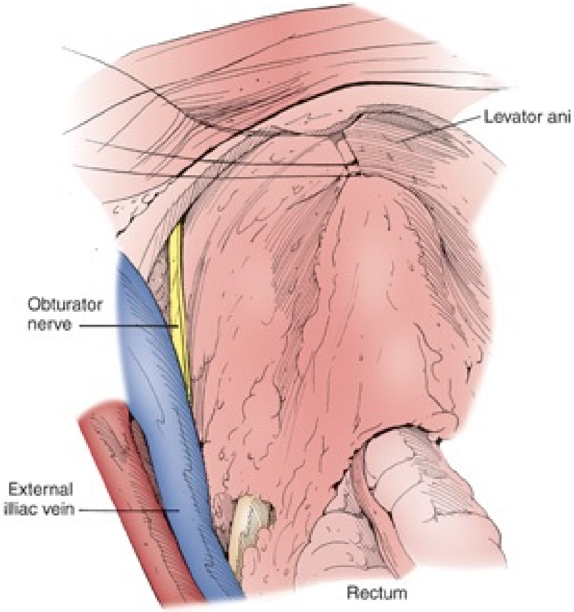


FIGURE 19.8 The specimen is removed. Final hemostasis is achieved by two to three interrupted sutures of 3-0 polyglactin between the two medial borders of levator ani muscles.

Variations on a Theme

Extended Lymphadenectomy

The procedure was first suggested by Skinner on the basis that extending lymphadenectomy can improve the results of advanced locoregional disease (5,6). In this operation, the field of dissection extends proximally along the great vessels up to the level of origin of inferior mesenteric artery (7).

To this end, the posterior parietal peritoneum is incised cranially on the left side along the paracolic gutter and on the right side along the small intestinal mesentery as far as the ligament of Treitz. The fibrolymphatic tissues lateral to, in front of, and between the aorta and inferior vena cava are cleared. Dissection is continued distally to remove the lymphatic tissues along the common iliac arteries (common iliac group) and in the intercommon iliac region (presacral nodes). The procedure is then completed as previously described. The dissected field as well as the cleared anatomic regions is outlined in Figure 19.9A–C. The initial report had indicated that extended lymphadenectomy could provide survival benefit for patients with high-stage disease (8).

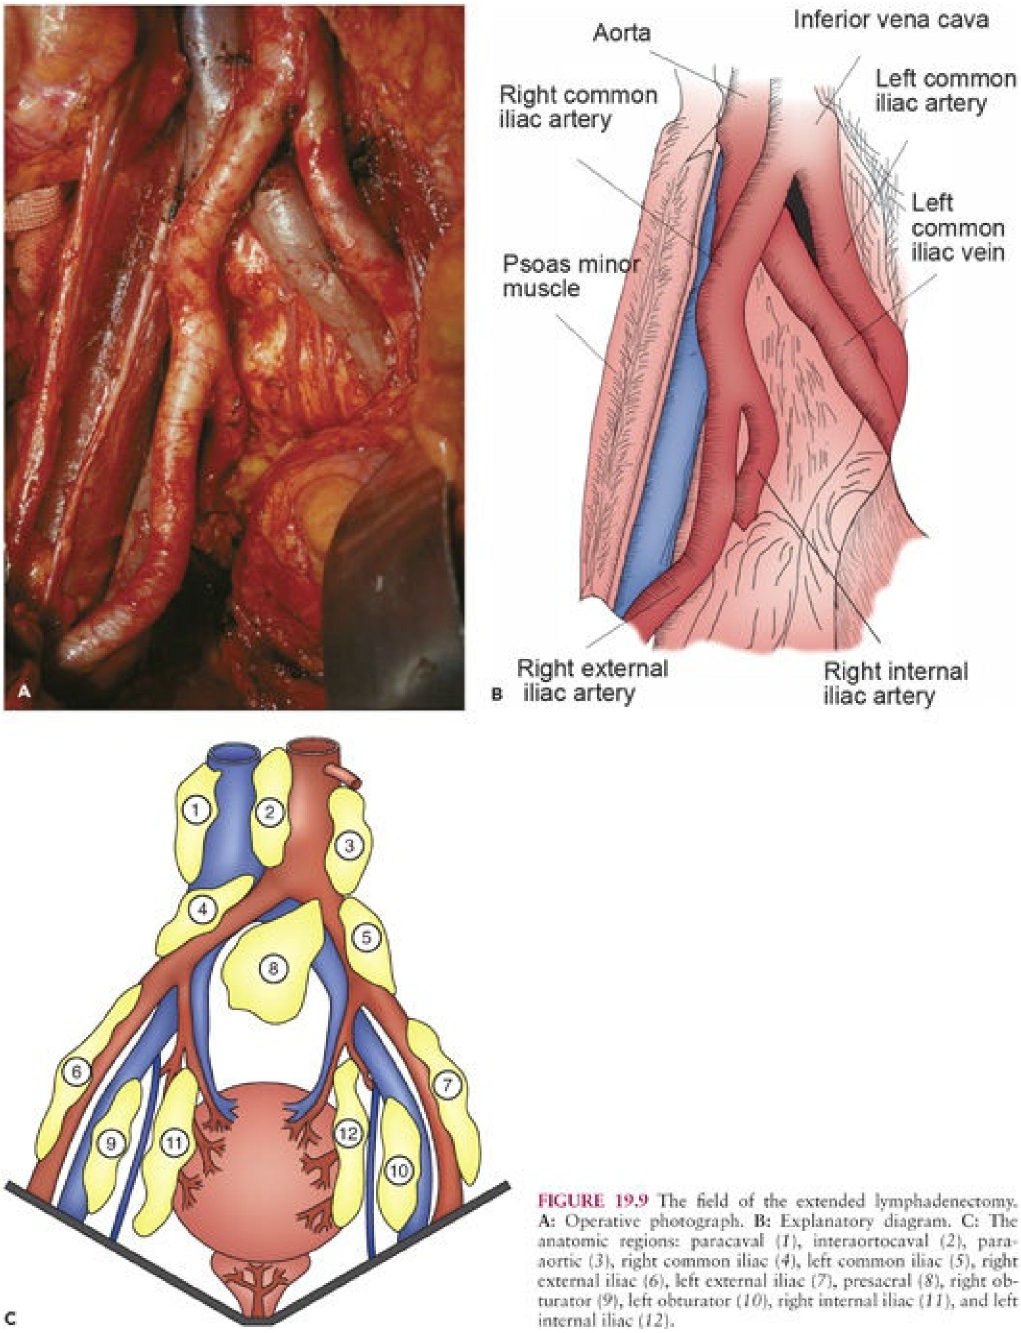

FIGURE 19.9 The field of the extended lymphadenectomy. **A:** Operative photograph. **B:** Explanatory diagram. **C:** The anatomic regions: paracaval (*1*), interaortocaval (*2*), para-aortic (*3*), right common iliac (*4*), left common iliac (*5*), right external iliac (*6*), left external iliac (*7*), presacral (*8*), right obturator (*9*), left obturator (*10*), right internal iliac (*11*), and left internal iliac (*12*).

One-Stage Cystoprostatourethrectomy

Urethrectomy is indicated in a subpopulation of patients with multifocal tumors, diffuse carcinoma in situ, or tumor involving the bladder neck and/or the prostate. Following incision of the puboprostatic ligaments and control of the prostatic venous plexus described, traction is applied on the cystectomy specimen in a cephalad direction. The urethra is dissected from the urogenital diaphragm with a long pair of dissecting scissors. In this manner, 2 to 3 cm of the membranous urethra can be mobilized. The pelvis is temporarily packed with gauze, and further steps are carried out perineally without urethral transection.

A midline incision in the perineum is usually employed. The skin, subcutaneous tissue, and the bulbocavernosus muscle are incised in the midline. The Foley catheter can now be palpated in the urethra. The urethra is dissected sharply from the overlying corpora cavernosus. Further dissection is carried out in the direction of the glans penis. Traction on the urethra results in inversion on the penis, allowing dissection of the urethra as far as the coronal sulcus. The penis is then allowed to restore its normal position. The urethral meatus is circumscribed sharply, and the glans penis is incised in the midline to allow dissection of the fossa navicularis. The entire penile urethra is now free. The glans penis is reconstructed by a few sutures of interrupted 3-0 chromic catgut.

Attention is now focused on dissection of the bulbar urethra. The relatively avascular tissues ventral to the bulbar urethra and beneath the symphysis pubis are dissected first. Thus, the corresponding part that had been previously dissected in the pelvis can be reached, and the pelvic and perineal exposures joined. Dissection is further developed laterally and posteriorly with control of the bulbar urethral arteries. In this manner, the urethra is freed totally, and the whole specimen is removed in one block (Fig. 19.10A–H).

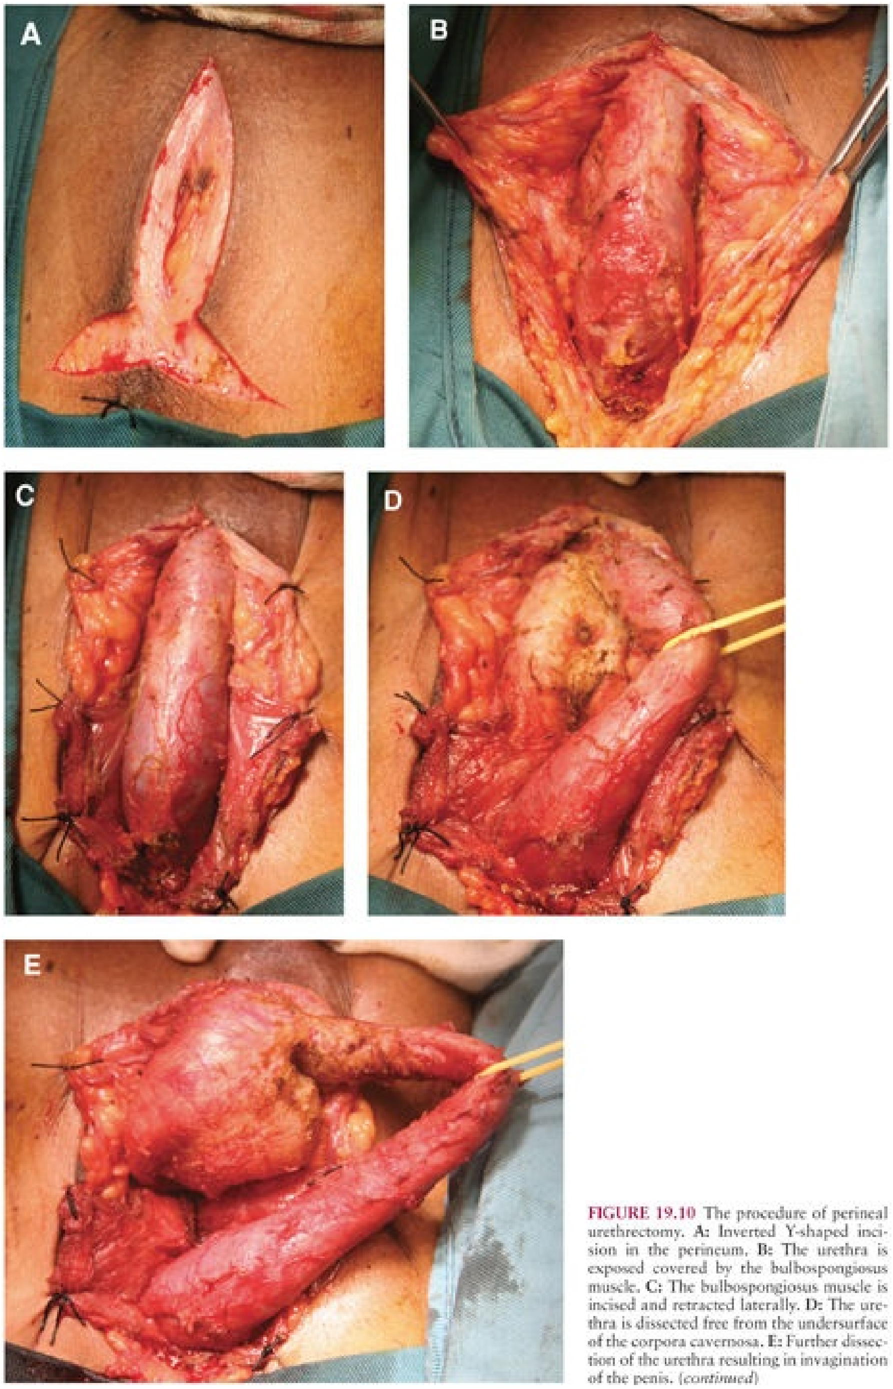

FIGURE 19.10 The procedure of perineal urethrectomy. **A:** Inverted Y-shaped incision in the perineum. **B:** The urethra is exposed covered by the bulbospongiosus muscle. **C:** The bulbospongiosus muscle is incised and retracted laterally. **D:** The urethra is dissected free from the undersurface of the corpora cavernosa. **E:** Further dissection of the urethra resulting in invagination of the penis. (*continued*)

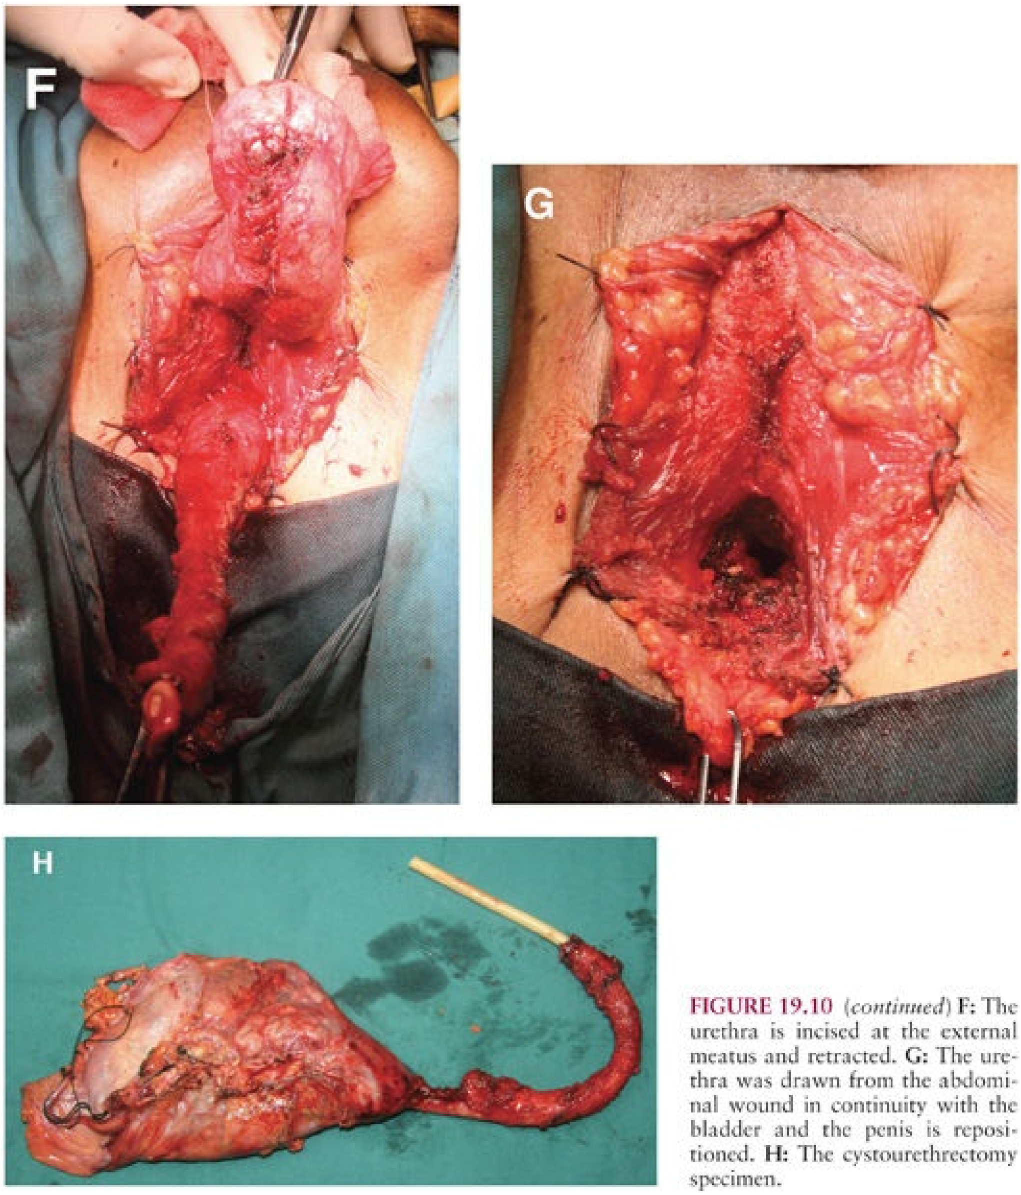

FIGURE 19.10 *(continued)* **F:** The urethra is incised at the external meatus and retracted. **G:** The urethra was drawn from the abdominal wound in continuity with the bladder and the penis is repositioned. **H:** The cystourethrectomy specimen.

Alternatively, the procedure can be carried through a prepubic approach (9). The prepubic area is exposed by extending the midline incision over the pubis until the root of the penis is exposed. The root of penis is held with the index finger of the left hand and by continuous upward traction; the penile body is brought into the prepubic incision. The Buck fascia is then incised to expose the distal urethra. The corpus spongiosum is sharply dissected off the corpora cavernosa and freed from the body of penis until the fossa navicularis and urethral meatus are reached. The urethra is transected distally and the dissection continues proximally toward the root of penis. A right-angle clamp is then passed from the pelvic area and the distal urethra is grasped and brought in to the pelvis with special attention to control the bulbar vessels. Finally, the entire urethra can be pulled safely from the abdominal incision.

Radical Cystoprostatectomy with Orthotopic Bladder Substitution

A standard radical cystoprostatectomy is performed except that the final stages of the operation must be done with attention to detail to avoid damage to the urethra and periurethral musculature. The integrity of these structures has a central role in the functional success of orthotopic substitution. Following lymphadenectomy and control of the pedicles, the endopelvic fascia on either side of the prostate is opened by the tip of a blunt pair of scissors. A right-angle clamp is used to lift the fascia from the underlying venous plexus, and then it is further incised medially until the puboprostatic ligaments are reached. These ligaments are carefully severed at the point of their insertion in the pubic bone. The prostatic venous plexus is controlled by one or two suture ligatures of 3-0 polyglactin just distal to the vesicoprostatic junction. A transverse incision is made proximal to these sutures and extended by sharp dissection with scissors toward the apex of the prostate. The catheter is palpated in the urethra, the anterior wall of which is then incised just distal to the prostatic apex. The exposed Foley catheter is transected, clamped, and held for traction. At this point, three stay sutures of 4-0 polyglactin are placed through the urethra at the 3, 9, and 12 o'clock positions, incorporating the mucosa as well as the periurethral musculature (Fig. 19.11). These sutures prevent retraction of the urethra following its complete transection and are used later for the urethroileal anastomosis. The posterior urethral wall is then incised to expose the dorsal fibrous raphe formed by the fascia of Denonvilliers, which is lifted from the anterior surface of the rectum by a right-angle clamp and divided. The divided fascia is then included in two posterior stay sutures at the 5 and 7 o'clock positions for its later incorporation in the urethroenteric anastomosis (Fig. 19.12A and B).

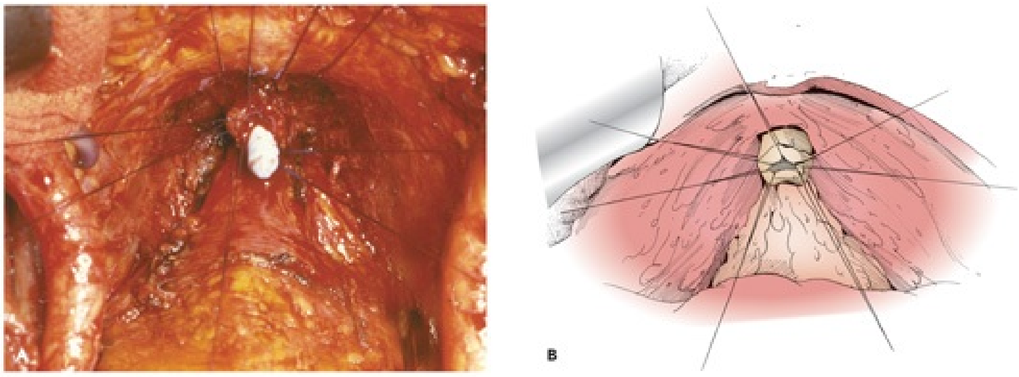

FIGURE 19.12 Transection of the urethra is completed and further stay sutures applied. These will prevent retraction of the urethral stump and will be later used for the urethroileal anastomosis. A: Operative photograph. B: Explanatory diagram.

Radical Cystoprostatectomy with Nerve Sparing

This procedure was initially described by Schlegel and Walsh (10). It can be carried out in an antegrade or a retrograde manner, although in our practice, we prefer the antegrade approach. During radical cystectomy, there are two points where the neurovascular bundle could be injured: (a) posterolateral to the prostate and (b) behind the seminal vesicles. If the extent of the pathology allows the surgeon to avoid these areas, potency could be preserved.

Bilateral lymphadenectomy with creation of the space between the rectum posteriorly and the bladder, seminal vesicles, and prostate anteriorly is carried out as previously described. By a combination of blunt and sharp dissection, the lateral surface of the seminal vesicles is freed from the medial aspect of the vesicoprostatopelvic fascia. This allows the control of these ligaments at a more ventral plane. As a result, the neurovascular pathway behind the seminal vesicles is avoided. These pedicles are controlled by a series of simple interrupted sutures of 3-0 Vicryl. The use of heavy clamps, clips, and diathermy should be avoided. The dorsal vein complex is now controlled, and the urethra isolated carefully from the adjacent fascia. The urethra is then transected, and the Foley catheter is clamped and held for traction. The prostate can thus be elevated superiorly. A right-angle clamp is used to identify branches of the neurovascular bundle to the prostate. These are ligated and divided, freeing the prostate from all its lateral attachments.

Prostate-Sparing Radical Cystectomy

Several authors have advocated retaining the prostate in some selected patients for whom orthotopic diversion is contemplated (11,12). It was suggested that preserving the prostate in whole or in part can circumvent problems related to continence and results in the preservation of erectile functions. However, serious concerns were raised by other authorities of the possible increased oncologic risk following such a procedure. In a review by Hautmann and Stein (13), it was reported that the incidence of prostatic carcinoma in cystoprostatectomy specimens ranged between 29% and 46% and that of prostate transitional cell carcinoma (TCC) between 33% and 58%. In a prospective pathologic evaluation of 425 cystoprostatectomy specimens at our institution, there was histologic evidence of adenocarcinoma of the prostate in 21.2% of cases and concomitant noncontiguous TCC in 6.4% (14). In view of all of these observations, we feel that the potential oncologic risks of prostate-sparing cystectomy outweigh any small and possible functional benefits. Properly conducted radical cystoprostatectomy with orthotopic substitution should remain the standard for treating invasive bladder tumors.

Postoperative Management

Intravenous alimentation and nasogastric suction are maintained until normal bowel activity is resumed. We continue systemic antibiotics for 3 days postoperatively. Chest exercises and physiotherapy to the lower limbs should be carried out. Subcutaneous heparin should be administered if indicated. The tube drains are removed when drainage becomes <100 mL per day. It is advisable to estimate the creatinine content of the fluid to ensure that it is not the result of a urinary leak. Patients with an ileal conduit can be discharged on the 10th to the 12th postoperative day. Following orthotopic substitution, patients are usually kept in the hospital for 3 weeks. Before discharge, a pouchography is carried out to make sure that there are no leaks from the neobladder or from the urethroileal anastomosis.

OUTCOMES

Complications

The two most serious complications that may occur during the procedure are excessive blood loss and rectal perforation. Sudden massive bleeding is usually venous in origin, arising from tributaries of the external iliac vein during the lymphadenectomy: the deep circumflex iliac vein laterally and an abnormal obturator vein medially. Since both are located near the inguinal ligament good retraction, illumination, and suction are needed. A laceration of the external iliac vein is then sutured with 5-0

Prolene.

Another source of bleeding is in relation to the dorsal vein complex. Dissection of this area has to be deferred to the final phase of the procedure. This venous complex is usually injured when the puboprostatic ligaments are incised. Compression of the bleeding area by a piece of gauze (4 × 8 cm) and the tip of a long thin blade of a Deaver retractor is necessary until the dissection of the urethra is completed. Thereafter, bleeding is controlled by one or two interrupted 3-0 sutures of polyglactin acid placed between the two medial borders of the levator ani muscles.

The most serious source of bleeding is typically from the internal iliac vein or one of its tributaries. Sudden excessive bleeding occurs from the depth of a narrow deep recess. Blind attempts to control the bleeding with clamps usually fail and result in more damage. In our experience, one has to achieve an initial temporary control by packing. One or two 4 × 8 cm pieces of moist gauze are sufficient. The pack is tightly and constantly compressed for a few minutes and then is left in place. The operator should proceed with further operative steps until the specimen is removed. Now, the working space is wide enough to allow manipulations under vision. The ipsilateral external iliac and common iliac veins as well as the main stem of the internal iliac artery are controlled by bulldog clamps. The gauze pack is then removed. There will still be some back bleeding, but with the help of a little suction, the bleeding vessels are readily located and easily secured by suture ligation using 4-0 silk.

The other serious intraoperative complication is rectal perforation. This usually takes place during the final phase of the operation if the space between the prostate and rectum was not adequately and completely opened. Under such circumstances, traction on the specimen will lead to tenting of the anterior wall of the rectum. Sharp dissection with scissors or application of clamps would result in an injury of the anterior wall of the rectum well below the peritoneal reflection. If this injury is recognized, the tear is meticulously repaired. The edges are trimmed and closed in two layers using 3-0 polyglactin acid: the first through and through, and the second inverting as a fascia muscular layer (Lembert technique). An omental flap is raised, brought down to the pelvis, and sutured over the repair for additional security. The pelvic cavity is then thoroughly irrigated with l% solution of kanamycin in saline. At the end of surgery, while the patient is still under anesthesia, anal dilation is carried out up to three to four fingers to establish adequate decompression. Generally, by following these principles, one can avoid the need of a temporary proximal colostomy.

The 90-day mortality rate following a contemporary cystectomy is 2.3% (15). Infectious complications were most common (24%) followed by genitourinary (17%), gastrointestinal (15%), and wound-related complications (9%). Septic complications including abdominal and/or pelvic abscesses, wound sepsis, and septicemia are treated by the appropriate antibiotics and drainage of the infected collection. This is best achieved by ultrasound-guided aspiration and/or by insertion of a percutaneous tube drain. Urinary collections (urinoma) are drained under ultrasound guidance. If the source of leak is the ureterointestinal anastomosis, a percutaneous nephrostomy tube is inserted until healing is achieved and checked with an antegrade study. Prolonged ileus is treated by nasogastric suction, intravenous alimentation, and hyperalimentation if necessary. Wound dehiscence should be immediately repaired by proper closure using tension sutures.

Results

Radical cystectomy has evolved as the standard therapeutic modality for muscle-invasive bladder cancer. It can be accomplished with very low mortality, and technical innovations with nerve sparing and orthotopic substitution can provide many patients with a good quality of life with minimal functional losses.

All contemporary series demonstrate that radical cystectomy can result in a substantial rate of cure with overall survival ranges between 44.3% and 58% (1,16). For low-stage tumors (<T2), the survival could be as high as 75%. With further stage progression, the survival expectancy is decreased. Radical cystectomy with pelvic lymphadenectomy also provides a survival advantages for cases with nodal disease (5-year recurrence-free survival in the range of 34% to 43%) (17). Cisplatin-based neoadjuvant chemotherapy has demonstrated a 5% overall survival benefit and should be incorporated into the management decision of all eligible patients with muscle-invasive bladder cancer (18). Evidence has also been provided that adjuvant cisplatin-based polychemotherapy improves the chances of survival among patients with advanced locoregional disease (19).

CHAPTER 20 RADICAL CYSTECTOMY IN WOMEN

MIRIAM HADJ-MOUSSA, JOANNE LUNDGREN, CHERYL T. LEE, AND TODD M. MORGAN

In 2013, 72,000 new cases of bladder cancer were diagnosed in the United States; almost 17,000 occurred in women, with 4,300 dying from their disease (1,2). Although most urothelial carcinomas are noninvasive, up to one-third of patients present with muscle-invasive disease. In addition, 15% to 30% of patients presenting with non–muscle-invasive tumors will eventually progress to muscle invasion. Radical cystectomy remains the most effective single-modality treatment for patients with muscle-invasive bladder cancer, refractory high-risk non–muscle-invasive disease, and especially lymph-node negative disease with reported 10-year recurrence-free survival of organ-confined lymph-node negative (≤pT2N0) disease between 69% and 87% (3,4). Improvements in processes of care, particularly at high-volume centers, have led to a reduction in perioperative mortality and long-term survival, further strengthening the role of cystectomy (5–8).

Historically, radical cystectomy in women has posed several technical challenges and concerns, including (a) bleeding from the paravaginal tissues and venous plexus around the urethra, which can be brisk and tedious to control; (b) an intraoperative position change for the surgeon during urethrectomy; and (c) vaginal reconstruction, which can be complex, requiring tissue flaps to maximize organ function.

More recently, additional challenges have related to female organ preservation. Radical cystectomy in women has traditionally been equated with anterior exenteration, including resection of the bladder, urethra, uterus, ovaries, and the anterior one-third of the vagina. This approach is certainly indicated for extensive posterior invasive bladder tumors at risk for reproductive organ involvement. However, tumor involvement of adjacent reproductive organs is rare, suggesting that the routine removal of female reproductive and sex organs is not necessary to achieve local cancer control (9). Studies have yet to identify female patients with skip lesions involving the urethra, allowing surgeons to proceed with nonstomal diversions when intraoperative frozen-section analysis of the urethral margin is negative (10,11). Moreover, the increasing attention to preserving quality of life after cancer surgery provides another incentive to spare part or all of the reproductive organs and urethra when feasible.

INDICATIONS FOR SURGERY

Radical cystectomy is indicated for patients with muscle-invasive urothelial malignancy or non–muscle-invasive disease refractory to transurethral resection and intravesical therapy. Additionally, select patients with high-risk non–muscle-invasive disease may elect to undergo so-called “early cystectomy” at the time of their initial presentation. The presence of intractable local symptoms, failure of bladder preservation strategies, and divergent histology are other indications for radical cystectomy.

Muscle-Invasive Disease

The standard therapy for muscle-invasive bladder cancer in women is radical cystectomy. Survival after cystectomy for muscle-invasive disease is closely related to pathologic tumor stage. In patients without lymph node involvement, Stein et al. (4) reported 10-year recurrence-free survival rates of 87% in T2, 76% in T3, and 45% in T4 disease. Lymph node involvement varies with tumor stage, ranging from 18% of patients with T2a disease to 45% of patients with T3/T4 disease, and the 10-year recurrence-free survival rate in these patients was reported to be 34%.

Non–Muscle-Invasive Disease

Radical cystectomy should seriously be considered as an alternative to intravesical therapy in patients with high-grade T1 disease which is (a) recurrent, (b) associated with carcinoma in situ, and/or (c) combined with adverse histologic features (mixed histology, lymphovascular invasion, inverted growth pattern, or nested variant). Patients with non–muscle-invasive disease resistant or refractory to endoscopic resection and intravesical therapy (particularly bacille Calmette-Guérin) are at significant risk of progression, and repeated courses of intravesical therapy can compromise overall survival (12,13). This may be due to the 30% incidence of understaging in patients with noninvasive disease (13). Divergent histology is identified on 25% of transurethral resection of bladder tumor specimens and has been shown to correlate with high-grade and invasive disease (14).

Failure of Alternative Therapies

Alternatives to cystectomy can include systemic chemotherapy, radiation therapy, and aggressive transurethral resection of the tumor, ideally in combination. Although there are no randomized trials comparing bladder-sparing regimens with radical cystectomy, these bladder-sparing modalities have historically been offered to patients who have a solitary tumor <5 cm in size, clinical stage T2 disease without hydronephrosis, minimal or no carcinoma in situ, and no evidence of extravesical disease. Patients who are poor surgical candidates (due to age or medical comorbidities) or refuse cystectomy are also considered for organ preservation strategies.

A significant proportion of these patients will have a complete response to maximal endoscopic resection with chemoradiation (15). More recently, newer chemoradiation regimens have been proposed, even for clinical T1 tumors, in an effort to provide greater sexual and urinary quality of life in bladder cancer patients (16). Concurrent chemoradiation does appear to be more effective than radiotherapy alone, with a phase 3 trial showing 48% 5-year survival in a cohort receiving fluorouracil and mitomycin compared to 35% 5-year survival in a cohort receiving radiation alone (17). Lifelong routine surveillance is critical in this cohort, and 30% to 40% of patients will ultimately require salvage radical cystectomy for disease recurrence (15,18).

Intractable Local Symptoms

Side effects of intravesical therapies are generally mild and managed conservatively. More serious side effects including severe bladder contracture are rare, occurring in <1% of patients treated with intravesical therapy; however, these can also be managed with cystectomy (19). This decision requires an active discussion between the physician and patient to balance the risks of surgical intervention with the impact of patient symptoms on quality of life.

PREOPERATIVE CONSIDERATIONS

Age and Medical Comorbidities

While cystectomy is readily applied to younger populations, the elderly often have limited access to radical surgery and are counseled toward nonsurgical interventions. However, cystectomy is often the best treatment option for invasive bladder cancer in the elderly who are in reasonably good health, because they may be more likely to have extravesical disease at the time of cystectomy (20). Invasive urothelial carcinoma is not an indolent disease, with cancer-associated death being high in the first 3 to 4 years. Thus, for an otherwise healthy 75-year-old woman, it may represent the biggest risk to her health. Bladder cancer patients of all ages often have multiple medical comorbidities, impacting both perioperative and long-term all-cause mortality and should be discussed when considering cystectomy (21). Elderly patients, in particular, need to be extensively counseled regarding the risks of surgery because 90-day mortality is as high as 13% in individuals older than 75 years undergoing radical cystectomy (7).

Functional Outcomes and Quality of Life Measures

When proceeding to definitive surgical treatment in the female bladder cancer patient, the physician should consider the woman's age, sexual function, and childbearing status in conjunction with her clinical stage. For premenopausal patients with carcinoma in situ, early invasive disease (T1), or anterior low-volume T2 disease, radical cystectomy should be performed with intent to preserve the vagina, uterus, ovaries, and urethra, potentially preserving sexual and urinary function. In addition, it is important to consider the need to maintain body image by offering continent and orthotopic diversions, the formation of which has been associated with continence rates between 76% and 82% (11,22,23). Even after the initial postoperative adjustment period, Gacci et al. (24) showed that incontinent diversions were associated with significantly lower rates of physical and emotional well-being in female bladder cancer patients. Table 20.1 outlines our paradigm for the extent of surgical intervention. Indications for urinary diversion are outlined in Section I of this book.

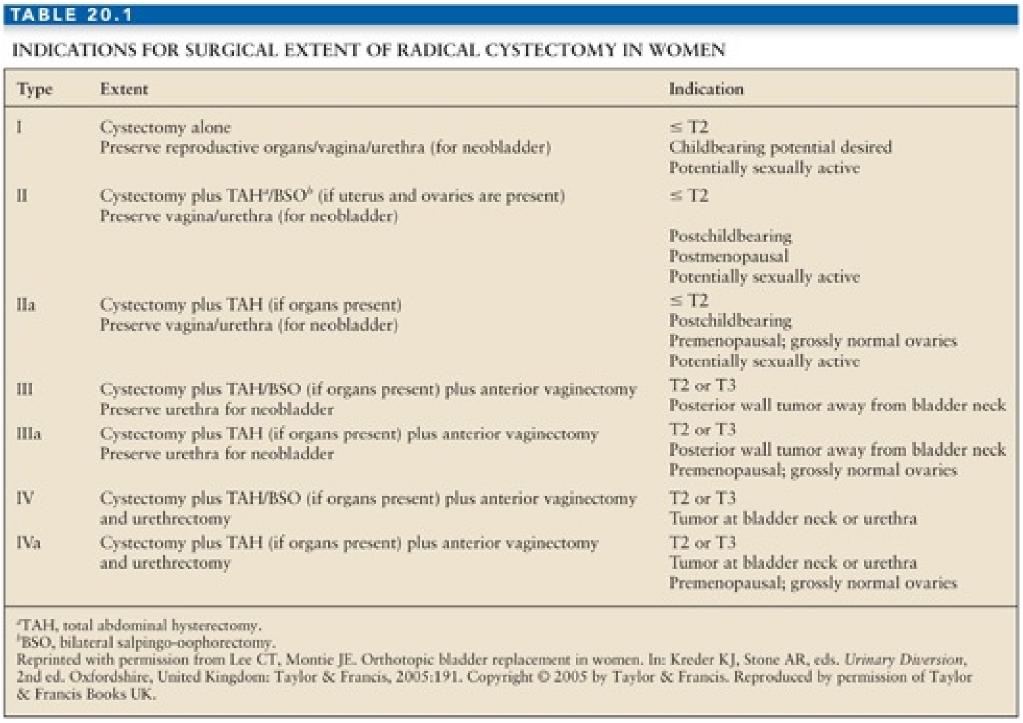

TABLE 20.1

INDICATIONS FOR SURGICAL EXTENT OF RADICAL CYSTECTOMY IN WOMEN

Type	Extent	Indication
I	Cystectomy alone Preserve reproductive organs/vagina/urethra (for neobladder)	≤ T2 Childbearing potential desired Potentially sexually active
II	Cystectomy plus TAH[a]/BSO[b] (if uterus and ovaries are present) Preserve vagina/urethra (for neobladder)	≤ T2 Postchildbearing Postmenopausal Potentially sexually active
IIa	Cystectomy plus TAH (if organs present) Preserve vagina/urethra (for neobladder)	≤ T2 Postchildbearing Premenopausal; grossly normal ovaries Potentially sexually active
III	Cystectomy plus TAH/BSO (if organs present) plus anterior vaginectomy Preserve urethra for neobladder	T2 or T3 Posterior wall tumor away from bladder neck
IIIa	Cystectomy plus TAH (if organs present) plus anterior vaginectomy Preserve urethra for neobladder	T2 or T3 Posterior wall tumor away from bladder neck Premenopausal; grossly normal ovaries
IV	Cystectomy plus TAH/BSO (if organs present) plus anterior vaginectomy and urethrectomy	T2 or T3 Tumor at bladder neck or urethra
IVa	Cystectomy plus TAH (if organs present) plus anterior vaginectomy and urethrectomy	T2 or T3 Tumor at bladder neck or urethra Premenopausal; grossly normal ovaries

[a] TAH, total abdominal hysterectomy.
[b] BSO, bilateral salpingo-oophorectomy.

PREOPERATIVE CARE

Optimization of preoperative performance and nutritional status helps reduce the risk of perioperative complications and may be associated with improved perioperative as well as overall survival (2,25). Patients are encouraged to augment their diet with protein and caloric supplements if they have anorexia or significant unintended weight loss. Although mechanical bowel preparation was formerly the standard of care, increasing evidence over the past 10 years has suggested that this is likely unnecessary and can be safely omitted in patients undergoing urinary diversion with small intestine. Large et al. (26) showed that a GoLYTELY (polyethylene glycol/electrolytes) bowel prep did not appear to impact rates of perioperative infection or bowel complications. In another study, where patients were prospectively randomized to undergo or not undergo mechanical bowel preparation prior to radical cystectomy and ileal urinary diversion, a nonstatistically significant increase in complication rate was observed in the group receiving a bowel preparation (27). Wound prophylaxis is achieved in the perioperative period with a second-generation cephalosporin antibiotic administered over a 24-hour period.

The authors of this chapter have also begun short-term perioperative administration of alvimopan (Cubist Pharmaceuticals, Inc, Lexington, Massachusetts) for most patients because it has been shown to reduce the time to return of bowel function and is well tolerated by patients (28). Alvimopan is contraindicated in patients who have taken opioids for more than a week prior to surgery and patients with end-stage renal disease. Patients should be counseled regarding a potential increase in the risk of myocardial infarction, although this has not been observed with short-term alvimopan use. Pneumatic compression stockings and 5,000 units of low-dose unfractionated subcutaneous heparin are administered prior to induction of anesthesia for deep venous thrombosis prophylaxis. Enhanced Recovery After Surgery pathways have been used to reduce complications and length of stay after colorectal surgery and are being studied for cystectomy patients to optimize perioperative care (29).

SURGICAL TECHNIQUE

Anatomic Considerations

Female Continence

An understanding of the female continence mechanism in women is critical prior to consideration of an orthotopic neobladder. There are two continence mechanisms in women (30). The first is the proximal urethra, smooth muscle fibers of which are innervated by autonomic fibers from the pelvic plexus that course adjacent to the bladder neck and vagina. These nerves often are transected during a radical cystectomy. The second is the rhabdosphincter, intermingled smooth and striated muscle fibers located in the middle to lower one-third of the urethra. Somatic innervation of the striated muscle fibers is via the pudendal nerve and appears to be the critical sphincter mechanism for continence in women (30). Because the rhabdosphincter is present in the middle to lower urethra, and the somatic nerves run below the endopelvic fascia along the levator ani, the entire bladder and bladder neck can be resected without compromising eventual continence. Importantly, complete resection of the bladder is necessary to minimize the amount of transitional epithelium left behind and thus reduce the risk of local tumor recurrence as well as hypercontinence after orthotopic urinary diversion. Alteration in the anatomic relationships between the remnant urethra and its fascial attachments also contribute to incontinence, so care should be taken to preserve the endopelvic fascia and pubourethral ligaments in patients undergoing orthotopic neobladder creation in order to minimize the risk of long-term incontinence (10).

Female Sexual Function

A similar pelvic plexus supporting erectile function exists in both men and women. Anterior exenteration with removal of the urethra has been shown to result in clitoral devascularization with decreased sexual arousal due to disruption of the neurovascular bundles lateral to the anterior vagina (31). In addition, resection of the vagina is often associated with disruption of the autonomic neurovascular plexus, further compounding the impact on sexuality. Meticulous preservation of all of the lateral portions of the vaginal wall as well as the urethra can avoid injury to the pelvic plexus and may reduce the impact on sexual function (32). Furthermore, vaginal reconstruction after vaginectomy traditionally results in a greatly shortened or narrowed vault often not compatible with vaginal intercourse (33). The physical and psychosocial ramifications greatly undermine sexual function. Similarly, the presence of an incontinent stoma can greatly affect female sexual function and body image following cystectomy (24). In a retrospective study of Egyptian women who had undergone non–nerve-sparing cystectomy, El-Bahnasawy et al. (22) found stomal diversions to be associated with significantly reduced sexual function.

Anterior Exenteration

Patients are positioned in either a modified lithotomy position with Allen-type stirrups or in a frog-leg position in order to allow sterile access to the vagina and urethra. The vagina and perineum must be well prepared with an iodine or Betadine scrub. An infraumbilical vertical midline incision gives ideal exposure; however, patient habitus or a planned extended lymph node dissection may necessitate an extension of this incision another 2 to 3 cm superiorly. The urachal remnant provides a convenient handle for traction on the bladder (Fig. 20.1). The peritoneum is divided along the lateral umbilical ligaments (Fig. 20.2), and the round ligament is ligated and divided. A self-retaining retractor, such as a Bookwalter device or omnitractor, will maintain exposure. The fallopian tubes and ovaries are present and nonfunctional in this predominantly postmenopausal population and thus are typically removed with the uterus, cervix, and anterior vagina. The gonadal vessels and suspensory ligament are divided above the ovaries (Fig. 20.3). The ureters are mobilized with substantial periureteral adventitia to preserve optimal blood supply and later divided at the bladder hiatus (Fig. 20.4). Ligation and division of the uterine and vaginal arteries branching from the hypogastric artery is usually required to accomplish this.

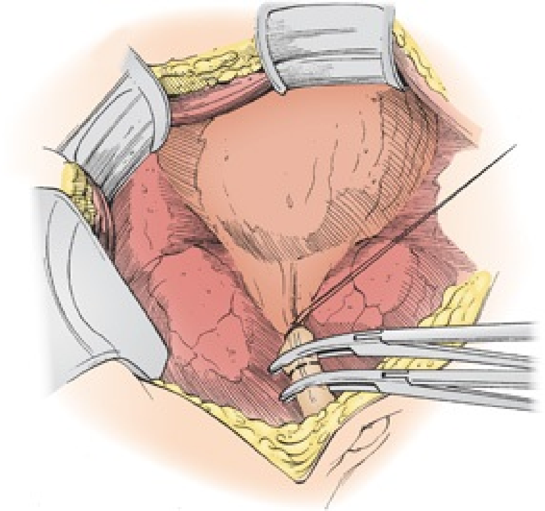

FIGURE 20.1 The urachal remnant provides a convenient handle for traction on the bladder through the case and is divided between Kelly clamps and ligated.

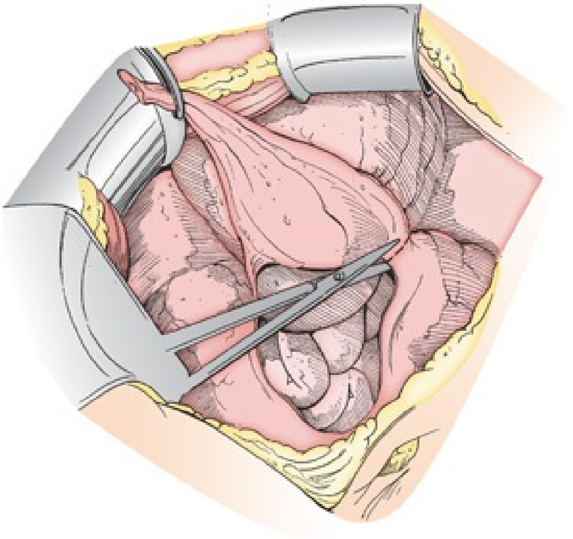

FIGURE 20.2 The division of the peritoneum follows the course of the lateral umbilical ligament until the round ligament is identified, clipped, and divided.

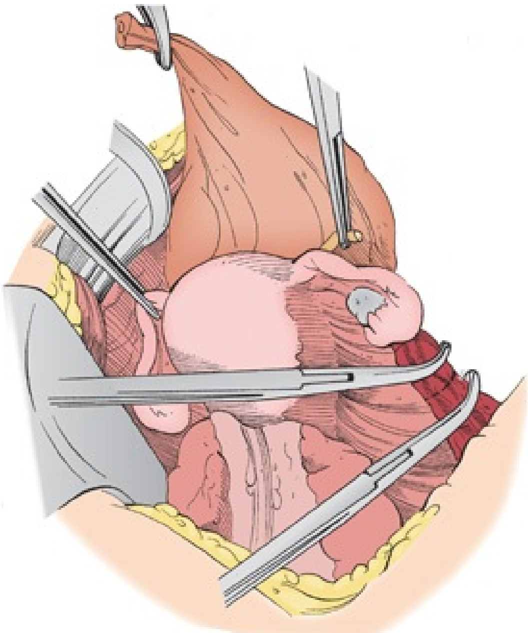

FIGURE 20.3 The fallopian tubes and ovaries, if present, are commonly removed with the uterus and bladder. The gonadal vessels, surrounded by the suspensory ligament, are divided and ligated cephalad to the ovary.

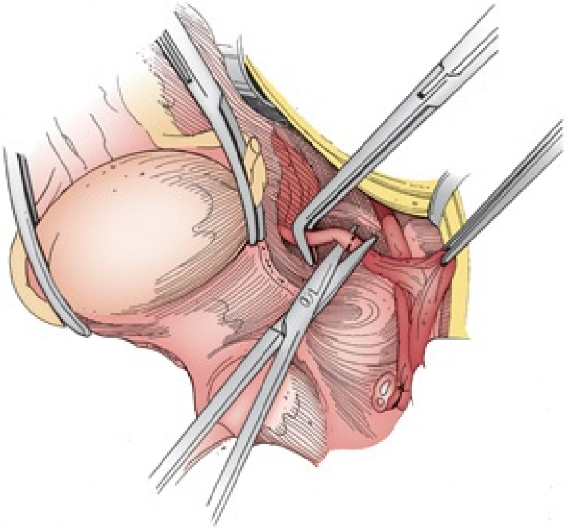

FIGURE 20.4 Each ureter is mobilized with a large amount of periureteral adventitial tissue to preserve optimal blood supply. The ureter is divided a short distance above the bladder.

The lateral blood supply to the bladder and uterus is isolated as it courses from the internal iliac artery and vein. The endopelvic fascia and the perirectal “fat pad” are exposed with medial traction on the bladder and ureter. The index finger is used to bluntly develop a plane just medial to the well-defined superior vesical artery, aiming obliquely toward the perirectal tissue. This will isolate the superior vesical artery, which requires ligation. Several small associated arteries and veins can be ligated and divided at this point, thus controlling the lateral pedicle under direct vision (Fig. 20.5). Medial traction on the bladder with fingers above and below the pedicles enhances exposure. Alternatively, these vessels may be controlled during ligation and division of the vaginal wall (below).

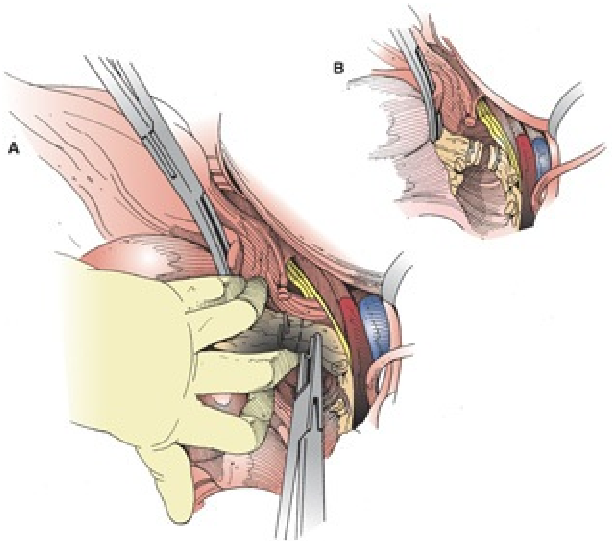

FIGURE 20.5 Division of the lateral pedicle is one of the more important technical aspects of the procedure. The endopelvic fascia should be well exposed with blunt dissection. A perirectal fat pad lying adjacent to the rectum defines the lower limit of the lateral pedicle coursing from the internal iliac vesical. Medial traction on the urachal remnant and retraction of the ureter medially allow an index finger to create a plane just medial to the origin of the superior vesical artery outlining the lateral pedicle. The caudad extent of blunt dissection is the perirectal fat tissue. **A:** The medial traction on the bladder with the surgeon's nondominant hand easily exposes the entire pedicle. **B:** The superior vesical artery is ligated, but the remainder of the small vessels can be controlled with clips on both sides.

After division of the lateral pedicles on each side, the technique is modified depending on the type of extirpative procedure to be performed. In a classic anterior pelvic exenteration, the bladder, uterus, bilateral fallopian tubes and ovaries, anterior vaginal wall, and urethra are removed en bloc (Fig. 20.6). This is warranted for a deeply invasive posterior bladder wall cancer. Alternatively, partial or complete preservation of the reproductive organs can be considered, especially if orthotopic urinary diversion is planned, as described later. To mobilize the anterior pelvic organs, an incision is made in the posterior peritoneum down to the rectovaginal cul-de-sac. Blunt and sharp dissection in the midline mobilizes the posterior vaginal wall; this mobility will allow the posterior vaginal wall to be rolled anteriorly away from the rectum for vaginal reconstruction.

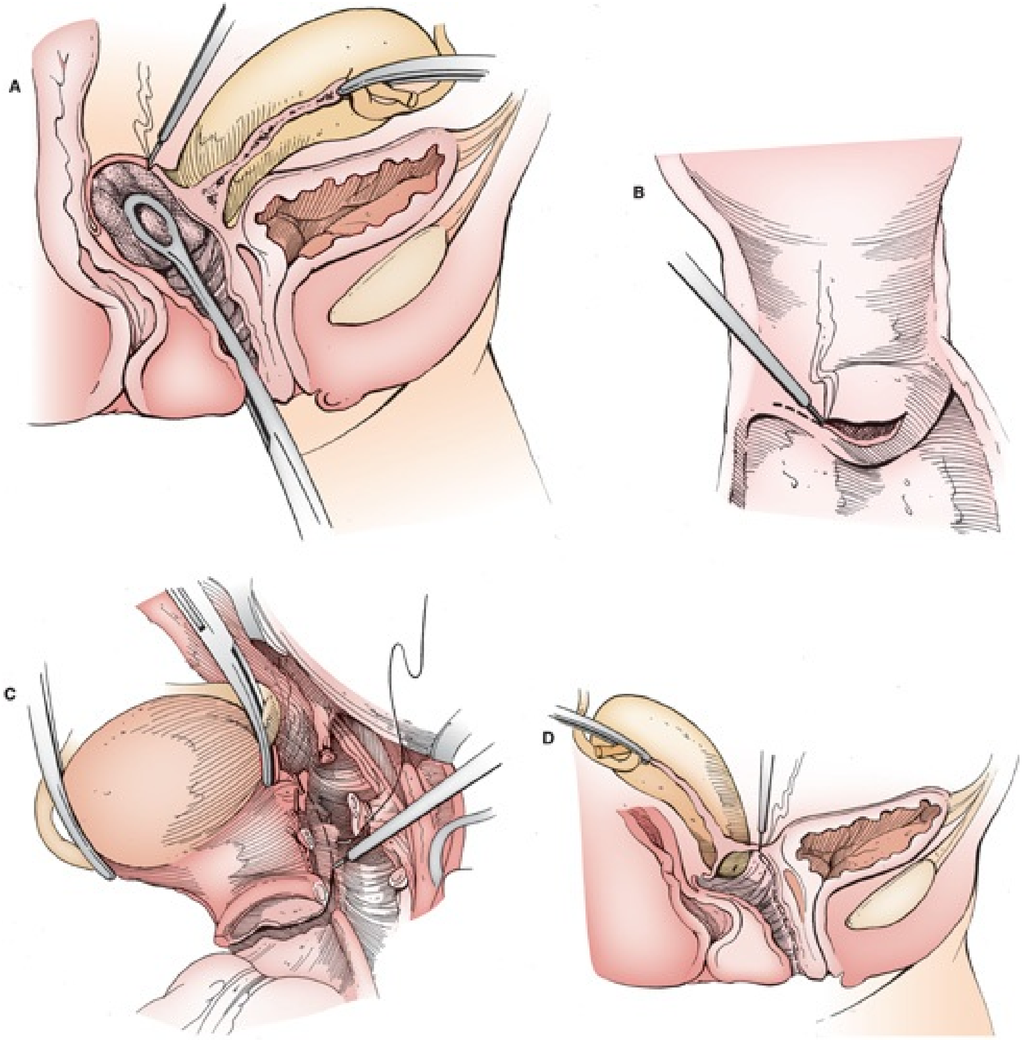

FIGURE 20.6 The classic anterior pelvic exenteration includes removal of the bladder, uterus, bilateral fallopian tubes and ovaries, anterior vaginal wall, and urethra. **A and B:** An incision is made with cautery at the apex of the vagina. This is often facilitated with a Betadine-soaked sponge stick placed in the vagina on upward traction. The incision should be as close as possible to the posterior aspect of the cervix. **C:** The incision is then carried around laterally along the anterolateral aspect of the vagina. There is commonly a rich blood supply to the lateral aspect of the vagina, and this is most easily controlled with multiple suture ligatures in a stepwise fashion. The incision stops just before the endopelvic fascia. **D:** With this dissection, the entire anterior vaginal wall, posterior bladder wall, and urethra are removed en bloc.

A Betadine-soaked sponge stick is placed in the vagina, elevating the apex of the vagina just posterior to the cervix. Cautery is used to open the apex of the vagina in the midline; this incision is carried laterally down the anterior vaginal wall on each side with care taken to remove only a narrow strip of the vaginal wall in order to facilitate vaginal closure (Fig. 20.6A–C). A variety of electrosurgical devices can be useful in this maneuver (e.g., LigaSure, Olympus PKS, harmonic scalpel), greatly minimizing venous bleeding from the vaginal wall. Alternatively, a surgical stapler (e.g., Endo GIA) can be utilized to ligate and divide the vaginal wall. Additional bleeders from the adjacent tissue may be controlled with 2-0 Vicryl suture ligatures and/or hemoclips. This dissection is continued to the bladder neck. If cutaneous diversion is planned, the pubovesical attachments are sharply divided and the proximal urethra is mobilized. Depending on the tumor location, a portion of the proximal urethra can be sharply dissected off of the anterior vaginal wall, which is transected at the bladder neck, leaving a portion of the anterior vaginal wall intact within the pelvis. This preserves a greater portion of the vagina and allows for an easier vaginal reconstruction later. The dissection then moves to the perineum after reasonable hemostasis has been achieved within the pelvis.

Urethrectomy

To perform the urethrectomy, the labia are retracted laterally with suture ligatures. Army-Navy or self-retaining retractors provide exposure to the urethral meatus. An inverted U-shaped incision is made around the urethra (Fig. 20.7A), and the urethra is mobilized anteriorly and laterally. If the patient is in a frog-leg (rather than lithotomy) position, this maneuver is performed by leaning over the perineum. Next, returning to the pelvic approach, suture ligatures are placed in the venous plexus anterior to the urethra, analogous to control of the dorsal venous plexus in men. Further simultaneous antegrade dissection can help to direct the retrograde dissection from the perineum until there is continuity between the pelvis and perineum. Ultimately, the anterior vaginal wall posterolateral to the urethra is divided to connect with the pelvic dissection, permitting removal of the entire specimen. If the patient is frog-legged, more of the dissection can be performed from the pelvic approach by using a finger to hook the Foley catheter where it exits the urethra and pulling it up into the pelvis. This exposes the urethral meatus, which can then be excised in its entirety. Alternatively, a circumferential periurethral incision can be made, preserving a portion of the anterior vagina located posterior to the urethra (Fig. 20.7B and C). Subsequent simultaneous antegrade and retrograde dissection will allow complete urethral mobilization and excision, as noted earlier.

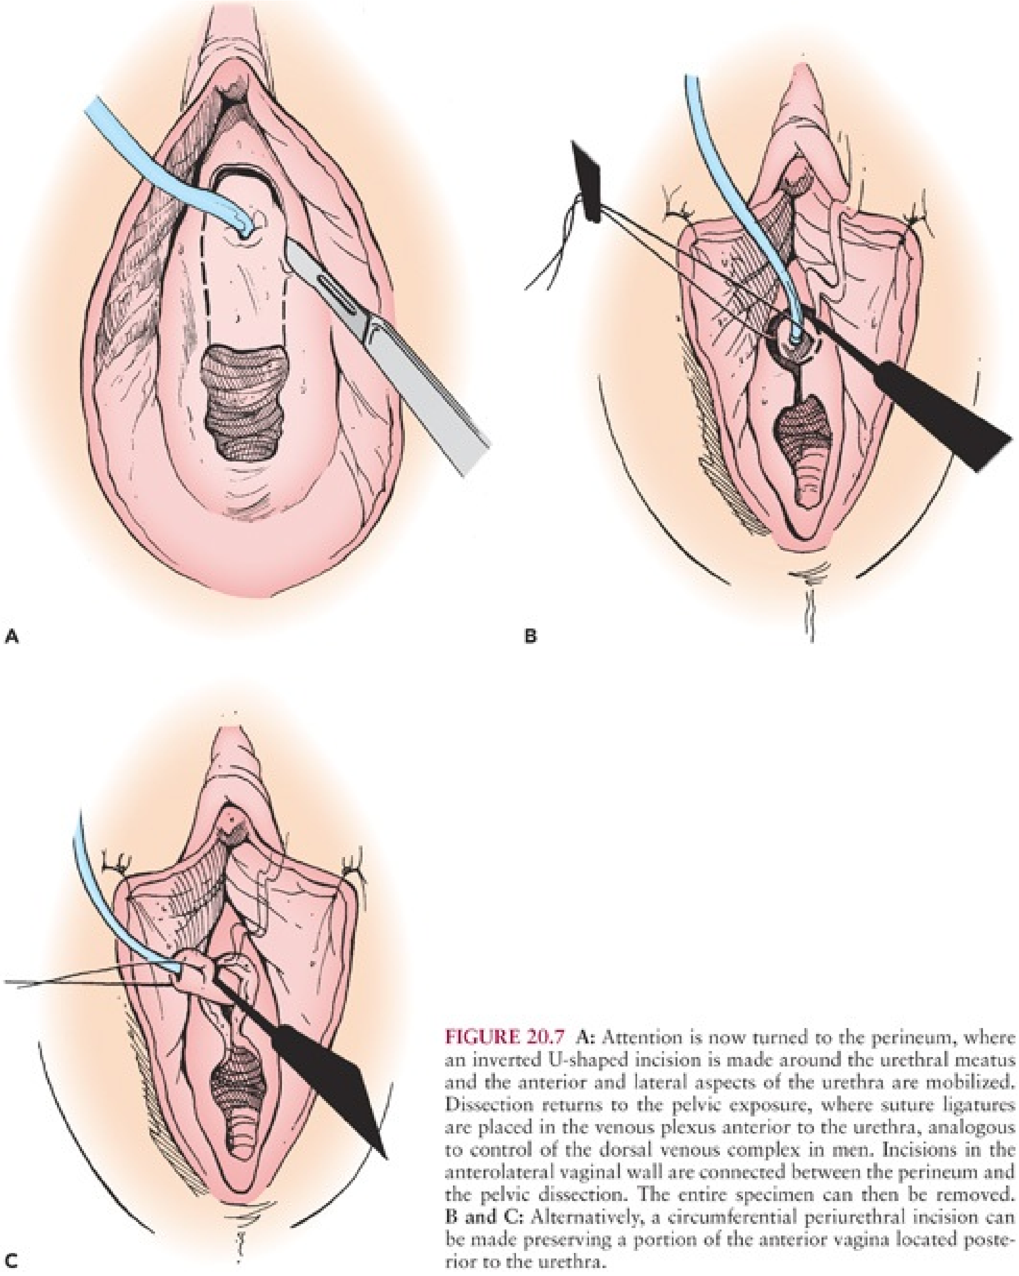

FIGURE 20.7 **A:** Attention is now turned to the perineum, where an inverted U-shaped incision is made around the urethral meatus and the anterior and lateral aspects of the urethra are mobilized. Dissection returns to the pelvic exposure, where suture ligatures are placed in the venous plexus anterior to the urethra, analogous to control of the dorsal venous complex in men. Incisions in the anterolateral vaginal wall are connected between the perineum and the pelvic dissection. The entire specimen can then be removed. **B and C:** Alternatively, a circumferential periurethral incision can be made preserving a portion of the anterior vagina located posterior to the urethra.

Vaginal Reconstruction

The vagina is reconstructed by rotating the apex of the posterior vaginal wall anteriorly in a clamshell fashion in order to create a foreshortened vagina that maintains the previous width (Fig. 20.8). Additional mobilization of the apex of the vagina off of the rectum is sometimes required in order to ensure the vaginal closure is tension-free. A stay suture in the apex of the posterior vaginal wall brings the vaginal wall to the perineum, if a total anterior vaginectomy was required; this flap of vagina is sutured to the periurethral vaginal tissue anteriorly in the midline and then sequentially on each side. After two to three interrupted sutures are placed on each side from the perineum, additional sutures higher up on the vaginal wall are more easily placed from the pelvic exposure. A watertight closure provides optimal hemostasis of the paravaginal tissue.

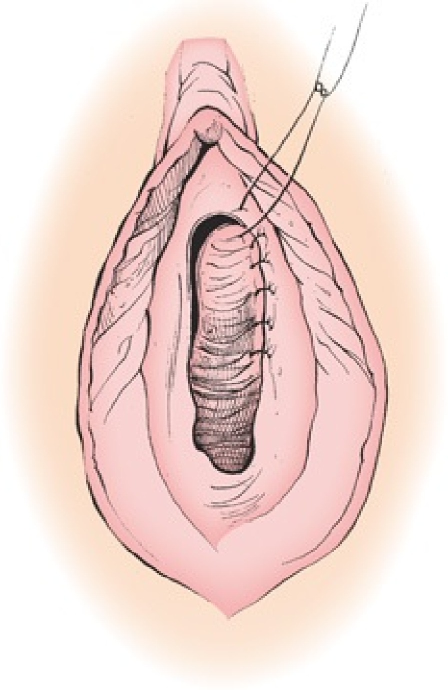

FIGURE 20.8 Several methods of closure of the vagina are feasible. One that appears to supply strong support of the pelvis uses the posterior vaginal wall as a flap to create a neovagina. This foreshortens the vagina but does not narrow it as a side-to-side closure does and thus provides for a better return of sexual function, if appropriate. A suture is placed in the apex of the posterior vaginal wall from above; this is used to bring the posterior flap of the vagina down to the perineum. Several sutures are placed from below, incorporating a full thickness of the periurethral vaginal tissue to the posterior vaginal wall flap. Sutures closer to the apex of the vagina are more easily placed from the pelvic exposure.

If the tumor characteristics permitted partial anterior vaginectomy, and a portion of the anterior vaginal wall was preserved within the pelvis below the bladder neck, the posterior vaginal flap is apposed to this anterior stump within the pelvis (see Fig. 20.8). The lateral walls are then closed sequentially from within the pelvis with running Vicryl suture. Using this approach, a circumferential urethral incision would have been used (Fig. 20.7B), and the prevaginal tissues identified in the perineum would then be sutured to the retropubic tissues with running or interrupted Vicryl suture. A vaginal pack soaked in Betadine or estrogen cream (e.g., Premarin) is left in the vagina for 24 hours.

Reproductive Organ Preservation

In appropriately selected patients, all or part of the female reproductive tract can be preserved. Certainly, the age, childbearing status, and sexual function of the patient must be considered when planning radical extirpative procedures (Table 20.1). If the disease is felt to be organ-confined and located favorably, it is reasonable in young women with childbearing potential to spare the reproductive organs, since it is increasingly clear that most female organs are uninvolved by primary bladder cancer and that local recurrence is uncommon (9,11,34,35). The ovaries, in particular, are very rarely involved (36). When orthotopic diversion is planned in the sexually active postmenopausal woman with a tumor site away from the trigone or bladder neck, the anterior vagina should be preserved.

The surgical approach begins with a similar midline incision as described for anterior pelvic exenteration followed by the development of the extravesical space. The urachus is divided, and peritoneal flaps are developed on either side of the bladder. The round ligament is ligated, and the ureters are mobilized as described previously. A sponge stick is placed in the vagina to readily identify the vaginal apex and cervix and also to provide countertraction. The plane between the posterior bladder and anterior vaginal wall is developed (Fig. 20.9). This dissection must hug the anterior vaginal wall so as not to compromise the cancer surgery but also to avoid the troublesome bleeding that can be encountered when the dissection is in the wrong plane. A potential advantage of this approach is avoidance of the rich vascularity of the vagina, which is appreciated when the entire anterior vaginal wall is resected. During this dissection, care should be taken to avoid entry into the vagina, which could increase the risk of fistula formation when orthotopic diversion is planned. In this circumstance, an omental flap can be used to cover the vaginal repair.

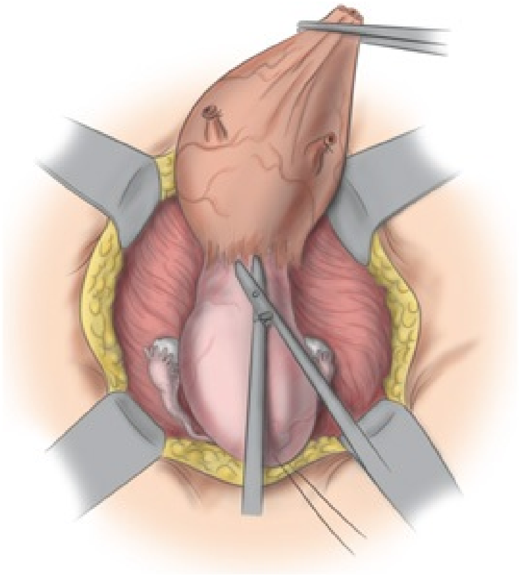

FIGURE 20.9 When partial or complete female pelvic organ preservation is planned with or without orthotopic urinary diversion, a plane is created sharply between the posterior bladder wall and anterior vagina. Care should be taken to avoid entry into the vagina as this increases the risk of fistula formation. Vaginotomies should be closed. (Reprinted with permission from Lee CT, Montie JE. Orthotopic bladder replacement in women. In: Kreder KJ, Stone AR, eds. *Urinary Diversion*, 2nd ed. Oxfordshire, United Kingdom: Taylor & Francis, 2005:190. Copyright © 2005 by Taylor & Francis. Reproduced by permission of Taylor & Francis Books UK.)

If appropriate, the uterus, fallopian tubes, and ovaries may be left in situ. This is an optimal choice for the sexually active female with low-volume or early-stage disease who has concerns about future fertility. If hysterectomy is required after vaginal-sparing surgery, a sharp incision is created at the vaginal apex and carried circumferentially around the cervix, preserving as much vaginal tissue as is feasible. The vaginal cuff is closed using 3-0 Vicryl in a continuous fashion, followed by an additional layer of 2-0 Vicryl interrupted Lembert sutures.

Retrograde Dissection and Urethral-Sparing Technique

In planning for orthotopic diversion, modifications in the technique of pelvic exenteration are necessary when approaching the bladder neck and urethra. It is important to maintain the integrity of the endopelvic fascia and thus preserve the support of the external sphincter in order to facilitate long-term continence. Dissection of the lateral wall of the vagina should also be avoided to prevent injury to the neurogenic innervation of the rhabdoid sphincter. Lastly, the bladder neck must be removed entirely to minimize postoperative urinary retention and maximize the removal of urothelial tissue.

Once the bladder has been mobilized off the vagina down to the bladder neck, fine sutures are used anteriorly in the periurethral tissue as necessary for hemostasis of the venous plexus. The urethra is amputated sharply at the junction with the bladder neck, avoiding distal mobilization or dissection of the urethra (Fig. 20.10). After the bladder has been removed, a sample of the urethra is circumferentially excised from the specimen or the urethral stump (if necessary) and sent for frozen section to ensure a negative urethral margin. Exposure is often ideal for the enterourethral anastomosis which can be aided by applying perineal pressure. The authors prefer six to eight fine absorbable sutures using 2-0 Monocryl, taking small bites on the urethra. Mobility of the intestinal reservoir to the urethra is generally not a problem in women, although it can be in men.

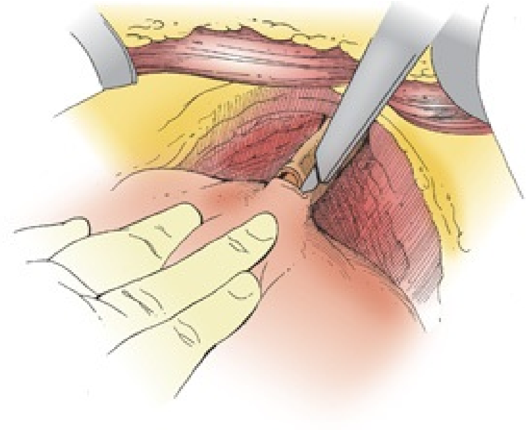

FIGURE 20.10 In the situation in which an orthotopic diversion is planned, neither the endopelvic fascia nor the anterior venous plexus is disturbed. An incision is made in the anterior urethra just distal to the junction with the bladder neck. The urethra is divided completely, and the dissection of the bladder off the anterior vaginal wall can be done in either an antegrade or retrograde fashion.

In the initial experience with orthotopic diversion, the concern for stress incontinence was such that anterior urethral fixation sutures were placed to prevent hypermobility of the urethra. This maneuver is not only unnecessary (unless documented stress incontinence from hypermobility is evident preoperatively) but could also be counterproductive by contributing to increased urinary retention or "hypercontinence." A possible additional mechanism for postoperative urinary retention may be exacerbation of a preexisting but previously insignificant cystocele. After the cystectomy, the urethra is fixed anteriorly and the patient voids by Valsalva maneuver after relaxing the external sphincter. If a cystocele is present, the increased abdominal pressure needed for voiding across the fixed urethra and bladder neck could be blunted by the cystocele. Increasing posterior support of the pouch with ventral suspension near the dome and of the vaginal stump has been described to minimize this side effect (37).

Robotic Cystectomy

There are some specific considerations for female robotic cystectomy. Patients are positioned in the low lithotomy position, the table placed in steep Trendelenburg, and prepped from the xiphoid through midthigh, including the genitals. A Foley catheter is placed and often a vaginal sponge stick or vaginal manipulator. Some surgeons elect to place a uterine manipulator at the beginning of the procedure to facilitate control of the uterus during the surgery (38).

Port placement proceeds in a similar fashion as for a male patient, and, following docking of the robot, the ureters are identified and dissected down to the level of the bladder. In order to maximize ureteral length, the ovarian pedicles can be identified and divided, and the cardinal, round, and uterosacral ligaments may be divided bilaterally prior to ligating and dividing the distal ureters. Next, retracting the uterus anteriorly, the junction between the uterus and posterior vaginal wall is divided. The posterior vaginal fornix is incised transversely and carried down to the vaginal sponge stick or manipulator with care taken to preserve as much vaginal wall as possible. Alternatively, a vaginal-sparing procedure may be performed. Attention is then turned to the anterior dissection where the bladder is dropped off of the abdominal wall. The dorsal venous complex may be suture ligated if necessary. The vaginal wall incisions are carried distally past the urethra so that the urethral meatus can be identified under direct vision and circumferentially incised (39,40). The anterior vaginal wall is removed en bloc with the bladder and urethra and the specimen is placed in an Endo Catch bag, which may be delivered through the vagina. Vaginal reconstruction is then performed.

All modifications performed in the open procedure may also be performed via a robotic approach. For example, in carefully selected patients, a reproductive organ–sparing operation can be performed. The uterus is retroverted, and with the bladder retracted anteriorly, it is carefully dissected off the uterus down to the cervix. The dissection is continued along the anterior vaginal wall and down to the bladder neck being careful not to thin either the vaginal wall or bladder (40).

Postoperative Care

Establishment of a critical care pathway is useful for cystectomy patients (41,42). Compliance with the ideal postoperative course is difficult after cystectomy because of a high frequency of comorbid disease and complications, which may delay discharge even if they are not life-threatening (43,44). Epidural analgesia, patient-controlled analgesia, and nonsteroidal anti-inflammatory agents are useful adjuncts to provide better postoperative pain control, which translates into better pulmonary hygiene, ambulation, and return of bowel function. The authors no longer routinely utilize nasogastric decompression postoperatively, although orogastric decompression can be helpful intraoperatively. Overall, excellent pain control, judicious use of diuretics to combat fluid retention, and aggressive pulmonary toilet are important strategies to prevent complications. Early ambulation, intermittent compression stockings, and unfractionated heparin (5,000 U just prior to the surgery and every 8 hours thereafter) are currently used for deep venous thrombosis prophylaxis (45). Routine perioperative parenteral nutrition is not necessary in the well-nourished patient; however, the clinician should consider this therapy in the early postoperative period for nutritionally debilitated patients or those likely to have prolonged ileus. In our experience, approximately 10% to 20% of patients need postoperative nutritional support.

OUTCOMES

From July 1995 through June 2013, we have performed 1,574 cystectomies; 342 (22%) patients were women. The median age in women was 67 years old. For us, age has not been a deterrent to providing definitive treatment in a patient with a reasonable life expectancy. This is reflected by the fact that 40% of patients undergoing cystectomy at our institution are older than 70 years, including 10% of patients older than 80 years. In addition, 32% of our patients are obese (body mass index >30 kg per m^2), and 49% of patients have an American Society of Anesthesiologists class of 3 or higher, suggesting greater operative risk. Adding to the patient complexity are the 33% of women receiving neoadjuvant systemic chemotherapy, which impacts nutritional status prior to surgical intervention. Currently, at our institution, this usually consists of gemcitabine and cisplatin or methotrexate, vinblastine, doxorubicin, and cisplatin regimens. Carboplatin is used in place of cisplatin for patients unable to receive cisplatin.

Our median operative time was 5.8 hours for women, which is comparable to the operative time for men; this time included anesthetic induction and reversal. Our median length of stay for women undergoing cystectomy is 8 days, reflecting our willingness to offer cystectomy to an often medically complex group of patients. Urinary diversion consisted of 63% ileal conduit, 35% orthotopic neobladder, and 2% cutaneous continent diversion, reflecting our continued use of orthotopic diversion in women.

COMPLICATIONS

Cystectomy remains a difficult operation in men or women, with a mortality rate of 1% to 3% (5,43,44). Twenty percent to 30% of patients will have a complication delaying discharge (44). Many of the specific complications after cystectomy are a consequence of the urinary diversion. Complications from the cystectomy portion include bleeding with subsequent coagulation abnormalities and rectal injury. Pelvic bleeding can be more difficult to control in women. Since 1995, the median blood loss in our female cohort has been 600 mL. A rectal injury should be extremely rare in women (due to the interposed vagina) and seen only in association with prior surgery or radiation therapy. The most frequent complications experienced in our female cystectomy series were urinary tract infection in 21%, prolonged ileus in 15%, wound infection in 8%, anemia requiring blood transfusion in 5%, clostridium difficile colitis in 5%, and intra-abdominal abscess in 3%. Thirty-day mortality was less than 1%.

The postoperative care after cystectomy requires a diligence over and above that seen with other urologic procedures. Some complications are preventable. A regimented, reproducible plan for the technique of cystectomy and diversion is enormously helpful to prevent errors during a 4- to 6-hour operation. Some complications are unavoidable, but recognition early in their evolution may drastically minimize the negative consequences, and a high index of suspicion is essential. Early recognition of a complication may prevent a cascade of other successive complications that may ultimately lead to increased morbidity or mortality (46).

CHAPTER 21 BLADDER DIVERTICULECTOMY

SARAH FRAUMANN FARIS AND SAM S. CHANG

Bladder diverticula are the herniation of the bladder mucosa through the detrusor muscle fibers and are classified as either congenital or acquired. Congenital diverticula are postulated to be due to an inadequately developed or thin muscular wall, which is especially vulnerable near the intravesical ureter resulting in a common association with vesicoureteral reflux (1). Bladder diverticula are more common in males, typically present <10 years old and are often solitary and in smooth-walled bladders on cystoscopic examination. In contrast, acquired bladder diverticula are secondary to the elevated intravesical pressures generated as a result of bladder outlet obstruction. The most common causes of outlet obstruction include benign prostatic hyperplasia, urethral stricture disease, bladder neck contracture, posterior urethral valves, and neurogenic voiding dysfunction such as detrusor sphincter dyssynergia. They typically present in males >60 years old and are often multiple and found in association with bladder trabeculation (2).

Diverticula are typically located in the weakest points of the bladder including the ureteral hiatus (paraureteral or Hutch diverticulum) and both posterolateral walls (1–3). The diverticular wall is composed of mucosa, subepithelial connective tissue or lamina propria, occasional muscle fibers, and adventitial tissue, and at times, a fibrous capsule or pseudocapsule may be present (Figs. 21.1 and 21.2) (2,4).

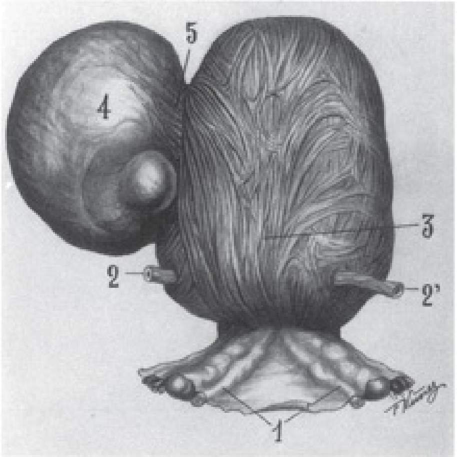

FIGURE 21.1 Posterior view of bladder and diverticulum: ampulla of vas deferens (*1*), ureters (*2* and *2'*), posterior longitudinal bundle of the outer layer of the detrusor (*3*), diverticulum (*4*), and circular fibers of the middle layer of the detrusor around the diverticular neck (*5*).

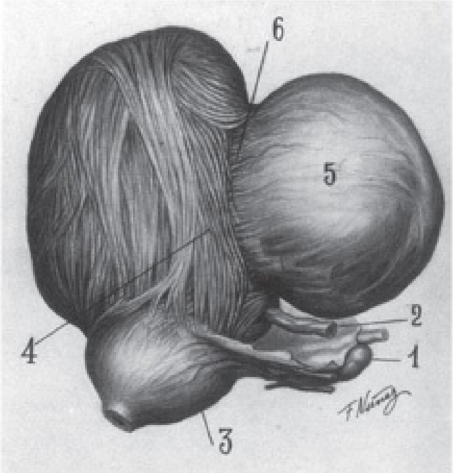

FIGURE 21.2 Lateral view of bladder and diverticulum: seminal vesical (*1*); ureter (*2*); prostate (*3*); anterolateral longitudinal fibers of the outer layer of the detrusor (*4*); diverticulum (*5*); and fine, circularly oriented fibers around the diverticular neck (*6*).

DIAGNOSIS

Acquired bladder diverticula are often asymptomatic and found during the workup for recurrent urinary tract infections, lower urinary tract symptoms, or hematuria. When signs and symptoms are present, they include irritative or obstructive voiding symptoms, pelvic pain or fullness, and hematuria. Urinary stasis often results in recurrent infections that can be difficult to eradicate and may also result in bladder stones. Bladder cancer can also develop in diverticula, and urine cytology should be considered. When evaluating for a bladder diverticula, the differential diagnosis includes urachal, prostatic utricle and müllerian duct cysts, ectopic ureteral insertion, and "pseudodiverticular" images observed in cystograms such as bladder ears, hourglass bladder, everting ureterocele, and vesicular hernias. Other less frequent congenital anomalies should also be considered, such as vesicourachal diverticulum, incomplete bladder duplication, and septation of the bladder (1,5).

Given the nonspecific nature of the presenting symptoms, diverticula are commonly diagnosed on radiographic imaging. Imaging provides important information regarding the number, location, size, and anatomy of the diverticula. A voiding cystourethrogram (VCUG) with lateral, oblique, and postvoid views provides information on the extent of the diverticulum, if there is associated vesicoureteral reflux and the degree of bladder emptying. Additionally, ultrasound, contrast-enhanced computerized tomography (CT) scan and magnetic resonance imaging (MRI) can be useful for the evaluation of associated masses or ureteral obstruction (Fig. 21.3).

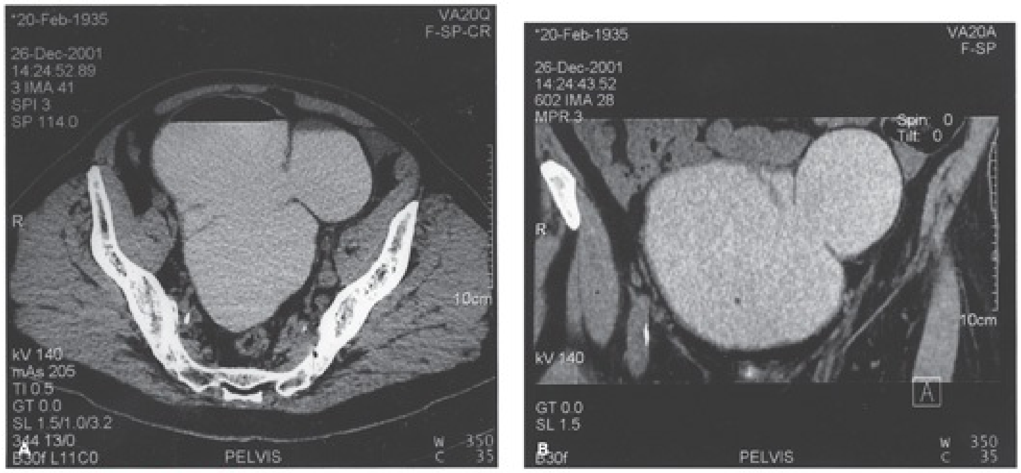

FIGURE 21.3 Contrast-enhanced CT scan demonstrating a large posteriorly based bladder diverticulum seen on (A) transverse and (B) sagittal images.

A video urodynamics study should be strongly considered to assess bladder anatomy, compliance, and contractility, and identify bladder outlet obstruction and neurogenic voiding dysfunction. It is important that underlying urologic abnormalities are addressed concurrently or prior to definitive surgical treatment of a bladder diverticulum. Prior treatment of the underlying etiology may result in resolution of the initial signs or symptoms, improve bladder emptying, and possibly render further surgical interventions unnecessary (2).

Cystourethroscopy should be performed to exclude urethral stricture disease and bladder neck contracture and rule out occult pathology such as a stone or carcinoma within the diverticulum (6). The entire surface of the diverticulum should be visualized, and the relative location of the ureteral orifices and bladder neck should be noted to assist in planning for any potential surgical procedure. Any suspicious mucosal lesions should be biopsied with extreme care taken to avoid bladder perforation.

INDICATIONS FOR SURGERY

All underlying urologic abnormalities should be addressed concomitantly or prior to definitive surgical treatment of a bladder diverticulum to prevent recurrence. Patients who have improved bladder emptying and symptomatology after relief of outlet obstruction can be managed expectantly with surveillance. In patients who have significantly impaired bladder contractility on preoperative urodynamics, persistently poor bladder emptying after relief of obstruction, or who are unable or unwilling to undergo surgical treatment of the bladder diverticulum, clean intermittent catheterization (CIC) or an indwelling catheter can be effective treatment options (2). In these patients, and in the absence of future complicating factors, surveillance of the bladder diverticulum with cystoscopy and urine cytology, and monitoring of the upper tracts with renal ultrasound and renal function, may be all that is required.

Indications for surgical intervention include chronic infections, stones, persistent symptoms, upper urinary tract deterioration from vesicoureteral reflux or obstruction, diverticular rupture, and malignancy (2). Additionally, we recommend simultaneous resection of all poorly emptying bladder diverticula to improve voiding if a patient is scheduled for an open prostatectomy, cystolithotomy, ureteroneocystostomy, or YV plasty of the bladder neck.

Malignancy has historically been reported in approximately 1% to 10% of diverticula; however, recent reports have found rates as high as 33% to 36% in clinically significant adult diverticula (6–8). Approximately 92% of these tumors are urothelial carcinoma, whereas 6% to 8% are squamous cell carcinomas, likely induced from chronic stasis of urine and infection. Additionally, compared to bladder carcinoma in general, there is an increased frequency of variant subtypes including squamous cell, neuroendocrine, adenocarcinoma, plasmacytoid, and signet ring cell and can be seen in approximately 25% of cases(7,8). Additionally, approximately 20% of patients will have coexisting intravesical urothelial carcinoma (7). Because of this potential malignant risk and the fact that these tumors can be difficult to diagnose, some have advocated prophylactic diverticulectomy. Alternatively, a more conservative strategy may be offered that includes surveillance cystoscopy and urinary cytology obtained at 6- to 12-month intervals.

ALTERNATIVE THERAPY

Many children with congenital diverticula who are asymptomatic and without urinary tract infections do not require therapy and a conservative approach has been advocated (1). Saccules and small diverticula may be treated successfully by transurethral electrocoagulation of their mucosa when the primary obstructive disease is endoscopically resolved. In addition, robotic-assisted, single-port, and laparoscopic approaches to bladder diverticulum may be effective as an alternative to open surgery with the distinct advantage of shortened convalescence time (9,10).

PREOPERATIVE ASSESSMENT

Aside from laparoscopic approaches, which are modifications of open techniques, there are two methods of surgical therapy: transurethral resection of the diverticular neck and open diverticulectomy. In either case, urine cultures should be obtained and infection must be adequately treated prior to surgery. If the lesion is acquired due to obstruction, the obstruction must be relieved prior to repair of the diverticula because this may obviate the need for additional surgical intervention and, if diverticulectomy is still necessary, prevent recurrence and subsequent treatment failure (2). If the diverticulum is due to high detrusor pressure of neurologic origin, this must also be addressed prior to surgical correction.

SURGICAL TECHNIQUE

Transurethral Resection

Endoscopic management may be a good option for elderly patients, poor open surgical candidates, or those with smaller diverticula that can be addressed at the time of transurethral resection of the prostate (2). Transurethral resection of the diverticular neck is a well-recognized treatment for small to midsized diverticula when the opening is not immediately impinging on the ureter (11). Using the standard resectoscope a Collins knife, loop or right-angle hooked electrode can be used to open the ostium of the diverticulum down to the muscular fibers of the bladder. This can be performed circumferentially and allows for subsequent inspection of the entire diverticular wall and facilitates drainage. Subsequent fulguration of the mucosa with a rollerball electrode can then be used to ablate the mucosa of the inner wall which can potentially obliterate the diverticulum or significantly reduce its size (2).

Caution must be exercised when tumor is present within a bladder diverticulum. Owing to the lack of muscular backing, transurethral resection of bladder tumors within a diverticulum carries a high risk of perforation. Cold-cup biopsy and fulguration may be appropriate for low-grade, low-stage tumors. The holmium laser may also be of use in this unique situation because it has a small fiber with a shallow depth of penetration (only 0.3 to 0.5 mm) and would certainly lower the risk of perforation or injury to adjacent structures. In those patients with high-grade or large diverticular carcinomas, particularly those with narrow ostium in which the risk of endoscopic perforation or inadequate resection is high, open diverticulectomy/partial cystectomy or total cystectomy has been advocated.

Open Surgical Technique

Open bladder diverticula excision has been described using three different approaches: extravesical, intravesical (also known as transvesical), and combined intravesical and extravesical. The most commonly used procedures and the points of technique that we use are described in the following sections.

For all procedures, the patient is placed supine on the operating table and the table flexed to aid with exposure. The external genitalia are then prepped into the sterile field. A Foley catheter is placed into the bladder on the surgical field to allow for passive drainage and active filling of the bladder as needed throughout the procedure. If the diverticulum is known to be in close proximity to ureters, ureteral stents should be considered to aid with dissection and avoid ureteral injury. If multiple diverticula are present, concomitant resection of all poorly draining diverticula is recommended.

The bladder is approached via an infraumbilical midline or transverse extraperitoneal incision, although alternatively a Gibson incision may be used. The linea alba of the rectus fascia is divided in the midline, and the rectus abdominis are spread apart. The transversalis fascia is then divided and the pelvis entered with care taken to avoid entry into the peritoneum. The dissection is carried into the space of Retzius and the anterior bladder wall and bladder neck are identified. After reflecting the peritoneum cephalad off the bladder dome, a self-retaining retractor can be placed to aid with exposure. Stay sutures are then placed in the detrusor at the dome and a vertical or horizontal cystotomy is performed. The self-retaining retractor can be adjusted and additional stay sutures placed as needed. The trigone, ureteral orifices, bladder neck and mucosa, and all possible diverticular orifices are clearly visualized. Ureteral catheters can be placed at this time if necessary.

In cases of intradiverticular tumor, some have advocated the instillation of 40 mg of mitomycin C by urethral catheter before the surgery. Intraoperatively, we carefully protect the surgical field with moist, sterile towels draped around the wound to avoid possible tumor contamination during diverticulectomy. The bladder mucosa should be thoroughly inspected to rule out papillary tumors that may have gone unnoticed on the previous endoscopic examination. The mouth of the diverticulum can also be packed with a small gauze pad to minimize potential tumor spillage.

Intravesical or Transvesical Diverticulectomy

For small diverticula <2.5 cm in diameter, we evert the diverticulum by gently grasping the bottom with an Allis- or Péan-type clamp inserted through the ostium and pulling it into the bladder. Careful inspection is then performed to ensure that adjacent structures have not been inadvertently pulled into the bladder due to adhesions to the diverticular wall. The mucosa of the diverticulum is then circumferentially divided at the diverticular neck using electrocautery and the diverticulum removed. The resulting vesicular defect is closed with 3-0 chromic catgut or Vicryl in two separate submucosal and muscular layers. In case of a saccule, a fine ligature of the neck and resection of its everted mucosa will suffice. If fibrosis secondary to infection is absent, the majority of small diverticula can be rapidly and easily removed using this technique.

If this maneuver is not feasible because of peridiverticular adhesions, we proceed to sharply divide the mucosa circumferentially around the diverticular orifice. The plane between the diverticular wall and surrounding fibrous pseudocapsule is identified. Gentle traction is then placed on the edges of the diverticular neck using Allis-type clamps. The external diverticular wall is carefully dissected free from the surrounding pseudocapsule in the periadventitial plane using a combination of blunt and sharp dissection and delivered into the bladder lumen. The bladder wall is then closed as previously mentioned (Fig. 21.4).

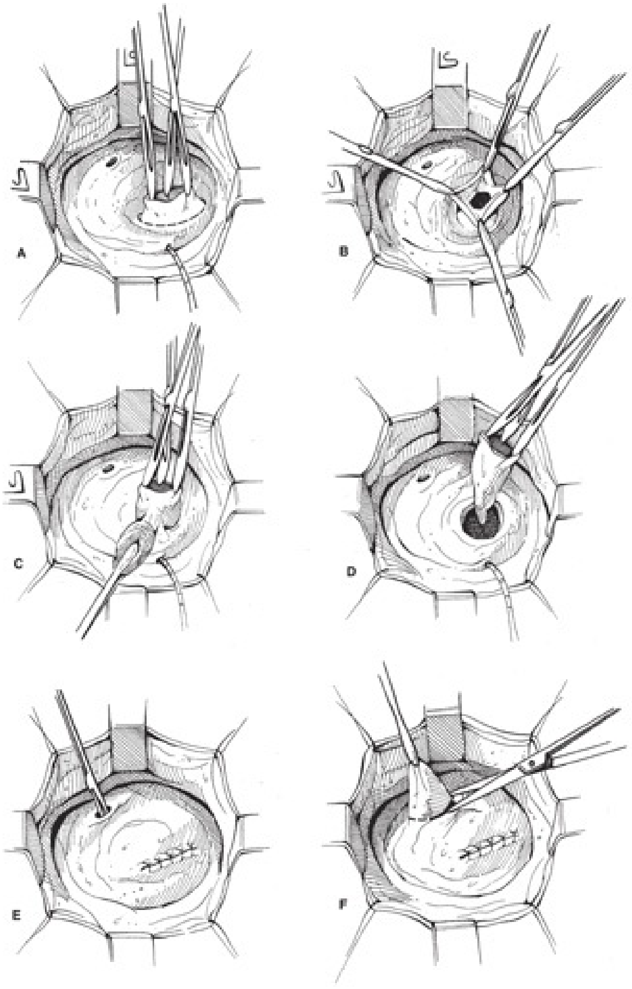

FIGURE 21.4 Technique of intravesical diverticulectomy. **A:** Diverticulum identified and (**B**) everted into the bladder. **C:** Inspection performed to ensure adjacent structures are not adherent to diverticular wall. **D:** Diverticular mucosa circumferentially divided at diverticular neck and diverticulum removed. **E:** Vesicular defect closed in two layers. **F:** Repeat as necessary.

Combined Intravesical and Extravesical Diverticulectomy

In patients with large diverticula or diverticula with significant peridiverticular inflammation, a combined intra- and extravesical approach is recommended. The bladder is opened and the diverticular ostium identified. Typically, a 7Fr or 8Fr ureteral catheter is placed into the ipsilateral ureter to aid with identification and to avoid inadvertent ureteral injury. Consider leaving an indwelling double-J ureteral stent for 2 to 3 weeks if the dissection is extensive. The surgeon can insert their index finger into the diverticulum bringing the neck outside of the bladder and assisting with the identification of the entire diverticulum. Alternatively, the diverticular sac can be filled with a moist gauze to unfold its wall and delimit its margins as accurately as possible. Overlying tissue is dissected free from the anterior bladder neck. The anterior neck of the diverticulum is then identified and incised extravesically with electrocautery (Figs. 21.5 and 21.6).

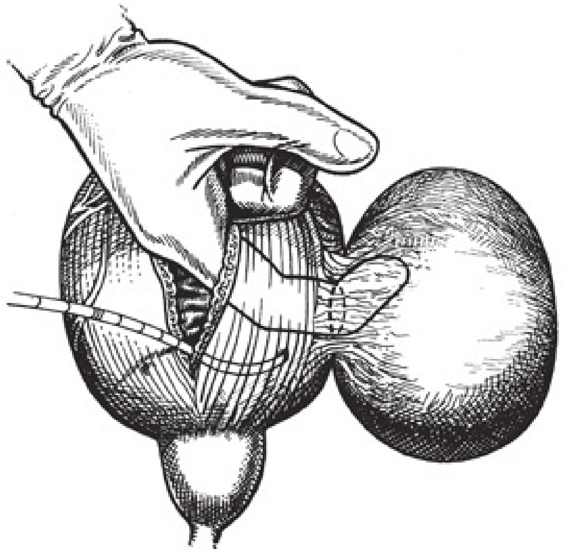

FIGURE 21.5 Procedure of combined intravesical–extravesical diverticulectomy. A finger is inserted into the bladder diverticulum from within the bladder.

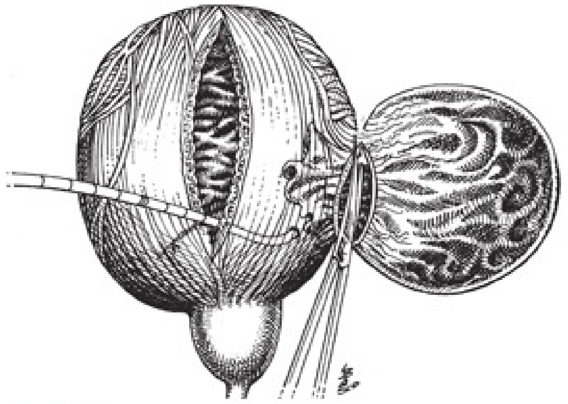

FIGURE 21.6 Procedure of combined intravesical–extravesical diverticulectomy. Once the diverticulum has been dissected, the mouth of the diverticulum is excised sharply.

Allis-type clamps are used for traction on the edges of the diverticulum, and the neck is circumferentially dissected from the bladder. The sac wall is then dissected from its surrounding pseudocapsule using a combination of sharp and blunt dissection. It is important to keep in mind that the ureteral course may have been distorted by the diverticulum, and the ureter may be closely adherent to the diverticular wall if repeated infectious processes have occurred. When extensive peridiverticular inflammation is present, it may be prudent to simply denude the diverticular mucosal lining with fine scissors or with the cutting current and the ball electrode from inside the diverticular cavity and then place a suction drain within it (first described by Pousson in 1901 and Geraghty in 1922).

The bladder wall and cystotomy are closed in two layers with absorbable 3-0 interrupted or continuous sutures and then the closure tested by filling the bladder. We leave a 10Fr closed suction drain in the space of Retzius and a urethral 18Fr or 20Fr Foley catheter, both of which may be removed after 5 or 6 days. For more extensive cases, those requiring large cystotomies, or in situations where there is prolonged drain output, the Foley catheter may be left in place for 10 to 14 days and a cystogram may be indicated prior to catheter removal.

OUTCOMES

Complications

The most serious complication of excision of a bladder diverticulum is an injury to the intramural or pelvic ureter during dissection. Placement of an ipsilateral ureteral catheter should help avoid this complication or aid in prompt recognition and repair. Small ureterotomies can be primarily repaired with absorbable 5-0 or 6-0 chromic or Vicryl and stented. If the distal ureter is severely damaged or completely severed, it is preferable to carry out ureteral reimplantation with or without a psoas hitch. More proximal injuries to the ureter may require a Boari flap or a transureteroureterostomy. End-to-end suture of ureteral edges is not recommended because there is a high likelihood that it will be complicated by urinary fistula or ureteral stenosis, which will further aggravate the situation.

Other potential complications include urinary fistula, urinary tract infection, bowel injury, and pelvic abscess. A less serious complication includes vesical urine leakage, which may cease spontaneously if the Foley catheter is maintained for additional days, providing the obstructive pathology has been resolved.

Results

Approximately one-third of bladder diverticulum are cured or significantly improved with transurethral resection. For benign disease, open excision is generally curative for that particular lesion, although correction of the underlying cause (e.g., outlet obstruction) is essential to prevent recurrence or the formation of additional diverticula. Historically, the prognosis of patients with carcinoma in the diverticula is generally poor. This has been attributed to the difficult and often delayed diagnosis and early escape from the confines of the bladder due to the lack of muscularis backing. However, more contemporary reports suggest relatively high 5-year survival rates of approximately 70%, attributed in part to earlier detection through improved radiographic imaging and a lower threshold for cystoscopy in the presence of hematuria, coupled with early aggressive surgical treatment (6,8). Nevertheless, due to the relative paucity of cases, treatment recommendations for these unique situations will continue to be based largely on patient characteristics and surgeon preferences.

CHAPTER 22 BLADDER AUGMENTATION

STEPHEN MARK

Augmentation cystoplasty remains the surgical treatment of choice for the medically resistant neurogenic and nonneurogenic overactive bladder. The management goals are the provision of a low-pressure, large-volume storage reservoir typically emptied by clean intermittent catheterization (CIC) to provide renal preservation, continence, and a low risk of urinary tract infections (UTIs). Studies confirm a significant improvement in quality of life of patients and treatment with a durable outcome (1). Lifelong follow-up is required due to the high rate of complications and the potential need for reoperation. Concern for malignancy following bladder augmentation seems to have waned, and regular cystoscopic surveillance is not recommended. Future prospects of tissue engineering to provide an augmentation patch remain in evolution. Patients with incontinent urinary diversions like ileal conduits more frequently develop UTIs and upper tract deterioration compared to those with large, low-pressure reservoir employing the urethra as a continence method (2).

HISTORY

Augmentation cystoplasty was first described in 1888 in a canine model and first performed in 1889 in humans (3,4). The technique, however, only became popular in the 1950s for treatment of the contracted bladder from infections such as tuberculosis (TB) and schistosomiasis (5). The advent of CIC in the 1970s and an article by Bramble (6) further expanded the use of augmentation cystoplasty.

Over time, the bowel segment used for augmentation has expanded to include stomach (gastrocystoplasty), ileum (ileocystoplasty), cecum (cecocystoplasty), and sigmoid (colocystoplasty). Gastrocystoplasty is now contraindicated due to the greater risk of malignancy (7). Ileum remains the segment of bowel most preferred for augmentation on the basis of its availability, tissue mobility, and lowest rate of complication (8). Approximately 20 cm of terminal ileum is retained for its absorption function with a low long-term metabolic complication rate.

More recently, the number of augmentation cystoplasties has decreased (9). This reduction is due to a lower incidence of spina bifida, the long-term potential of malignancy, and an increase in alternative treatment options. Tissue engineering, despite a small clinical trial in humans, remains experimental (10).

PATIENT ASSESSMENT

The indications for augmentation cystoplasty remain the medically resistant overactive bladder from neuropathic and nonneuropathic origin. The four main groups of patients presenting for AC are congenital, idiopathic, inflammatory, and neuropathic in etiology (Table 22.1).

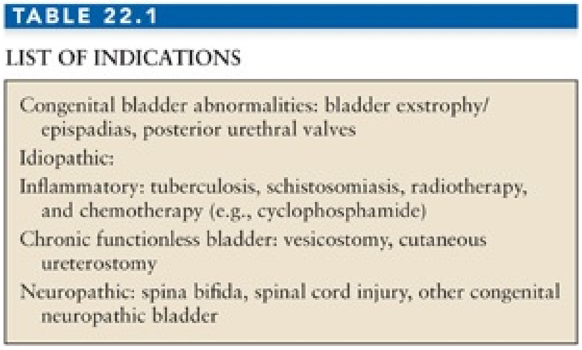

TABLE 22.1

LIST OF INDICATIONS

Congenital bladder abnormalities: bladder exstrophy/epispadias, posterior urethral valves

Idiopathic:

Inflammatory: tuberculosis, schistosomiasis, radiotherapy, and chemotherapy (e.g., cyclophosphamide)

Chronic functionless bladder: vesicostomy, cutaneous ureterostomy

Neuropathic: spina bifida, spinal cord injury, other congenital neuropathic bladder

Patients with congenital abnormalities present during surveillance after primary treatment with either risks of renal deterioration or persistent incontinence. The goals are a high-volume, low-pressure bladder with an ability to fully empty by CIC.

Patients with chronic inflammatory conditions need to have malignancy ruled out first by cystoscopic assessment and bladder biopsy.

Intractable incontinence from idiopathic detrusor overactivity is an indication for augmentation cystoplasty. In this group, the renal function is rarely at risk and treatment is aimed at managing incontinence. The initial treatments may include anticholinergic medication, sacral nerve stimulation therapy, botulinum toxin detrusor injection, and detrusor myomectomy (11,12). Postoperatively, a number of these patients can void efficiently but most require CIC, and it should be trialed preoperatively to confirm patient compliance.

In patients with a neuropathic bladder, the goals of management are renal preservation, continence, and protection against UTIs. These patients need to be intelligent, well-motivated, supported, have adequate hand function, and be able to undertake CIC. The majority of patients require CIC to empty their bladder to reduce the risk of UTI. Patients with progressive neurologic or cognitive diseases such as multiple sclerosis and/or dementia are poor candidates for augmentation cystoplasty because their ability to perform CIC may deteriorate with time. This makes them more dependent on caregivers for catheterization or a long-term catheter, which puts them at risk of recurrent UTIs. Those patients unable to catheterize because of their anatomy such as a wheelchair-bound female spina bifida patient should be considered for a continent catheterizable stoma (Mitrofanoff) along with an augmentation. Patients unable to self-catheterize because of their anatomy, motivation, hand function, or intelligence could lastly be considered for an incontinent urinary diversion. There is an integral role for continence nurse practitioners here to assess patients and families preoperatively and troubleshoot postoperative problems. These vital colleagues increase the patients' ability to remain independent and have good outcome.

In general, patients with significantly impaired renal function are a relative contraindication to augmentation cystoplasty because reabsorption of electrolytes can increase their risk of acidosis and further impairment of renal function. In a contrary view, however, augmentation cystoplasty may protect against further reduction in renal function and is useful in patients who require renal transplantation secondary to severe bladder dysfunction. Careful follow-up is required in this patient group to prevent dehydration, maintain regular bladder emptying to reduce the risk of acidosis, and acute medical problems.

Evaluation

The cornerstone of bladder assessment is video urodynamics. This assesses the bladder and the outlet and should confirm the decision to proceed with augmentation cystoplasty. The presence or absence of vesicoureteral reflux can be confirmed. However, reflux is typically a secondary phenomenon and is generally not surgically corrected with a ureteric reimplant (13). Reflux is usually corrected by increasing capacity and lowering the pressure of the bladder.

Assessment of the bladder outlet remains difficult. This is undertaken by incorporating patient history, renal function, and observation during urodynamics. The abdominal leak point pressure measures outlet resistance and suggests whether an outlet procedure should be undertaken with augmentation. Occasionally, urethral pressure profilometry and sphincter electromyography are used.

Bowel Segment Options

The bowel segments used depend on availability and the presence of any preexisting bowel disease (8). Ileum is the preferred bowel of choice after retaining 20 cm of terminal ileum for gut absorption. The expanding use of the appendix as a Malone antegrade continence enema (MACE) procedure for bowel management makes the cecum and terminal right ileum often somewhat adhered within the peritoneal cavity, reducing its mobility (14). Ileum is still used in the majority of these circumstances for augmentation, and if required, the MACE may be done synchronously or asynchronously with augmentation.

Gastrocystoplasty was increasingly used especially where short bowel syndrome is a potential consequence of further bowel segment removal and the bladder and the gastric wall seen as easier to tunnel a catheterizable channel through. More recently, this has reduced in popularity and is now contraindicated due to the increased risk of malignancy (7). The ileocecal region had been popular in the past, combining the terminal ileum and the cecum in an augmentation patch. This is not recommended due to increased risk of bowel dysfunction due to the loss of the ileocecal valve. The sigmoid colon has been used where small bowel will not easily mobilize into the pelvis. It is thicker walled and occasionally large and redundant in neuropaths where there is associated constipation.

Colocystoplasty has, however, been shown to have increased mucus production, a greater risk of urinary infection and a greater risk of complications requiring reoperation, and thus, it is a secondary choice for augmentation (15).

Ileum, as previously stated, remains the most popular bowel segment due to its mobility, lower production of mucus, and lower long-term complications.

ALTERNATIVE THERAPIES

More recently, several options have become available for the resistant overactive bladder. Botulinum toxin injections have been shown to be effective in both the neuropathic and nonneuropathic population. Given the low morbidity of this procedure, it can be tried prior to augmentation cystoplasty; however, its high cost and need for repeat injections are a barrier to widespread use, especially in younger patients (11). Sacral nerve stimulation has been used for refractory urge incontinence due to the nonneuropathic causes (12). It has not proven to be as popular due to the lower success rates and cumbersome implant.

Autoaugmentation of the bladder, also known as detrusor myomectomy, involves the excision of detrusor muscle over the dome and anterior wall of the bladder. This theoretically allows a diverticulum of epithelium to distend, thereby improving storage capacity and bladder compliance. This procedure is significantly less morbid, has the advantage of not incorporating mucus-producing bowel into the urinary tract, and almost uniformly allows patients to void spontaneously. Despite this, it has been less successful and it is not recommended in neuropathic patients (16). It has a small role in nonneuropathic patients who are younger with intractable urge incontinence especially associated with persistent nocturnal enuresis. Laparoscopic and robotic bladder augmentation has been reported, but this procedure is still investigational (17).

Other nonautologous tissue such as Teflon, Silastic, Gore-Tex, and bovine dura have been used for augmentation, but complications associated with bladder anastomosis, contracture, fistula, leakage, and stone formation have precluded their use (8). Tissue engineering is an innovative alternative. A small clinical trial has been reported in children with spina bifida. However, the short-term and long-term results have not been as promising. Clinical trial and experimental work are still under way to improve this novel alternative (10).

SURGICAL TECHNIQUE

The principles of augmentation cystoplasty are to enlarge the bladder with detubularized bowel segment, providing a high-capacity lower pressure reservoir. Twenty to 30 cm of detubularized ileum can be patched as U or straight patch. This bowel needs to be placed in the pelvis without tension and remain well vascularized. The bladder is split in the sagittal or coronal plane widely to reduce the risk of an hourglass diverticulum forming. Absorbable sutures are used in a single-layer anastomosis and suprapubic plus urethral or stoma catheter drainage is required postoperatively. The patient should be taught CIC prior to augmentation cystoplasty because the majority will need to do this for emptying. If a continent catheterizable channel is to be used, stoma position should be confirmed preoperatively. If the patients are to have a concurrent MACE procedure, the continent diversion channel should be placed on the left side or in the umbilicus.

No special bowel preparation is required with normal diet allowed up until the day before surgery with clear fluids on the day of surgery up until 2 to 6 hours preoperatively. Due to the low or absent bacterial count in the terminal ileum, no bowel preparation is recommended. Prophylactic intravenous antibiotics are routine especially in patients with a ventriculoperitoneal (V-P) shunt where this should be manipulated out of the operation site if becomes visible during surgery.

The patients are placed supine on the operating theatre table with a slight table break to allow better access to the pelvis (Fig. 22.1). A catheter is placed into the urinary tract and the bladder emptied immediately preoperatively. A midline incision may be extended above the umbilicus if necessary and a laparotomy performed. A self-retaining retractor, a ring, or Bookwalter-type retractor is useful to improve access. A Pfannenstiel incision is occasionally undertaken, but it may be difficult to get access to the peritoneal cavity to bring the ileum down especially in neuropaths where the terminal ileum may be prefixed due to the lumbar lordosis.

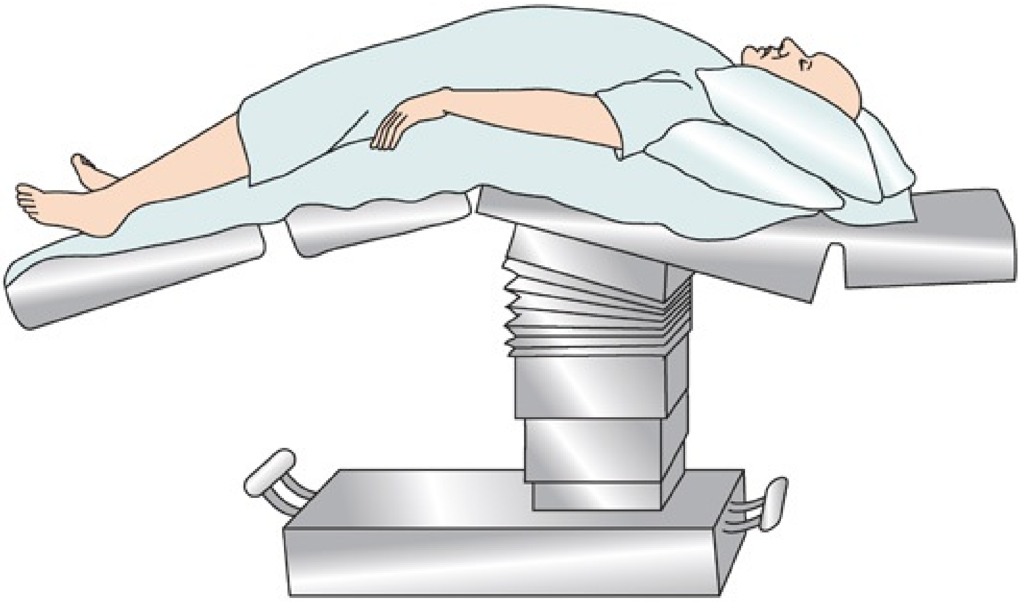

FIGURE 22.1 Patient position, supine with table extension to improve pelvic access.

Prior to harvesting a bowel segment or splitting the bladder, the bowel should be manipulated to the pelvis using Babcock or noncrushing clamps, just to make sure it is usable. Following laparotomy, the retropubic space is opened bluntly (Fig. 22.2). Stay sutures are placed at the dome of the bladder, and the bladder is split either in the sagittal or coronal plane (Fig. 22.3). Hemostasis is secured by diathermy, and the bladder incision is completed to within 1 to 2 cm of the intertrigonal bar and just above the bladder neck. Caution has to be undertaken around the site of the ureteric orifices, and if concerned, ureteric catheters can be placed for safety.

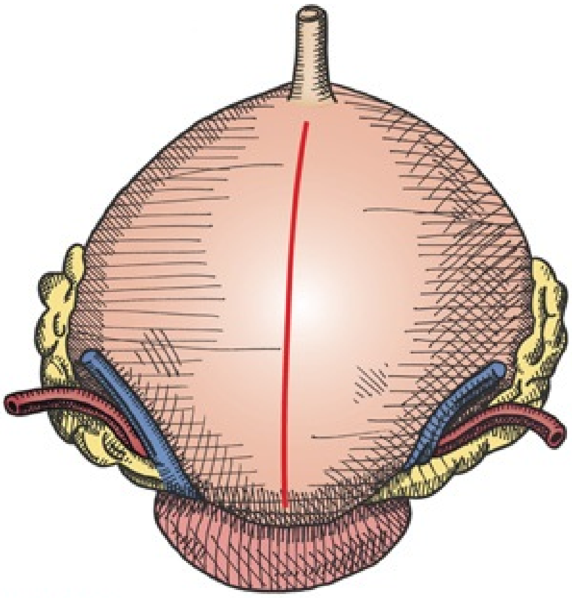

FIGURE 22.2 The peritoneum is dissected off the bladder which is incised in the saggital midline (Along the *red line*). The incision runs full thickness from just above the bladder neck, extended posteriorly to the level approximately 2 to 3 cm above the level of the ureters entering the bladder. This is facilitated by stay sutures placed at the bladder dome.

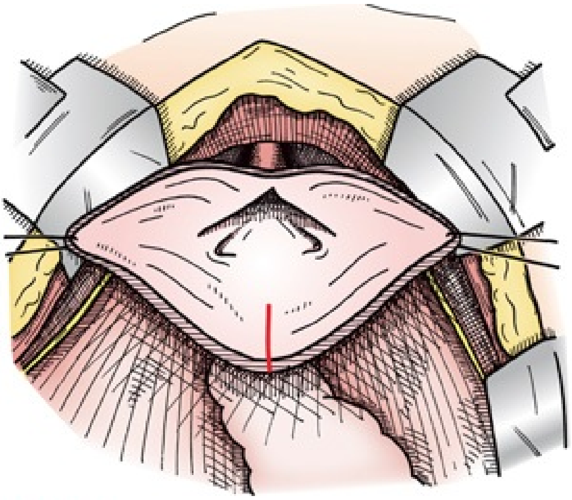

FIGURE 22.3 Bivalved bladder in sagittal plane to just above intertrigonal bar.

A bowel segment is selected approximately 20 cm from the terminal ileum, retaining two mesenteric vessels for blood supply (Fig. 22.4). The vascular pedicles through the mesentery can be divided by bipolar diathermy devices or suture division to allow this small bowel segment to be isolated on its vascular pedicle and remain well vascularized being brought into the pelvis. The bowel is divided between two noncrushing clamps and a bowel anastomosis performed. Increasingly, staples are used for the bowel anastomosis due to their speed; however, a single layer of absorbable sutures is more cost-effective. The mesentery may be left open or closed with interrupted or continuous sutures.

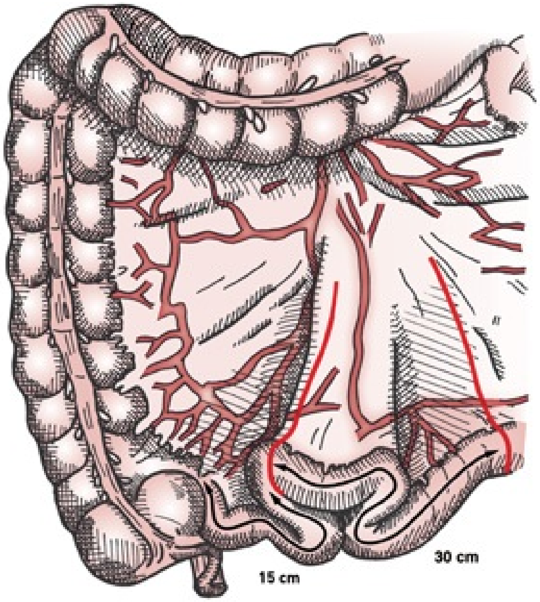

FIGURE 22.4 Approximately 15–20cm proximal to the ileocecal valve, a approximately 25–30cm segment of bowel is selected, the mesentery cleared, and the segment removed using standard techniques. The *red lines* indicate the division of the small bowel mesentry leaving a good blood supply to the ileal augment segment. *Double arrows* are identifying lumen and could be removed as add little.

The bowel is detubularized along its antimesenteric border and either constructed into a U loop or used as a single linear segment (Fig. 22.5). An alternative is to divide the bowel close to the posterior mesenteric surface to create an asymmetric segment of detubularized bowel and creating a U loop so that the vascular pedicle remains more posterior and the thin bowel wall anterior (Figs. 22.6 to 22.9). This allows extra mobility for the augmentation patch to reach the pelvis without tension. Continuous one-layer absorbable suture is used for the anastomosis between the augmenting bowel and bladder, beginning at the posterior aspect (Figs. 22.10 to 22.13). A suprapubic catheter can be placed and sutured to the peritoneal wall on the anterior surface to reduce the risk of a urine leak postoperatively and assist with bladder washouts (Fig. 22.14).

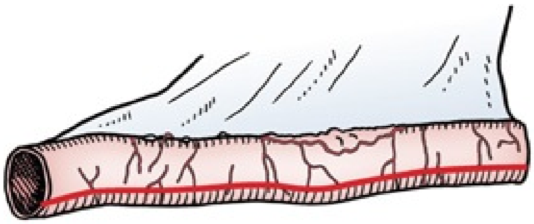

FIGURE 22.5 The ileum is opened along the antimesenteric border.

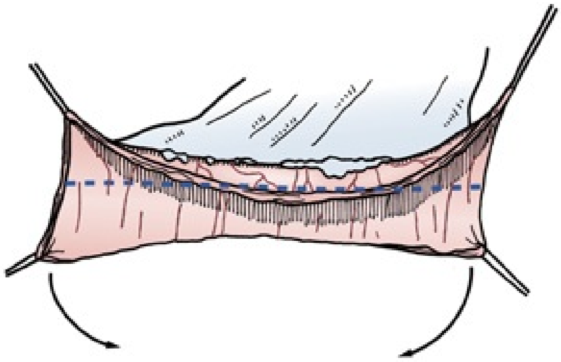

FIGURE 22.6 The ileum is mobilized toward the pelvis and posterior aspect opposed to create a U-shaped augmentation patch. The *dotted line* represents the location of the mesentry on the outer aspect of the ileum. The *curved arrows* indicate the movement of the bowle patch to create a U shaped patch.

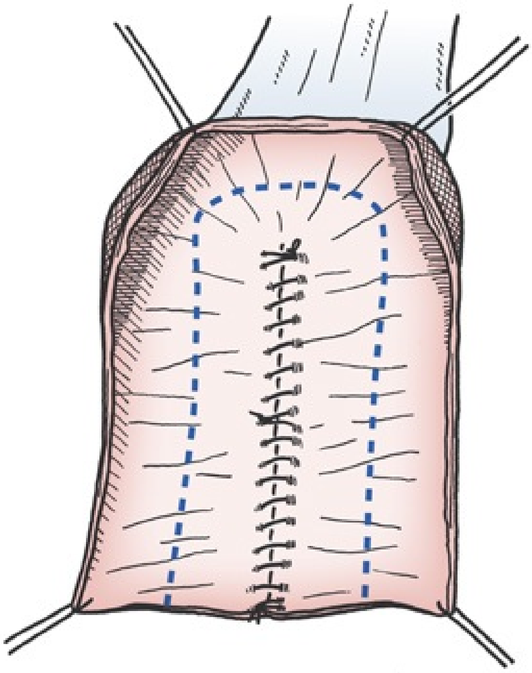

FIGURE 22.7 The posterior wall of the augment is completely closed. The *dotted broken line* indicates the position of the mesentry on the serosal surface.

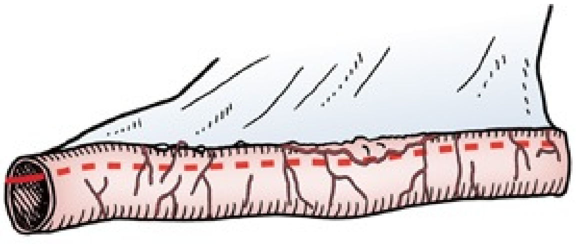

FIGURE 22.8 Alternative technique with incision to detubularize bowel placed more posteriorly to provide a longer anterior bowel flap. This modified technique facilitates a tension-free bladder anastomosis at times where the distance between the ileum and mesentery is greater. The *dotted red line* indicates the position of the bowel incision on the posterior aspect of the small bowel, near the mesenteric attachment.

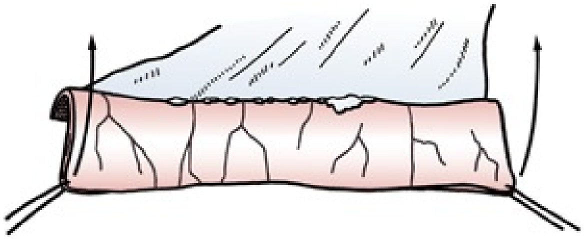

FIGURE 22.9 Larger augmentation bowel flap elevated to allow posterior closure into a cup shape. The *curved arrows* indicate the rotation of the bowel segment upward to give a longer portion of bowel anteriorly.

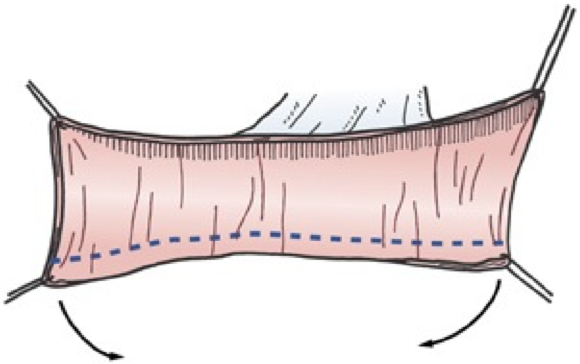

FIGURE 22.10 Bowel flap rotated posteriorly. The *dotted line* represents the location of the mesentery on the outer aspect of the ileum. The *curved arrows* indicate the direction the bowel is rotated to provide a cup shaped patch.

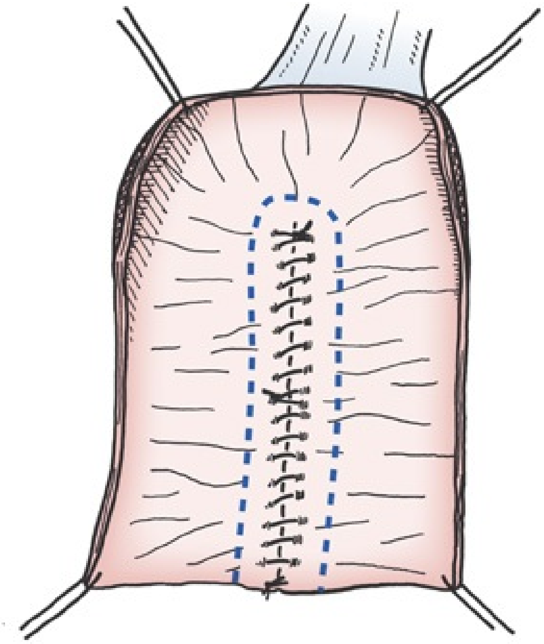

FIGURE 22.11 The posterior wall of the augment is completely closed. The *dotted line* represents the location of the mesentery on the outer aspect of the ileum.

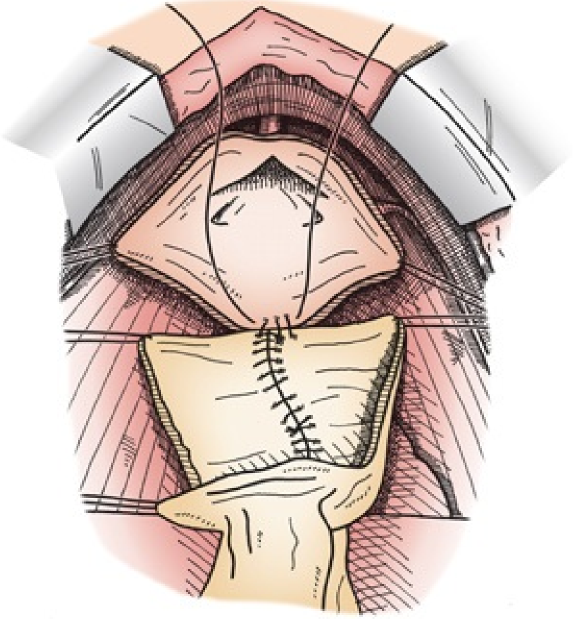

FIGURE 22.12 Initial suture placement for enterocystoplasty. Note this starts in the midline posteriorly with two running absorbable sutures.

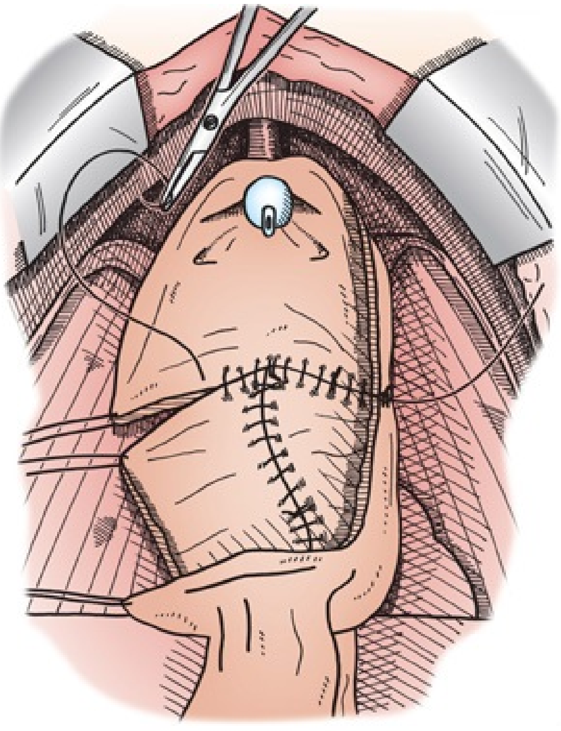

FIGURE 22.13 Closure of the posterior aspect of the enterocystoplasty. Note placement of the urethral catheter for postoperative urine drainage.

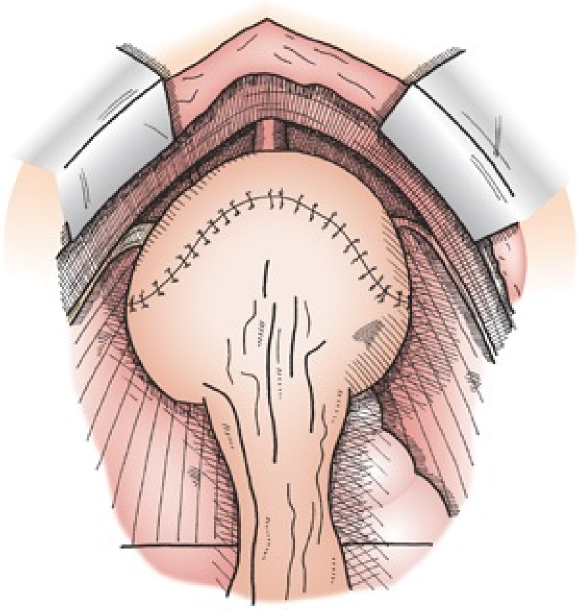

FIGURE 22.14 View of the completed enterocystoplasty. Note placement of urethral and suprapubic catheter for double drainage of urine. A drain is placed in the retropubic place and the wound closed in standard fashion.

If an outlet procedure is required to increase urethral resistance for continence, it should be undertaken synchronously (18). This can be by a procedure to increase static resistance such as a bladder neck sling or a dynamic device insertion such as an artificial urinary sphincter. There is a relative contraindication to placing such a prosthetic device after opening the small bowel; however, the risk of infection is low. Bladder neck closure is undertaken rarely at the same time as augmentation.

Dissection around the bladder neck for appropriate placement of a bladder neck sling can be undertaken more easily when the bladder is opened and urethral catheter visible within the lumen. Slings can be rectus fascia, skin or synthetic in nature, and tensioned to increased outlet resistance. Bladder neck closure is rarely required but can be facilitated with a two-layer closure interposing some vascularized tissue at the same time to reduce fistula formation.

If a continent catheterizable urinary diversion is planned, the stoma siting should be decided and marked preoperatively, and the patient counseled regarding catheterization. Often, the appendix has been used in a MACE procedure, and thus, this channel is not available for a Mitrofanoff type procedure. A Monti-type tube can be constructed using small bowel (19). The Monti tube is generally constructed over a 12Fr catheter sutured in place and can allow a form of drainage postoperatively to provide double drainage initially. The most proximal small bowel segment facilitates placement of the catheterizable channel on the left side of the abdomen. Tunnelling of the catheterizable channel in a ratio of 1:4 lumen diameter to tunnel distance is best undertaken through the thickened native bladder wall. If a catheterizable channel is planned, the bladder wall split can be placed in an eccentric fashion more toward the right side, creating a larger left-sided bladder wall plate. This anatomic modification minimizes tissue tension, provides a short straight channel, and improves the chances of a good outcome.

Catheter drainage from a channel exiting the umbilicus is also popular. In some series, this technique has been shown to have a higher incidence of stone formation possibly due to the less efficient drainage due to a higher catheterization channel in the abdominal wall. The catheterizable channel can have its skin site hidden via a rotation skin flap technique to facilitate cosmesis and improve body wall image.

Following augmentation cystoplasty plus or minus an outlet procedure, the peritoneal cavity is generally washed out and drains placed into the pelvic and peritoneal site. A suprapubic catheter plus stomal/urethral catheter is used for drainage. Complete wound closure with absorbable sutures and subcuticular skin sutures or staples is used.

Postoperatively, intravenous fluids maintain hydration and oral intake is commonly delayed until the ileus resolves. Intravenous antibiotics are generally continued for 48 hours, only if a V-P shunt is in place. The bladder is double drained with a suprapubic and stomal or urethral catheter and generally irrigated intermittently in the first 48 hours to reduce mucous obstruction. Clean intermittent catheterization is begun 2 to 4 weeks postoperatively, and the suprapubic catheter is removed when this is efficient. Clean intermittent catheterization is initially at regular intervals, occasionally waking at night to minimize overfilling. Daily irrigation reduces the risk of mucus-based stone formation and should be continued long term. Antibiotic prophylaxis may be undertaken at the time of intermittent catheterization but is not recommended long term.

Follow-up regimens vary. However, initial renal function and serum bicarbonate are monitored regularly. A renal ultrasound (US) is recommended annually both for surveillance of the kidneys and to determine if stone formation occurs. Vitamin B_{12} follow-up is generally not recommended for the first 5 to 10 years but may be integrated as part of long-term follow-up after that.

A pre- and postoperative protocol is provided in Table 22.2. The protocol can be modified if the results are abnormal according to clinical need.

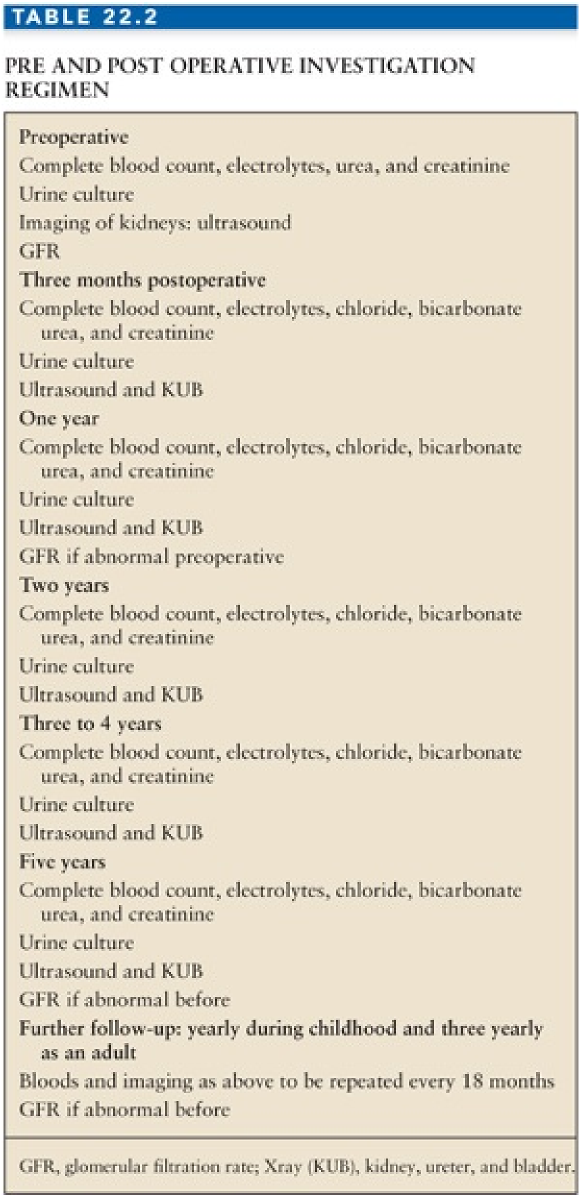

TABLE 22.2

PRE AND POST OPERATIVE INVESTIGATION REGIMEN

Preoperative
Complete blood count, electrolytes, urea, and creatinine
Urine culture
Imaging of kidneys: ultrasound
GFR
Three months postoperative
Complete blood count, electrolytes, chloride, bicarbonate urea, and creatinine
Urine culture
Ultrasound and KUB
One year
Complete blood count, electrolytes, chloride, bicarbonate urea, and creatinine
Urine culture
Ultrasound and KUB
GFR if abnormal preoperative
Two years
Complete blood count, electrolytes, chloride, bicarbonate urea, and creatinine
Urine culture
Ultrasound and KUB
Three to 4 years
Complete blood count, electrolytes, chloride, bicarbonate urea, and creatinine
Urine culture
Ultrasound and KUB
Five years
Complete blood count, electrolytes, chloride, bicarbonate urea, and creatinine
Urine culture
Ultrasound and KUB
GFR if abnormal before
Further follow-up: yearly during childhood and three yearly as an adult
Bloods and imaging as above to be repeated every 18 months
GFR if abnormal before

GFR, glomerular filtration rate; Xray (KUB), kidney, ureter, and bladder.

OUTCOME

The outcome of ileal augmentation cystoplasty is generally very good, improving quality of life, preserving renal function, and improving continence (1,13,15). UTIs are a risk, and if occur, a review of technique and completeness of CIC is useful.

Generally, outcomes are best when patients undergo augmentation cystoplasty for the correct indication have good preoperative education, the correct surgery is undertaken, and postoperative care carefully instituted. This has been increasingly overseen by continence nurse practitioners. They are also called on to review catheterization difficulties, oversee independence of patients within the community, and re-present to a clinic environment for troubleshooting problems if issues have occurred. These continence nurses have become integral in the successful management of these complex patients.

COMPLICATIONS

Complications can be categorized as early and late. The incidence of complications overall is 28% early and 44% late. Up to 30% of patients required reoperation (20). Early complications include those affecting the bowel, urinary tract, and wound. Bowel complications include persistent ileus, bowel obstruction, and bowel leak (6% to 9%). Sepsis, especially involving a V-P shunt is rare. Wound infections are commonly seen in up to 6% of patients (15). Early urinary tract complications include sepsis, leakage, and obstruction (5% to 15%). Suction drains are placed postoperatively, and if a urine leak occurs, the drains are taken off suction and regular flushing of the urinary catheters continues to allow draining of the urine. Commonly clear fluid drains from the peritoneal cavity and, in the setting of V-P shunt, could potentially be cerebrospinal fluid. Mucous obstruction is not uncommon, early and regular flushing of both the suprapubic catheter and stomal/urethral catheter can reduce the incidence. Subsequently, patients are taught to flush their urinary diversion daily or if there is mucous obstruction.

Late complications again can be divided into those related to the bowel, the urinary tract, and renal function. Bowel complications are commonly due to mechanical obstruction from adhesions, which occurs in up to 9% of patients (20). Diarrhea, which can be difficult to control especially in some neuropathic patients, is due to loss of the ileocecal valve and/or an incompetent anal sphincter (21). Malabsorption syndromes such as low vitamin B_{12} leading to megaloblastic anemia are rare (22).

Renal function requires observation over time as does acid-base balance. Metabolic acidosis is uncommon if patients are selected properly and bladder emptying is regular and complete. Screening should be undertaken for this postoperatively and treatment with oral bicarbonate is usually successful.

Long-term urinary tract complications are more common. Recurrence of a “hostile” bladder with high pressure and low capacity is rare but occasionally occurs and presents with either continence issues or renal tract dilation (23). Occasionally, reaugmentation is required, but initially, conservative measures with anticholinergics, intravesical anticholinergics, or botulinum toxin can be tried. Urinary incontinence which occurs either from the outlet or a catheterizable channel usually requires reoperative surgery. Catheterization difficulties can be due to stenosis or angulation of the Monti channel or appendix. Skin stenosis is not uncommon requiring occasional dilatation, stomal plugs, or reoperative surgical procedures. Prevention of these complications is generally by proper patient selection and careful intraoperative technique.

UTIs are commonly seen in 4% to 43% of patients (24). It is useful to divide these between simple lower tract infections and pyelonephritis with a risk of sepsis. Microbiology confirms the organism, but care needs to be taken to separate asymptomatic bacteriuria from a UTI. Renal US and kidney, ureter, and bladder Xray (KUB) can determine if there are anatomic risks for recurrent UTI, and subsequent management is typically dependent on these investigations. Prophylactic oral antibiotics are not routinely recommended except potentially in patients with renal transplant. If there is no anatomic cause for UTI, careful focus on CIC technique is helpful in making sure complete emptying is undertaken.

Bladder stones are often seen in between 25% and 50% of patients and typically related to hydration and bladder irrigation (20). They are seen more commonly following colocystoplasty due to higher mucus production. Bladder stones often present with hematuria, incontinence and recurrent lower UTIs, or on routine surveillance. Renal US and KUB will identify the stones. Treatment can either be endoscopic, laparoscopic, or open, depending on stone size and number.

Spontaneous bladder perforation is a feared complication with significant mortality. The patient may have few presenting symptoms and signs but rapidly develop sepsis (25). A combination of poor emptying (a full bladder), a competent bladder outlet with blunt abdominal trauma, sometimes quite minimal can cause rupture. Clinical suspicion should be high, and a computerized tomography cystogram is the investigation of choice. Early laparotomy and repair plus drainage is standard; however, some cases can be managed conservatively with drainage, antibiotics, and careful observation (26).

Malignancy risk has been anecdotally overestimated, and studies suggest patients with intermittent catheterization and those with neuropathic bladders have slightly higher malignancy risk than the general population (7,27). With ileocystoplasty, it is not recommended that routine surveillance is undertaken for malignancy by cystoscopic assessment or urine cytology. Gross hematuria is a strong indicator of pathology and mandates routine investigations. Gastrocystoplasty and patients with augmentations for inflammatory conditions such as TB need regular cystoscopy due to higher malignancy risk (2% to 10%) (28,29).

SPECIAL CIRCUMSTANCES

Complex reconstructions in the urinary tract also have some special situations worth mentioning. These include transitional care from pediatric to adult health care, pregnancy, and renal transplant.

Transitional care has evolved as a dilemma for patients who have complex urologic conditions transferring their care from pediatric urologists and institutions to adult urologists and adult institutions. With the advent of pediatric urology as a subspecialty and the separation of institutions, this process has gained increasing concern as to potential gaps in this complex patient's care. Where institutions are combined (adult and pediatric), this transition appears easier. If transition is poorly managed, patients have a high risk of social and medical complications. There is some evidence to suggest variable age of transition based on patient maturity, availability of appropriate services, and adult urologists to undertake and oversee care improves transition outcome.

Pregnancy and augmentation cystoplasty is more commonly seen. Urologic consultation is recommended during pregnancy, but a normal vaginal delivery appears safe. Vaginal delivery is not recommended where patients have an artificial urinary sphincter in situ (30). If cesarean section is required, urologic presence is to reduce the risk of complications. A classic cesarean section through a transperitoneal wound is recommended. The mesentery of the augmentation is often pushed sideways from the gravid uterus, and under direct vision, cesarean section can be undertaken. The bladder should be drained preoperatively and left to drain for at least 48 hours postoperatively and appears safe when done in conjunction with a urologist.

The timing of augmentation cystoplasty in patients with chronic renal impairment awaiting transplant is controversial (31,32). There are risks and benefits for the augmentation being undertaken before, at the same time, and after renal transplant. If renal transplant is organizable as with a living donor, augmentation cystoplasty can be undertaken electively 4 to 6 weeks prior to the transplant, with bladder cycling performed prior to the renal transplant. Subsequently, the transplant is undertaken with the transplanted ureter anastomosed into the augmented bladder. The outcome of renal transplant in an augmented bladder appears to be similar to that of a renal transplant in a patient with a normal bladder.

CHAPTER 23 MANAGEMENT OF THE DISTAL URETER FOR NEPHROURETERECTOMY

GAVIN N. WAGENHEIM AND SURENA F. MATIN

The standard therapy for upper tract urothelial cell carcinoma of the renal pelvis or ureter is radical nephroureterectomy, with en bloc resection of the ureter and a cuff of bladder around the ureteral orifice. When performed using open surgery, this multiquadrant operation requires a long midline incision or two incisions for the nephrectomy in the upper retroperitoneum and the distal ureterectomy and bladder cuff resection deep in the pelvis. Because of the potential morbidity associated with this operation, alternative approaches such as the “pluck” and “intussusception” techniques were devised. Other modifications include transvesical and extravesical approaches to resect the distal ureter and bladder cuff; the extravesical approach can be done with or without opening the bladder. Using the extravesical approach without opening the bladder may avoid patient repositioning, but this approach violates the golden rule of excising the distal bladder cuff under direct vision, which is the only method of confirming complete excision. Transvesical and endoscopic approaches allow for excision of the cuff under direct vision but usually require patient repositioning and thus increase the operative time (1).

Laparoscopic nephroureterectomy has been shown to further reduce morbidity by eliminating the flank incision for the renal portion of the procedure, thus allowing for decreased postoperative analgesic use, reduced hospital stays, and more rapid convalescence (2). The development of robotic-assisted techniques has also driven attempts to decrease operative times, blood loss, and length of hospital stays (3). These less invasive approaches offer some advantages in reducing the intensity and duration of convalescence. However, because intact extraction of the specimen is recommended after laparoscopic nephroureterectomy (owing to the importance of pathologic staging and the propensity for urothelial carcinoma to implant into wounds), an open surgical approach to the distal ureterectomy may not necessarily require a much larger incision than would be required for the nephrectomy portion of the procedure.

DIAGNOSIS

The most common presenting symptom or sign of upper tract urothelial tumors is hematuria, which occurs in 56% to 98% of patients, and the second most common symptom or sign is flank pain present in approximately 30% of patients (4–6). The subsequent evaluation entails an upper tract imaging study with intravenous urography, computerized tomography, magnetic resonance imaging, or retrograde pyelography. Most patients have a filling defect that suggests an upper tract urothelial tumor. Whether both sides of the urinary system need to be evaluated with retrograde studies, selective cytology, or ureteroscopy, owing to the small chance of a bilateral tumor, depends on the individual practitioner. In general, if good-quality imaging does not show any abnormalities on the contralateral side and an obvious mass appears on one side, additional evaluation of the normal-appearing side is not necessary.

All patients require evaluation of the bladder given the highly similar biology of bladder and upper tract urothelial carcinoma. At this time, retrograde studies, selective cytology, and ureteroscopic evaluation may also be performed. Selective upper tract cytology has been shown to improve the diagnosis of upper tract urothelial carcinoma. The accuracy of detection of high-grade lesions, including carcinoma in situ, is nearly 80%, and this has definite prognostic value (7). Direct ureteroscopic evaluation and biopsy are also important aspects of the evaluation because the additional information is critical for risk stratification. The tumor architecture has been shown in multiple studies to have independent prognostic value; sessile tumors are more often associated with a high pathologic stage than papillary tumors (8). Biopsy results showing high-grade tumors are also associated with high-stage disease at least 65% of the time (9).

The combination of positive voided or selective cytologic findings with a radiographic abnormality consistent with an upper tract urothelial tumor may be considered adequate for diagnosis if nephroureterectomy is intended. However, this practice does not allow for complete clinical risk stratification to determine whether the patient may benefit from multimodal therapy prior to surgery. Given the significant loss of renal function following nephroureterectomy, many patients may not be eligible for postoperative chemotherapy if they are found to have high-stage disease (10). For patients in whom neoadjuvant chemotherapy is not indicated, positive cytologic findings combined with a radiographic abnormality may be sufficient to proceed with nephroureterectomy. If voided cytologic findings are positive, bladder biopsies are necessary to rule out bladder disease, and selective washings can be performed. Patients with positive selective cytologic findings and negative bladder and prostatic urethral biopsies but no identifiable lesion on the ureteroscopic image represent a diagnostic dilemma. Many practitioners consider this set of findings to be diagnostic of carcinoma in situ of the upper tract and treat with nephroureterectomy or topical therapy. Other practitioners recommend that these patients be followed closely rather than undergo nephroureterectomy without a definitive diagnosis.

Once urothelial malignancy is diagnosed, metastatic evaluation consists of abdominal and pelvic computerized tomography and chest imaging with radiography or computerized tomography. A bone scan is performed if the patient has bone pain, elevated alkaline phosphatase or serum calcium levels, or bony abnormalities appearing on other imaging studies. However, owing to lack of bone turnover in cases of bony metastases, a bone scan may be falsely negative. A complete blood count, serum electrolyte analysis with creatinine, and liver function tests should also be performed. If the estimated glomerular filtration rate is reduced (<60 mL per minute per 1.73 m^2), a renal scan to determine differential function may aid in decision making.

Patients found to have regional lymphadenopathy will not be cured with surgery alone and will experience systemic recurrence within a short time period. Thus, similar to patients with bladder cancer, these patients should undergo chemotherapy as the primary mode of treatment (11). Those who have an excellent response to chemotherapy may be considered for salvage surgery to include regional lymphadenectomy.

All treatment options, including the possibility of lymphadenectomy, should be discussed with the patient. The treatment plan must take into account prognostic variables that may be used to select patients for neoadjuvant systemic therapy, and patients should be counseled properly on the potentially increased likelihood of recurrence if advanced disease is found in the pathologic analysis. Clinical variables that affect the likelihood of recurrence include biopsy tumor grade, tumor architecture, the presence of hydronephrosis, and imaging findings suspicious for advanced disease. Clinical risk stratification is more important in upper tract urothelial malignancies than in bladder cancer, owing to the challenges and significant limitations of performing accurate clinical staging in the upper tract. Two preoperative nomograms that use a combination of the previously described factors can be used for more accurate clinical risk stratification and patient counseling for those with upper tract malignancy (8,12). For example, a patient whose biopsy findings show a high-grade sessile tumor has at least an 80% chance of having advanced disease in the final pathologic evaluation (8).

INDICATIONS FOR SURGERY

Nephroureterectomy

Radical nephroureterectomy with excision of the distal ureter and bladder cuff is the standard therapy for upper tract urothelial tumors. This procedure uses open, laparoscopic (standard or hand-assisted), or robotic-assisted surgical techniques. Several approaches to the distal ureter have been described, and there is no agreement on the ideal technique for distal ureter and bladder cuff excision (13,14). Radical nephroureterectomy with en bloc resection of the distal ureter, intramural tunnel, ipsilateral ureteral orifice, and bladder cuff is required for adequate management of upper tract urothelial carcinoma. This should be performed with controlled occlusion of the ureter or ureteral orifice. The risk of recurrence in ureteral stumps or periureteral meatus is 30% to 64% (14). Excision of this segment is critical because approximately 70% of ureteral tumors are found in the distal ureter (15). Thus, when choosing a method to dissect the distal ureter and bladder cuff, the surgeon must be aware of the presence and location of all tumors.

Lymphadenectomy

Radical lymphadenectomy in patients with bladder cancer has been shown to improve staging and prognosis (16). The effects of standard and radical lymphadenectomy on patient outcomes are still under investigation. However, recent studies have identified improved cancer-specific survival durations in patients with high-stage (pT3+) and high-grade (G3+) urothelial carcinoma of the upper urinary tract who underwent radical lymphadenectomy. Importantly, lymphadenectomy for low-stage cancer (pT2 or less) was not found to lead to the same improvement in cancer-specific survival (17). This highlights the importance of preoperative staging to guide the treatment plan.

Nodal involvement rates for tumors located in the renal pelvis, upper ureter, and midureter range from 20% to 30%. The nodal involvement rate for distal ureteral tumors is lower, approximately 10%. It has been suggested that tumors originating in the renal pelvis or proximal two-thirds of the ureter should be treated with radical nephroureterectomy as well as wide retroperitoneal lymph node dissection. This should include the hilar, paracaval, and retrocaval nodes on the right and the renal hilar and para-aortic lymph nodes on the left. Tumors located within the distal two-thirds of the ureter may be adequately treated with pelvic lymph node dissection, including the common, external, and internal iliac lymph nodes as well as the obturator nodes (18) (Fig. 23.1).

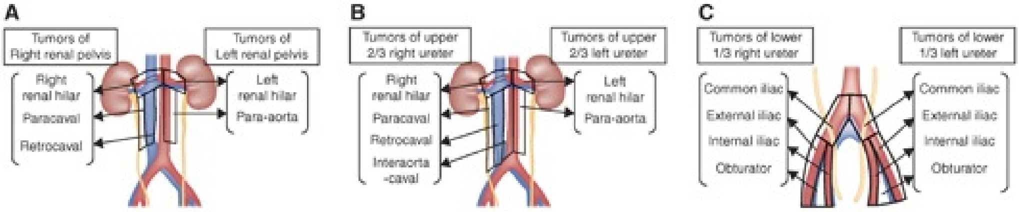

FIGURE 23.1 Regional lymph node schema according to primary tumor location. (Adapted with permission from Kondo T, Nakazawa H, Ito F, et al. Primary site and incidence of lymph node metastases in urothelial carcinoma of upper urinary tract. *Urology* 2007;69(2):265–269. Copyright © 2007 Elsevier Inc. All rights reserved.)

KIDNEY-SPARING THERAPY

Endoscopic resection and fulguration are acceptable for patients with low-grade, low-stage, and small tumor burdens. An alternative for a distal ureteral tumor is a distal ureterectomy with a ureteroneocystostomy or other reconstruction. Segmental resection and primary ureteroureterostomy may be considered in rare cases of tumors in the proximal ureter, and partial nephrectomy may be considered for even rare cases of isolated polar tumors with imperative indications; partial nephrectomy is rarely indicated (19). After complete endoscopic control or distal ureterectomy, adjuvant topical therapy with bacille Calmette-Guérin (BCG) or mitomycin C may be attempted to prevent recurrence, although the benefits of this strategy are not completely clear. For patients with urothelial carcinoma in situ, BCG topical therapy is considered primary therapy and the outcomes in this group appear to be similar to those with bladder carcinoma in situ in a limited experience (20).

SURGICAL TECHNIQUE

As can be seen by the myriad of options available, no single “standard” method to resect the distal ureter and bladder cuff has been determined, attesting to the challenge of aligning anatomy with disease management. Unofficially, most experts agree that either a formal intravesical approach (requiring clamshell incision of the bladder) or an extravesical approach with a formal bladder cuff is their primary technique. Some of the other techniques in the following sections have been associated with an increased risk of positive margins or have the potential for compromises in oncologic management. The authors suggest that the following factors are central tenets of surgical technique that should be adhered to regardless of the technique performed:

- Evaluation of the distal ureter for the presence or absence of tumors if alternative methods of management are considered
- Taking wide soft tissue margins around the ureter where disease is located; if disease has occurred at the intramural ureter, an en bloc partial cystectomy may be needed.
- Avoiding uncontrolled spillage of any fluid possibly containing cancer cells
- Visual confirmation of complete resection of the ureteral orifice and bladder cuff

Specific to this chapter, the last tenet is inarguably the single most critical point and the one that is most commonly compromised in practice.

Open Surgical Techniques

Intravesical Approach

Open surgical distal ureterectomy can be used in conjunction with any technique of nephrectomy.

After completing the nephrectomy and proximal ureteral dissection, place the patient in the supine position, with or without flexion of the table. Insert a three-way 20Fr urethral catheter into the bladder. Make a lower midline incision, divide the rectus fascia, develop the space of Retzius, and place a self-retaining retractor. Fill the bladder with saline and then open it longitudinally between two stay sutures, preventing and actively suctioning any fluid spillage. Place additional stay sutures at the apices of the bladder incision. Pack the dome of the bladder with a gauze sponge, and use a bladder blade to retract the bladder dome cephalad. Insert a ureteral catheter or feeding tube into the targeted ureteral orifice and sew it in place with a 4-0 suture. Use electrocautery cutting current to incise the mucosa no more than 1 cm around the ureteral orifice. Dissect the intramural ureter using tenotomy scissors and pinpoint electrocautery (Fig. 23.2).

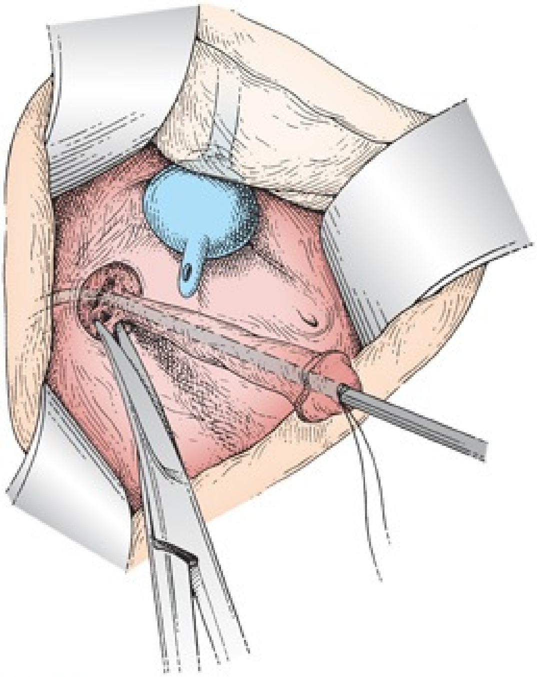

FIGURE 23.2 A ureteral catheter is secured to the ureteral orifice. Tenotomy scissors and electrocautery are used to dissect the intramural ureter. (Reprinted with permission from Lange PH. Carcinoma of the renal pelvis and ureter. In: Glenn JF, ed. *Urologic Surgery*, 4th ed. Philadelphia: JB Lippincott Co, 1991:273; used with permission.)

Dissect the entire distal ureter free to join the point of previous dissection completed during the nephrectomy portion of the procedure. Close the posterior bladder wall in two layers (2-0 absorbable sutures for the serosa and muscle and 4-0 absorbable sutures for the mucosa), and close the anterior bladder incision similarly. Insert a pelvic drain through a separate stab incision. Leave the urethral catheter in place for 3 to 5 days. Some practitioners use cystography to ensure that the bladder has healed prior to removing the catheter, whereas others remove the catheter and perform a voiding trial.

At times, the dissection of the distal ureter may be difficult and the ureter may need to be dissected extravesically as well. This may require division of the superior vesical artery and the entire lateral pedicle of the bladder to provide adequate access to the distal ureter.

Extravesical Approach with or without a Formal Bladder Cuff

A completely extravesical approach is best performed through a Gibson incision. After entering the retroperitoneal space and identifying the distal ureter, retract the bladder to the contralateral side. With this approach, division of the superior vesical artery and the entire lateral pedicle is crucial to facilitate dissection of the entire distal ureter. Identify the ureteral hiatus and dissect the intramural ureter using electrocautery. Cephalad traction on the ureter helps identify the bladder mucosa, but be careful not to tear the ureter. At this point, two options exist. The first and completely extravesical approach is to use a right-angle clamp to secure the ureteral orifice and then excise the ureter. Tie a 2-0 absorbable suture around the right-angle clamp to close the bladder mucosa, or use a running 4-0 absorbable suture. Close a second layer over the resection site using 2-0 absorbable sutures. The second option, which is more preferred by the authors, is to perform a formal resection of the bladder cuff by incising the mucosa and visually confirming complete resection of the ureteral orifice with the cuff. Place a stay suture on the apex of the cystotomy prior to complete resection of the ureter. Once the ureter and cuff are excised, close the incision in two layers as previously described. Manage drains and catheters as previously described.

Laparoscopic Extravesical Bladder Cuff Technique (21)

This technique is similar to the open surgical extravesical approach. Place the patient in a modified flank position for transperitoneal laparoscopic nephrectomy. Using flexible cystoscopy, insert a ureteral catheter. At the conclusion of the laparoscopic nephrectomy, dissect the ureter distally and place clips on the ureter to prevent extravasation of tumor cells. Retract the ureter cephalad and continue dissecting it distally to the bladder. After inserting a 10-mm port in the lower abdomen to facilitate resection of the distal ureter, incise the bladder just anterior to the ureter using electrocautery. Upon entering the bladder, the ureteral catheter identifies the ureteral orifice. Excise the posterior portion of the bladder cuff and detach the ureter after dividing the ureteral catheter. Suture the bladder closed using freehand laparoscopic suturing or other techniques. Manage drains and catheters as previously described.

Robotic-Assisted Techniques

Transvesical Approach (22)

With this technique, robotic assistance is used after laparoscopic management of the kidney. The robotic assistance portion includes the distal ureterectomy and bladder cuff resection, and the patient must be repositioned for these procedures. After dissecting the kidney and proximal ureter, occlude the ureter with a Hem-O-Lok clip or ligating suture. Place a fourth port on the contralateral side, in a line between the umbilicus and iliac crest. Place the patient in a steep Trendelenburg position and dock the robot using the three inferior port sites.

Next, distend the bladder and make a transverse incision along the posterior margin of the dome (Fig. 23.3). Identify the previously placed ureteral stent and place a stay suture through the stent and the ureteral orifice for retraction. Score the bladder circumferentially and dissect through the detrusor muscle. Free the final attachments extravesically (Fig. 23.4). Close the ureteral orifice defect from within the bladder in two layers, and close the incision in the dome extravesically in two layers. Extend the ipsilateral, lower abdominal port site to a Gibson incision to allow extraction of the specimen. Manage drains and catheter as previously described.

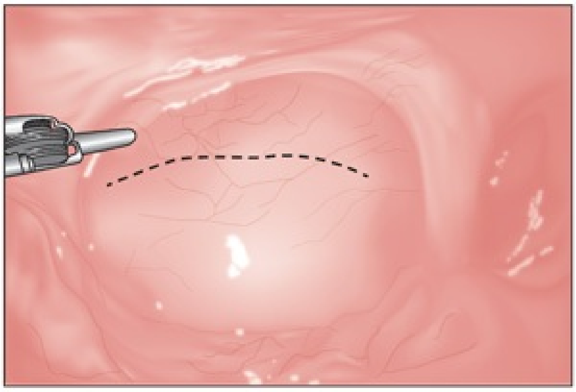

FIGURE 23.3 The *broken line* represents the location of the transverse incision in the posterior dome of the bladder.

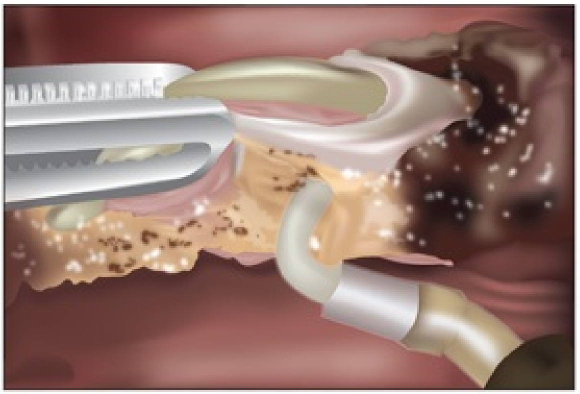

FIGURE 23.4 Ureteral attachments are freed extravesically.

Extravesical Approach with a Formal Bladder Cuff (3)

Place the patient in a modified flank position, disease side up, slight Trendelenburg, with the table flexed. For the procedure, place the camera port lateral to the rectus sheath and about 7 to 8 cm below the most cranial robotic port, which should be placed at the juncture of the lateral rectus and costal margin. Place the other two robotic ports inferior to the camera port, one 7 to 8 cm caudal and lateral to the camera port, which is about 2 to 3 cm lateral and cranial to the superior iliac spine, and the other 15 to 16 cm caudal to the camera port, which places it a few centimeters above the pubic bone. Dock the robot at an angle over the hip to facilitate angulation of the arms into the pelvis (Fig. 23.5).

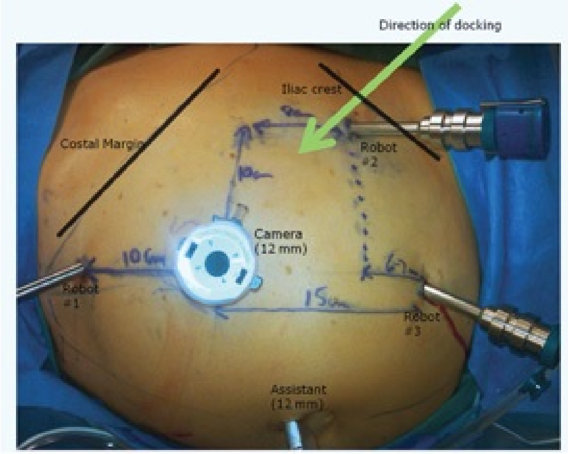

FIGURE 23.5 Ports and docking are shown for robotic-assisted nephroureterectomy for the extravesical approach with a formal bladder cuff. (Copyright © 2012 S.F. Matin.)

After dissecting the kidney, controlling the vasculature, and occluding the ureter, rearrange the instruments and use the caudal port as the retracting arm, the lateral port as the right arm, and the cranial port as the left arm. As before, with this approach, it is critical that the superior vesical artery and entire lateral pedicle of the bladder are ligated and divided to allow proper identification and full dissection of the entire ureter. The space of Retzius on this side also must be developed to allow rotation of the bladder medially. Dissect the ureter distally to the ureterovesicular junction. Distension of the bladder aids in identification of this landmark. Expose the detrusor to ensure an adequate margin for resection. Empty the bladder to prepare for cuff excision. After creating a cystotomy medial to the ureter and visually confirming a complete cuff, place a stay suture to prevent retraction. Use the retracting robot arm to retract the ureter or stay sutures cranially and excise the bladder cuff (Fig. 23.6). Then close the bladder in a running two-layer fashion with an absorbable suture. The Foley catheter should then typically be irrigated to ensure a watertight closure. Extract the specimen periumbilically or by extending one of the port sites. Manage drains and catheters as previously described.

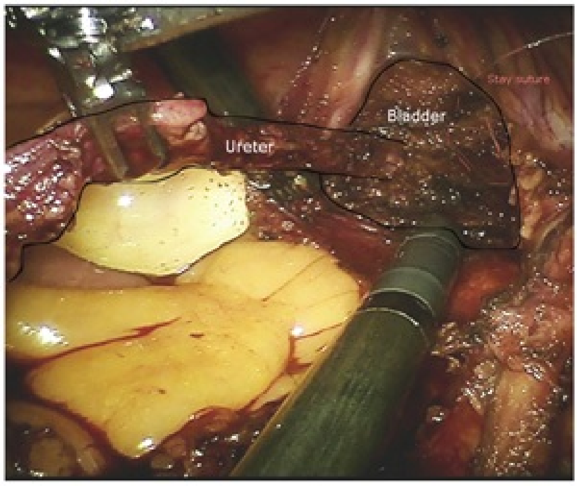

FIGURE 23.6 Excision of the bladder cuff using the ureter for cranial retraction is shown. (Copyright © 2012 S.F. Matin.)

Endoscopic Techniques

Except for the "pluck" procedures, all of the endoscopic techniques described in this section have been developed specifically for use in conjunction with laparoscopic nephroureterectomy. The techniques are described in the following sections in the settings in which they were initially described or are in common use at this time. The hand-assisted approach to laparoscopic nephroureterectomy may be preferable with particular techniques, as indicated in the following sections, but any approach to nephroureterectomy—laparoscopic or open surgical—can be used in conjunction with any of the following techniques, with modifications, as long as oncologic principles are maintained.

Transvesical Bladder Cuff Technique: Single Port (23)

After completing a nephrectomy with the patient in the modified flank position, dissect the ureter to the bladder. Place clips on the ureter to prevent tumor spillage.

Without repositioning the patient, fill the bladder with fluid through a three-way urethral catheter. Make an incision for a 10-mm laparoscopic port in the midline, three fingerbreadths above the pubis. Using the surgeon's hand via the hand-assist port, push the bladder upward toward the abdominal wall. Insert a spinal needle through the incision into the bladder to ascertain the proper angle and depth of entry, and then insert a 10-mm laparoscopic port directly into the bladder through the extraperitoneal space. Using a 24Fr resectoscope with a Collins knife through this port, and with the surgeon's hand alternately elevating the ipsilateral hemitrigone and retracting the ureter, incise around the ureteral orifice and intramural ureter with the Collins knife (Fig. 23.7). During the resection, controlling the height of the urethral catheter drainage bag controls the filling of the bladder. As soon as the ureter is detached, placing the drainage bag on the floor minimizes extravasation of urine and irrigant. Note that once the bladder has been opened into the retroperitoneum, it collapses quickly, so take care to keep the dissection at equal depth all around the orifice so that once the bladder collapses, the ureter can be pulled free easily.

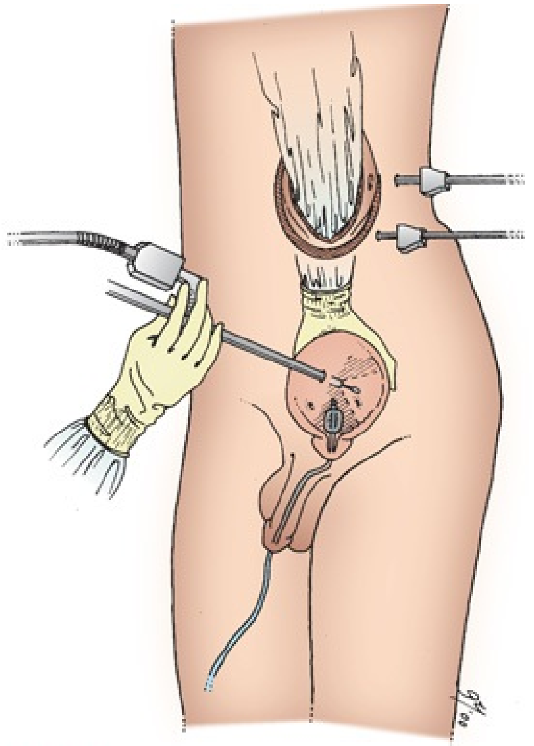

FIGURE 23.7 The surgeon's hand elevates the ipsilateral hemitrigone while the Collins knife is used to incise around the ureteral orifice. (Adapted with permission from Gonzalez CM, Batler RA, Schoor RA, et al. A novel endoscopic approach towards resection of the distal ureter with surrounding bladder cuff during hand assisted laparoscopic nephroureterectomy. *J Urol* 2001;165:484. Copyright © 2001 American Urological Association, Inc. Published by Elsevier Inc. All rights reserved.)

After specimen removal, remove the bladder port. Neither the port site nor the resection site needs to be closed, but placement of a pelvic drain through a laparoscopic port site is optional. The initial description of this technique includes cystography performed on postoperative day 7 to verify lack of extravasation prior to catheter removal, but in the authors' experience with this technique, the cystotomy is adequately healed by this time and a voiding trial is sufficient.

Transvesical Bladder Cuff Technique: Two Ports (24)

Prior to performing the nephrectomy portion of the procedure, place the patient in the lithotomy position. Perform cystoscopy to evaluate the bladder mucosa and distend the bladder. Under cystoscopic guidance, place two 5-mm balloon-tipped laparoscopic ports into the bladder just above the pubic bone on both sides of the midline, setting both ports to wall suction to prevent extravasation and overdistention of the bladder. Insert a 5-mm endoloop through the ipsilateral port, and then insert a 6Fr ureteral catheter cystoscopically into the targeted ureter. Exchange the cystoscope for a resectoscope with a Collins knife, which is used to incise around the ureteral orifice. Using a grasper inserted through the other laparoscopic port that is passed through the endoloop, retract the ureteral orifice anteriorly. After freeing up 3 to 4 cm of ureter, suspend the ureter from the anterior bladder wall with the grasper (Fig. 23.8); then, remove the ureteral catheter and tighten the endoloop around the ureter to occlude the lumen.

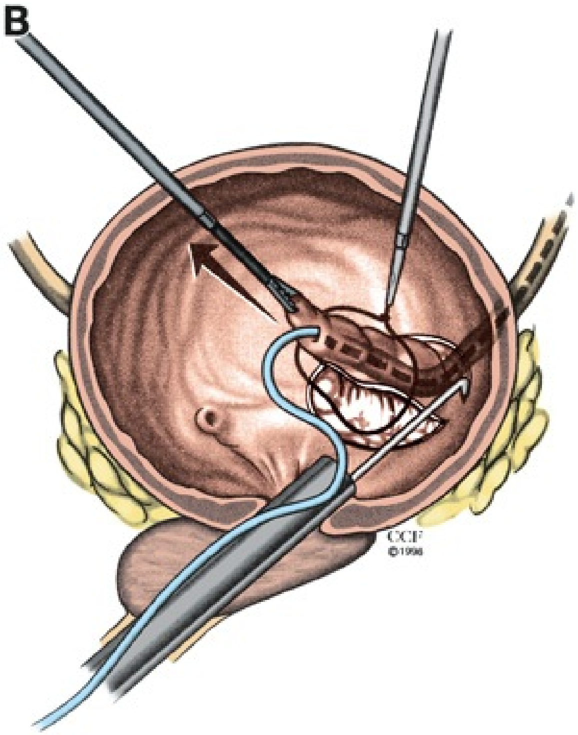

FIGURE 23.8 The Collins knife is used transurethrally while a grasper elevates the ureter and the endoloop is around the resected orifice. (Adapted from Gill IS, Soble JJ, Miller SD, et al. A novel technique for the management of the en bloc bladder cuff and distal ureter during laparoscopic nephroureterectomy. *J Urol* 1999;161:432. Copyright © 1999 American Urological Association, Inc. Published by Elsevier Inc. All rights reserved.)

After removing the laparoscopic ports, set a urethral catheter to gravity drainage. Perform the nephrectomy portion of the procedure after repositioning the patient, and with cephalad traction, dissect the ureter distally such that the distal ureter can be pulled into the operative space for intact removal. Again, a urethral catheter is left in place for 1 week, with the option of cystography to confirm adequate bladder healing prior to catheter removal.

Transurethral Bladder Cuff Technique

This technique is similar to the transvesical bladder cuff technique except that the resection is performed transurethrally, which obviates the need for placement of a transvesical port. One option is to use a flexible cystoscope with an electrocautery probe to perform the periureteral dissection (25). Another alternative is to position the patient in a combined lithotomy-semiflank position that allows simultaneous laparoscopic nephrectomy and transurethral access with a 24Fr resectoscope with a Collins knife (26).

Ureteral Unroofing Technique (27)

Prior to performing the nephrectomy portion of the procedure, place the patient in the lithotomy position. Perform cystoscopy and insert a ureteral dilating balloon (5-mm diameter, 10-cm length) into the targeted intramural ureter. Inflate the balloon to 1-atm pressure with dilute contrast material using fluoroscopic guidance. Exchange the cystoscope for a resectoscope with a Collins knife, and incise the ureteral tunnel at the 12 o’clock position along the entire length of the intramural ureter. Remove the dilating balloon and use a rollerball electrode to cauterize the edges and floor of the intramural ureter. Insert a 7Fr 11.5-mm balloon occlusion catheter into the renal pelvis and inflate it at the ureteropelvic junction to prevent urine extravasation. Connect this catheter, and a urethral catheter, to gravity drainage.

Take the patient out of the lithotomy position and perform the nephrectomy. Once this is completed, mobilize the distal ureter to the ureteral hiatus, dividing the superior vesical artery if necessary. Ligate and incise the remaining distal ureter and bladder cuff using an endoscopic stapler (Fig. 23.9), removing the ureteral balloon occlusion catheter just prior to engaging the stapler. Leave the urethral catheter in place for 3 to 5 days, removing it after cystography or a voiding trial demonstrates no urinary extravasation. A modification of the technique, which allows for nephrectomy to be performed before ureterectomy, is to manage the distal ureter with a stapler as described earlier and then reposition the patient into the lithotomy position. Use a resectoscope and a rollerball to ablate the intramural ureter until the staple line is visible.

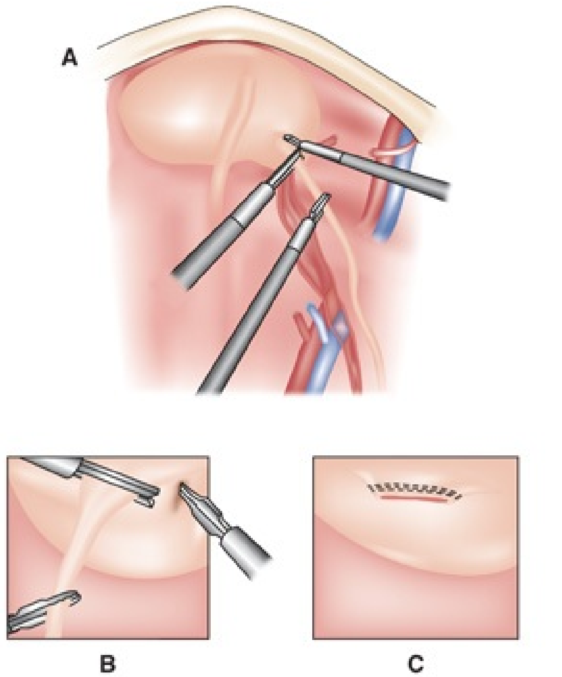

FIGURE 23.9 A: The endoscopic stapler is placed across the ureterovesical junction. B: Close-up view of the stapler across the ureterovesical junction. C: Staples are seen securing the bladder cuff.

Pluck Technique

Place the patient in the lithotomy position prior to performing the nephrectomy. Insert a ureteral catheter into the targeted ureteral orifice cystoscopically. Incise the ureteral orifice and surrounding bladder cuff with a Collins knife to the level of retroperitoneal fat. Alternatively, use a loop resectoscope to resect the orifice and intramural ureter. Set a 24Fr urethral catheter to gravity drainage. Take the patient out of the lithotomy position and perform the nephrectomy. Dissect the ureter distally and, with cephalad traction on the ureter, detach it from the bladder. Leave the urethral catheter in place for 7 days, removing it after cystography or a voiding trial.

A modification of this technique is to pass a 7Fr, 11.5-mm balloon occlusion catheter into the renal pelvis, snugging it down at the ureteropelvic junction, to minimize urine extravasation. Mitomycin can be instilled into the renal pelvis through this catheter (28).

Of note, a proper transurethral resection using the pluck technique will expose the extravesical space, and multiple case reports have documented tumor seeding associated with the pluck technique (29–31). The authors include this technical description for historical purposes but do not recommend its use.

Combined Open and Endoscopic Technique: Ureteral Intussusception (Stripping) (32)

Initially, with the patient in the lithotomy position, insert either a stone basket or ureteral catheter into the targeted proximal ureter. Reposition the patient and perform nephrectomy, dissecting the ureter to the pelvic brim. Clip the proximal ureter and then divide the ureter cephalad to the basket/ureteral catheter. Advance the stone basket into the retroperitoneum and open and close it to entrap the ureteral wall, or, if a ureteral catheter has been used, tie it to the ureter with a 0 silk suture (Fig. 23.10). Apply gentle traction to the stone basket/ureteral catheter to intussuscept the ureter into the bladder (Fig. 23.11). Then, use a Collins knife mounted on a resectoscope inserted transurethrally (after repositioning the patient into the lithotomy position) to incise the bladder cuff out of the urethra around the intussuscepted ureter while exerting traction on the stone basket/ureteral catheter.

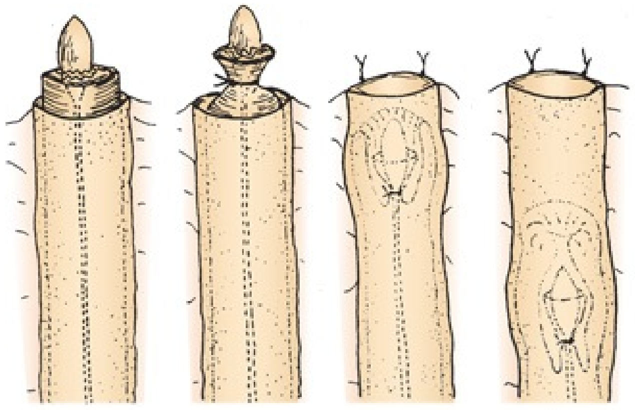

FIGURE 23.10 The proximal ureter is divided and secured to the ureteral catheter. The ureter is then intussuscepted as the catheter is removed. (Adapted from Angulo JC, Hontoria J, Sanchez-Chapado M. One incision nephroureterectomy endoscopically assisted by transurethral stripping. *Urology* 1998;52:204. Copyright © 1998 Elsevier Science Inc. All rights reserved.)

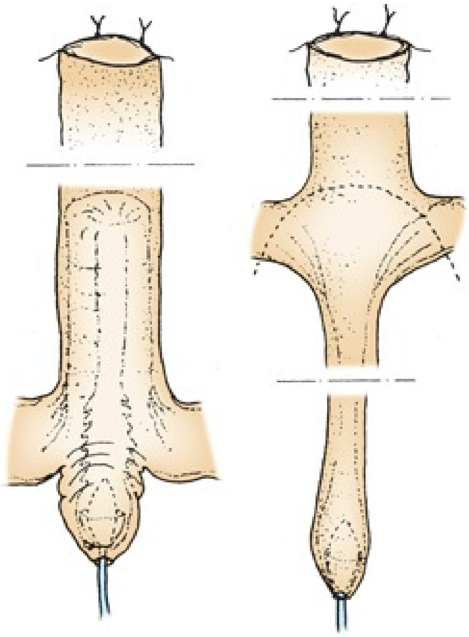

FIGURE 23.11 The catheter is retracted through the bladder wall and urethra. (Adapted from Angulo JC, Hontoria J, Sanchez-Chapado M. One incision nephroureterectomy endoscopically assisted by transurethral stripping. *Urology* 1998;52:204. Copyright © 1998 Elsevier Science Inc. All rights reserved.)

Place a urethral catheter for a minimum of 7 days, which can be removed after a normal cystogram or voiding trial. This technique should not be used for distal or midureteral tumors.

OUTCOMES

Survival durations and the probability of tumor recurrence associated with upper tract urothelial carcinoma are strongly driven by tumor stage. However, outcomes are also influenced by tumor grade, architecture, presence of lymphovascular invasion, and lymph node status. Radical nephroureterectomy is associated with a 5-year recurrence-free survival rate of 69%, and a 5-year cancer-specific survival rate of 73%. Importantly, patients with noninvasive (<pT1) upper tract urothelial carcinoma have been shown to have a 5-year recurrence-free survival rate of 95% and a 5-year cancer-specific survival rate of 96% (13).

Whether the method of managing the distal ureter and bladder cuff is linked with outcomes is not yet fully clear, owing to the strong influence of tumor factors and selection bias from retrospective studies. Although they are based on retrospective data, recent publications have shown no differences in recurrence-free, cancer-specific, or overall survival durations among the extravesical, intravesical, and transurethral approaches to the management of the distal ureter. Current data report 5-year recurrence-free survival rates of 66% for transvesical, 66% for extravesical, and 69% for endoscopic approaches. Similarly, data have shown 5-year cancer-specific survival rates of 71% for transvesical, 70% for extravesical, and 82% for endoscopic approaches and 5-year overall survival rates of 66% for transvesical, 66% for extravesical, and 69% for endoscopic approaches. However, notably, endoscopic management of the distal ureter has been reported to lead to a significantly higher intravesical recurrence rate than the transvesical or intravesical approaches (14). Specifically, multiple extravesical recurrences following pluck ureterectomy have been reported (32). These recurrences are typically not easily detectable or salvageable, and most patients will often succumb to disease progression.

COMPLICATIONS

Early complications include hematuria, retroperitoneal hematoma, and retroperitoneal abscess. Ureteral intussusception may be technically unsuccessful in 10% of patients. Prolonged urinary extravasation can in general be managed conservatively with urethral catheter drainage. Although not yet reported clinically, calculi could form on the staple line when the ureteral unroofing technique is used, or urothelial cells could survive in between the staples. Other factors to be considered in the choice of technique include the risk of tumor spillage, the need for visual confirmation of complete resection, the addition of a bladder incision, the need for repositioning, the desired approach to nephrectomy, and surgeon preference. Of these factors, the potential for tumor cell spillage and visual confirmation of complete resection of the distal ureter and bladder cuff are probably the most important regarding outcome. Local recurrence and port site seeding are of concern. Port site seeding has been reported, although the risk of potential seeding does not appear to be higher with laparoscopic techniques than with open surgical techniques (33).

CHAPTER 24 VESICOVAGINAL FISTULA

HAJAR I. AYOUB AND O. LENAINE WESTNEY

A vesicovaginal fistula (VVF) is an epithelialized or fibrous communication between the bladder and vagina. Physically, psychologically, and socially, it is a source of major distress for the patient contending with urine leakage from the vagina. Documentation of VVFs exists from as early as 1550 BC in the Eber papyrus of ancient Egypt (1). In 1845 James Marion Sims, considered the father of American gynecology, began his exploration into the challenges of treating the condition in Montgomery, Alabama (1). He is credited with developing the foundation of VVF repair and establishing sound surgical principles for repair of fistulas.

The causative factors leading to VVF formation can be broadly categorized into congenital and acquired (Table 24.1). The majority of cases fall into the iatrogenic and obstetrical trauma subcategories. In underdeveloped countries, the leading cause of VVFs is obstetric-related, in which prolonged labor causes ischemic pressure necrosis of the bladder and anterior vaginal wall. In contrast, obstetric trauma accounts for only 5% of VVFs in nations where modern health care is present. The leading cause of VVFs in industrialized countries is iatrogenic surgical trauma, accounting for 82% to 91% of VVFs. Ninety-one percent are due to gynecologic procedures, with 80% due to abdominal hysterectomy (2). The incidence of VVF after transabdominal hysterectomy is 1.0 in 1,000, as opposed to 0.2 in 1,000 after transvaginal hysterectomy. The incidence is highest (2.2 in 1,000) with laparoscopic hysterectomy (3). The most common location for a posthysterectomy VVF is the apex of the vaginal vault or "cuff" corresponding to an intravesical location just superior to the trigone (2). Theoretically, the fistula develops secondary to either unintentional inclusion of full-thickness bladder wall during closure of the vaginal cuff, an unrecognized bladder injury adjacent to the cuff suture line, or cuff abscess.

DIAGNOSIS

Classically, the postoperative VVF presents with "continuous" urine leakage from the vagina. The time of presentation peaks at 7 to 10 days after surgery but may be variable, with some patients presenting immediately after catheter removal, ranging up to 4 to 6 weeks after surgery (3). In the early postoperative period, there may also be associated ileus and abdominal pain due to intraperitoneal urine extravasation. VVFs due to pelvic irradiation usually have a delayed presentation, developing many months or years posttreatment due to progressive obliterative endarteritis causing tissue ischemia and necrosis.

The key to diagnosis of a VVF is a high index of suspicion. Often, a complete history and physical examination expose the pathology. In the case of less obvious fistula, a dye test is utilized to more clearly visualize the passage of fluid through the fistula. In its simplest form, a saline and dye (indigo carmine or methylene blue) mixture is instilled into the bladder via a Foley catheter while inspecting the vagina for leakage or staining of a previously placed tampon. The failure to identify any discoloration of the tampon may indicate a small fistula or ureterovaginal fistula. The second level of testing requires reinsertion of a vaginal gauze or tampon followed by administration of 5 mg indigo carmine intravenously to determine whether the source is ureteral. Dye from an ureterovaginal fistula may be present on the first gauze inspection prior to intravenous (IV) indigo carmine if there is vesicoureteral reflux, which can be determined with a voiding cystourethrogram (VCUG). An alternative to IV dye injection is oral phenazopyridine hydrochloride, but it requires several hours of lead time before examination. The combination of oral phenazopyridine with intravesical methylene blue furnishes a complete diagnostic picture (4). Identification of orange discoloration on the tampon indicates a ureterovaginal fistula, whereas blue staining in the mid or lower portion of the tampon is suggestive of VVF or proximal urethrovaginal fistula.

All patients should have cystography or VCUG as an initial imaging modality. An IV pyelogram (IVP) or retrograde ureterograms is essential for upper tract evaluation. However, CT urography and/or magnetic resonance imaging have been proven to be helpful in cases where conventional imaging modalities fail (4). Abnormalities to look for include extravasation into the vagina or peritoneal cavity or a displaced or partially obstructed ureter. In patients with VVF, up to 25% will have hydroureteronephrosis, with 10% having a concomitant ureterovaginal fistula (5). In patients with ureteral pathology, a retrograde pyelogram is warranted to evaluate for ureterovaginal fistula if the IVP is not definitive.

Cystoscopy is performed to localize and evaluate the VVF, which often has surrounding edematous mucosa. The size and number of VVFs, their location in relation to the ureteral orifices, any lesions such as foreign bodies (i.e., sutures), tumors, and tissue quality must be noted. If there is a history of malignancy, biopsy of the VVF is indicated to rule out recurrent tumor. Vaginoscopy is performed simultaneous with cystoscopy to assess the vaginal aspect of the fistula. If IVP and retrograde pyelograms are inconclusive, then a fistulogram may be performed transvaginally.

A urodynamic study is recommended to look for other factors that may contribute to the urinary incontinence and may require surgical correction (augmentation cystoplasty, incontinence surgery) with the VVF repair simultaneously. Bladder compliance, capacity, and leak point pressure should be assessed if possible. In cases of a large fistula, a Foley catheter may be used to intubate and occlude the fistulous tract to allow for filling of the bladder.

INDICATIONS FOR SURGERY

The issue of how long to wait before attempting surgical repair of a VVF has long been debated. By tradition, VVF repair is delayed 3 to 6 months to allow inflammation to resolve. In cases where a VVF is due to a complicated operation or after obstetric trauma, this rationale holds true. Moreover, reported success rates in obstetric-induced fistula are less than those posthysterectomy as one would expect based on the mechanism—ischemia. These success rates have ranged widely from 53.6% (6) to 97.5% (7,8), with an average closure rate of 86%. Bukar et al. (9) compared a total of 80 women with obstetric-related VVF with an average size of 5 cm, of which 51% presented early for VVF repair (<12 weeks) and 49% presented late (>12 weeks). Irrespective of early or late repair, no difference was reported regarding closure success rate; however, in the early closure group, the psychological, social, and financial burdens were significantly reduced (9). Furthermore, independent studies by Blaivas et al. (10) and Blandy et al. (11) demonstrated comparable results with early (6 to 12 weeks) repair in cases related to an uncomplicated hysterectomy.

Once surgical repair is planned, the approach needs to be selected—transvaginal, transvesical, or transabdominal. Often, the preference correlates significantly with the experience of the surgeon. Advantages of the transvaginal approach are less blood loss, shorter hospital stay, avoidance of a laparotomy, and thus decreased morbidity. Many reserve the transabdominal approach for those patients requiring concomitant intra-abdominal surgery (ureteral reimplantation, augmentation cystoplasty) or those patients with a narrow and deep vagina causing poor exposure to the VVF. However, Dupont and Raz (12) reported that nearly all VVFs can be accessed and repaired transvaginally.

NONSURGICAL THERAPY—CONSERVATIVE AND ENDOSCOPIC

Upon diagnosis, a trial of conservative therapy may be initiated depending on fistula size. Conservative management consists of prolonged bladder drainage with a Foley catheter, anticholinergic agents to prevent bladder spasms, antibiotics, and estrogen if the patient is postmenopausal. Successful closure of a VVF via conservative means can only be reasonably expected for small fistula—3 to 5 mm in diameter or less.

Other adjunctive minimally invasive treatments include attempts to destroy the epithelial lining of the VVF with fulguration (using electrocautery or laser) and use of occlusive substances. Dogra and Saini (13) reported on a group of eight fistula patients (five failed prior conservative therapy and three failed primary repair) in which holmium:YAG laser was successfully used for circumferential welding of the fistula (2 to 4 mm) in seven of eight patients. In the remaining patient, the procedure was abandoned for bleeding; however, the majority was dry at mean follow-up of 47 months (13).

Since the late 1980s, adhesive materials have been used to treat a variety of fistulas. There are two main types of glues used to treat VVF: fibrin, a biologic product, and synthetic cyanoacrylic glue. The experience with fibrin glue has longer reported follow-up.

A few small series have discussed on the use of fibrin glue to treat VVF demonstrating a good success rate (14,15). Schneider et al. (14) reported six cases using endoscopic techniques and found a 66% closure rate using glue compared with 88% success with a traditional repair. Although it may involve more than one injection to treat the fistula, fibrin glue promotes healing, is biodegradable, and has been used successfully in a large variety of urologic fistulas, including those caused by irradiation (14). Ghoreifi et al. (16) recently described a 100% success rate in 12 patients using autologous platelet-rich plasma injection and platelet-rich fibrin glue interposition (16).

Synthetic cyanoacrylic glue is a relatively newer product in occlusion therapy of fistulas. It polymerizes in 90 seconds once injected and can be used without difficulty in a wet environment such as the genitourinary tract; this, together with its antimicrobial properties, makes it an attractive option for the treatment of VVF. The best results are achieved in fistulas characterized by a long tract and diameter <1 cm. Application can be performed from either transvaginal or cystoscopic approaches with Foley catheter removal between 48 hours and 3 weeks depending on the size of the fistula. Generally, follow-up cystography is performed in 1 to 3 months.

The benefits of using occlusion therapy to treat VVFs include the ability to treat the fistula earlier rather than expecting the patient to endure the distressing symptoms of the fistula for up to 3 months while awaiting definitive surgery. Additionally, there is very low morbidity associated with occlusion therapy. There have been no reported complications from occlusion therapy treatment of VVF, other than the occasional necessity of removing excess glue endoscopically. Importantly, it does not preclude other forms of treatment if it is unsuccessful. Although occlusion therapy appears to be safe and efficacious in selected, small VVFs, more longer term and randomized studies are needed to evaluate its durability.

SURGICAL TECHNIQUES

Transvaginal Approach

Transvaginal VVF repair is the least invasive surgical approach because the vagina in its native state serves as a natural orifice facilitating performance on an outpatient (<24 hour admission) basis. The patient is placed in the dorsolithotomy position. If a narrow vagina is present or the VVF site is high lying, a Schuchardt posterolateral relaxing incision at the 4 o'clock position of the vaginal introitus and distal vaginal wall may be performed to improve exposure. A suprapubic catheter is positioned with a Lowsley retractor, and a urethral Foley catheter is placed. The labia minora are sutured to the inner thigh and a weighted vaginal speculum placed. The VVF is dilated to place an 8Fr Foley catheter. Applying gentle traction to the catheter aids in exposure and dissection of the VVF.

After submucosal injection of a vasopressin mixture (10 U per 100 mL normal saline), lidocaine with 1% epinephrine, or saline to elevate the anterior vaginal mucosa, the VVF is circumferentially incised. A posteriorly based inverted U-shaped incision is made with the apex continuous with the VVF incision (Fig. 24.1). If the VVF is situated deep in the vaginal vault, an anteriorly based U-shaped incision is utilized. The vaginal mucosa is dissected away from the perivesical fascia to form vaginal flaps anterior and posterior to the VVF (Fig. 24.2). Unless nonviable, the fistulous tract is not excised as excision enlarges the defect and risks injury to the intramural ureter. Left intact, the fistula tract also provides strength to the VVF closure, helping decrease the risk of VVF repair disruption due to bladder spasms.

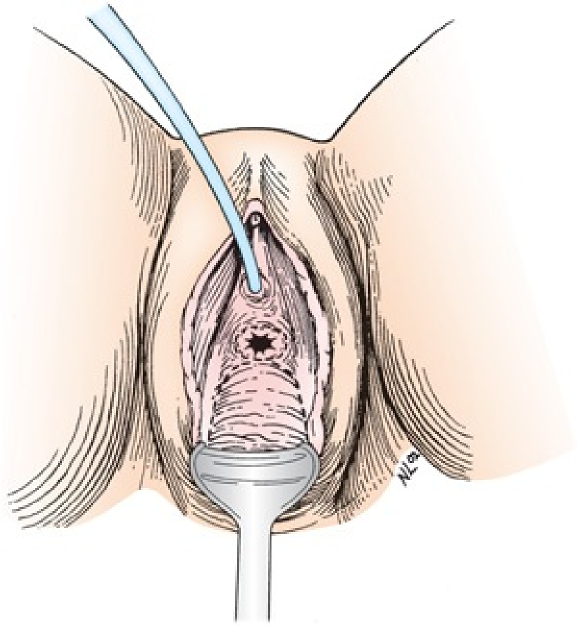

FIGURE 24.1 The apex of the vaginal inverted U incision is continuous with the circumferential fistula incision. (Modified with permission from Raz S, Bregg KJ, Nitti VW, et al. Transvaginal repair of vesicovaginal fistula using a peritoneal flap. *J Urol* 1993;150:56–59. Copyright © 1993 American Urological Association, Inc. Published by Elsevier Inc. All rights reserved.)

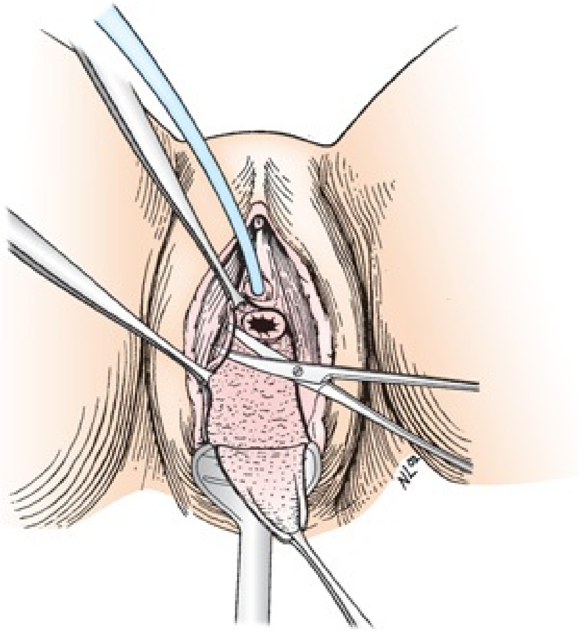

FIGURE 24.2 The vaginal mucosa is dissected away from the perivesical fascia. (Modified from Raz S, Bregg KJ, Nitti VW, et al. Transvaginal repair of vesicovaginal fistula using a peritoneal flap. *J Urol* 1993;150:56–59. Copyright © 1993 American Urological Association, Inc. Published by Elsevier Inc. All rights reserved.)

The fistula is closed in two nonoverlapping, perpendicular layers to prevent fistula recurrence. The first layer closes the fistula with interrupted 4-0 polyglycolic acid sutures, incorporating the vaginal wall overlying the VVF, the fistula tract, and the partial thickness of the bladder wall (Fig. 24.3). The second layer, using 2-0 polyglycolic acid sutures, imbricates the perivesical fascia and the deeper musculature of the bladder over the first layer in a tension-free fashion. The repair is checked for leaks by instilling indigo carmine into the bladder. The vaginal wall is advanced over the VVF repair and closed with an interlocking, running 2-0 polyglycolic acid suture. A Betadine-soaked vaginal pack is placed.

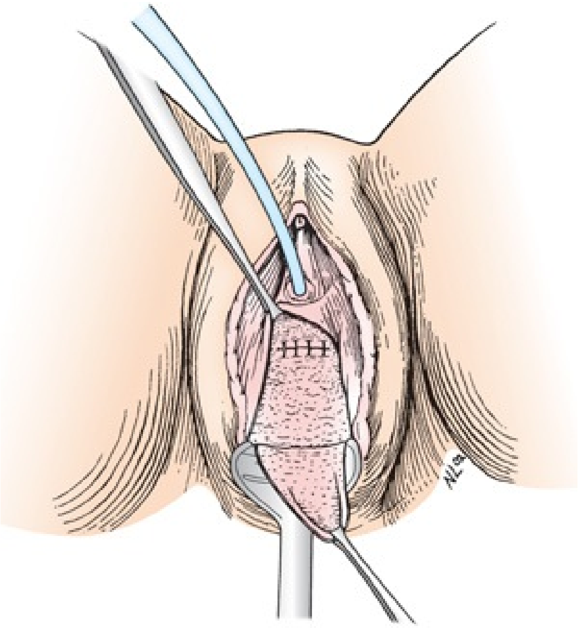

FIGURE 24.3 Closure of the first layer, including the fistulous tract and partial-thickness bladder wall. (Modified with permission from Raz S, Bregg KJ, Nitti VW, et al. Transvaginal repair of vesicovaginal fistula using a peritoneal flap. *J Urol* 1993;150:56–59. Copyright © 1993 American Urological Association, Inc. Published by Elsevier Inc. All rights reserved.)

If there is any concern about the repair, an interposing layer may be placed between the vaginal wall and bladder. The most common options are the Martius labial fat pad and the peritoneal flap.

Alternative tissues include labial, vaginal wall, gluteal, and gracilis muscle flaps. The Martius labial fat pad provides neovascularity and lymphatic drainage, fills dead space, and enhances granulation tissue formation. The flap is harvested by making a vertical incision on the labium majus; the underlying fibrofatty tissue is mobilized. The anterior portion of the graft is tied off (sacrificing the blood supply from the external pudendal artery), leaving the fibrofatty pad supplied by its posterior blood source: the posterior labial artery from the internal pudendal artery. A tunnel is developed from the vaginal incision to the labium majus; the labial fat pad is transferred through the tunnel to cover the VVF repair and secured in place with interrupted 3-0 polyglycolic acid sutures (Fig. 24.4). The tunnel must be sufficiently sized to prevent constriction of the fat pad's blood supply. The labial incision is closed with a 1/4-inch Penrose drain in place unless the graft bed is dry (Fig. 24.5).

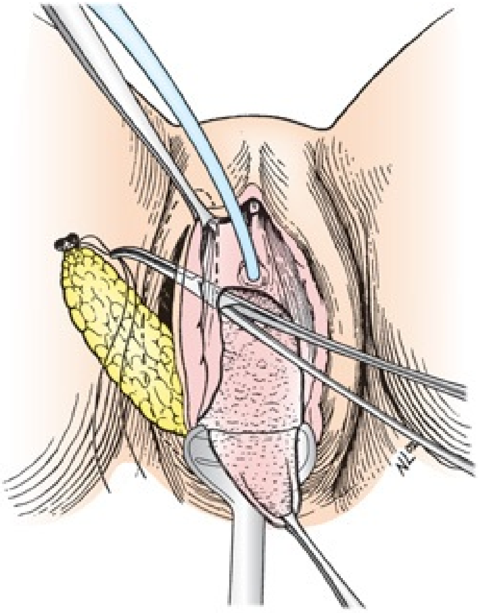

FIGURE 24.4 Using a right-angle clamp, the Martius flap is passed from the labial incision to the vaginal incision.

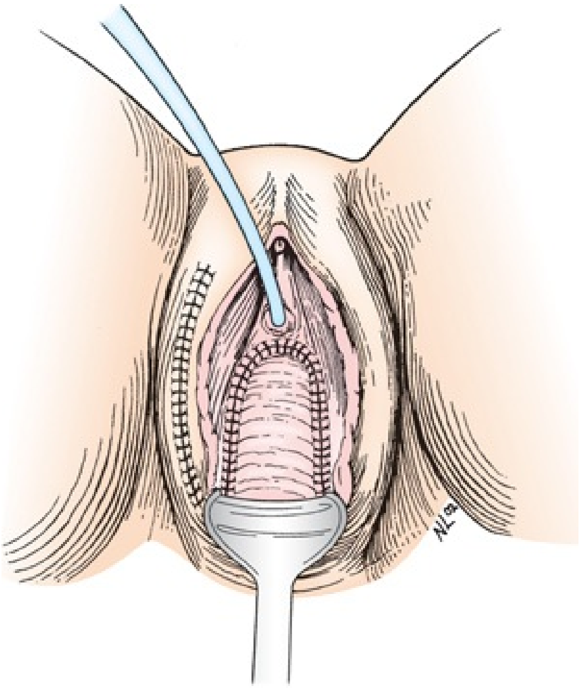

FIGURE 24.5 Closure of the labial and vaginal wall incisions.

Another effective method is peritoneal interposition as described by Dupont and Raz (12) for routine use in fistula repair. With further posterior dissection of the anterior vaginal wall from the bladder, the glistening surface of the peritoneum in the anterior cul-de-sac is exposed. Without entering the intraperitoneal space, the peritoneum is mobilized from the posterior bladder wall to bring it down into the vagina and suture it over the VVF repair site (Fig. 24.6). The peritoneal flap has a 96% success rate when used in transvaginal VVF repair (17).

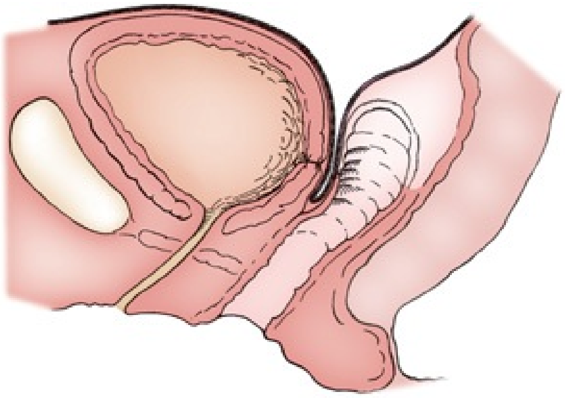

FIGURE 24.6 Interposition of the peritoneum between the bladder and vagina. (Modified with permission from Raz S, Bregg KJ, Nitti VW, et al. Transvaginal repair of vesicovaginal fistula using a peritoneal flap. *J Urol* 1993;150:56–59. Copyright © 1993 American Urological Association, Inc. Published by Elsevier Inc. All rights reserved.)

The vaginal pack is removed on postoperative day 1. The patient is given perioperative antibiotics and anticholinergics to prevent bladder spasms. Two weeks postoperatively, the urethral catheter and suprapubic tube are removed if the cystogram reveals no persistent fistula or extravasation. If a fistula is still present, bladder drainage continues for another 2 to 3 weeks and the cystogram repeated at that time.

Recently, a novel approach to transvaginal surgery has been described by Aybek (18) using a 30-degree optic lens and open surgery instruments transvaginally mimicking laparoscopy through a natural orifice. The authors reported success in all three women for which this technique was used with minimal blood loss and an overnight hospital stay (18).

Transabdominal (Intraperitoneal) Approach

The patient is placed in a low lithotomy position. Cystoscopy is performed to visualize and cannulate the VVF with a 5Fr to 6Fr ureteral catheter or guide wire. If unable to pass the guide wire through the VVF transvesically, it is passed from the vaginal side into the bladder, grasped cystoscopically, and brought out through the urethra.

A midline infraumbilical incision is made; the rectus muscle is split midline to enter the pelvis. The bladder is opened with a midline vertical cystotomy between two stay sutures (Fig. 24.7). The VVF is identified with the guide wire exiting its opening into the bladder. The urethral end of the guide wire is pulled into the cystotomy incision. The VVF’s position in relation to the ureteral orifices is noted and the ureters are cannulated with stents, if necessary. If there is any difficulty identifying the orifices due to local inflammation, IV indigo carmine may be administered.

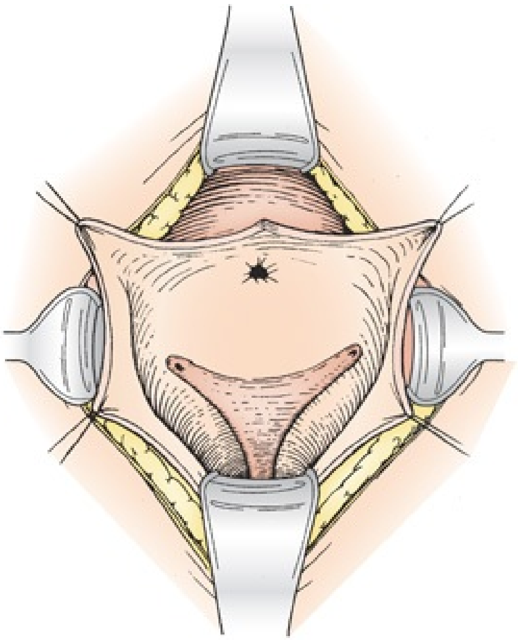

FIGURE 24.7 The bladder is opened in the midline without extending the cystotomy to the fistula.

Entering the peritoneal cavity, the dissection along the posterior bladder wall is carried out until the guide wire traversing the VVF is palpated, indicating the junction between the vagina and bladder. With a sponge stick or endoanal sizer in the vagina to help delineate the vagina, the bladder is carefully dissected away from the vagina. Wide mobilization of the bladder and vagina to allow tension-free closure of each side of the VVF is critical. The dissection bisects the fistula tract without excising the tract extending 1.5 to 2.0 cm beyond the VVF, allowing for tension-free closure (Fig. 24.8). Using interrupted 3-0 polyglycolic acid sutures, the vaginal defect is closed in two nonoverlapping layers. The bladder defect is also closed in two nonoverlapping layers, with running 4-0 polyglycolic acid and 3-0 interrupted sutures.

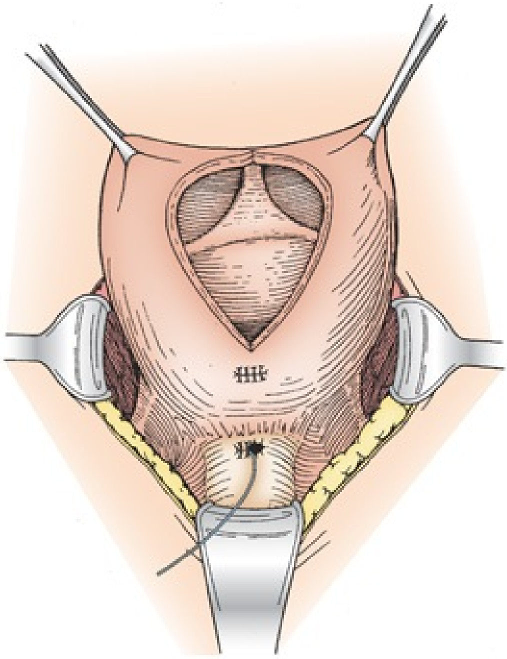

FIGURE 24.8 After dissecting between the bladder and vagina, both defects are closed in two layers.

After the bladder and vaginal fistulous defects are closed, attention is turned to developing an omental pedicle flap to interpose between the bladder and vagina. Evans et al. (19) recommended routine use of an interposition flap during intra-abdominal VVF repair, noting a success rates of

100% and 63% to 67% with and without a flap, respectively. Not only does the interposition flap add an extra layer to the VVF repair to prevent recurrence, but it also increases lymphatic drainage and decreases the risk of infected fluid collection. However, there have been several recent case reports where success of VVF was achieved without using a flap in patients with VVF recurrence after undergoing repair with tissue interposition (20).

The greater omentum is identified, and an omental flap based on the more reliable right gastroepiploic artery is developed (Fig. 24.9). The flap is brought down to the pelvis and placed between the bladder and vagina, covering the fistula repair (Fig. 24.10). The graft is secured in place with interrupted 3-0 polyglycolic acid sutures. Alternatives to omentum include lateral pelvic peritoneum, pericolic or mesenteric fat, and free bladder mucosal graft. The urachal flap, a newly reported alternative, was recently described by McCammon (21) associated with successful repair of 12 out of 13 patients with VVF (21). Of the 13 patients, none had previous pelvic irradiation and 5 had failed prior repair. The fistula size ranged from pinpoint to 1.5 cm, and most were located proximal to the trigone on the posterior wall. In the one failure who also suffered from a wound evisceration, she subsequently underwent successful repair using a Martius flap.

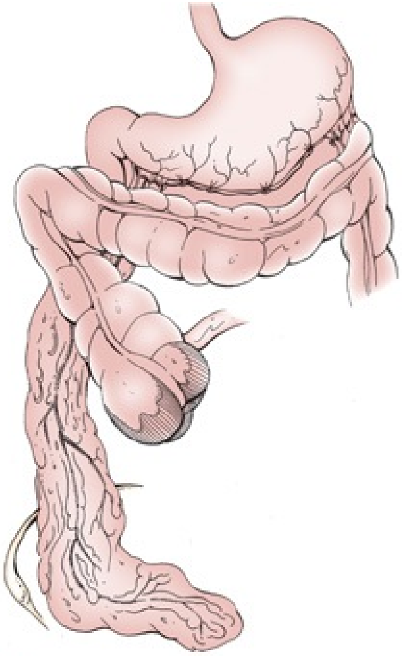

FIGURE 24.9 Development of an omental pedicle flap based on the right gastroepiploic artery.

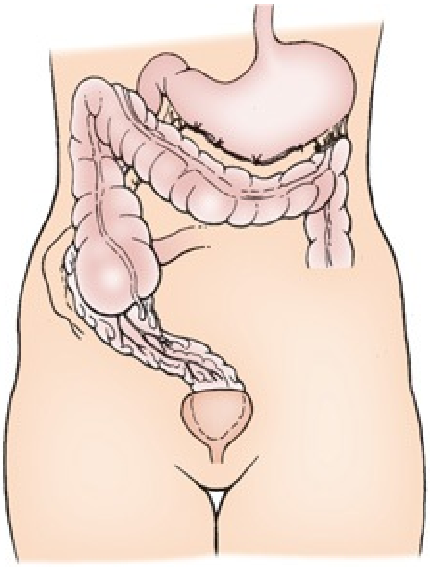

FIGURE 24.10 Placement of the distal end of the omental graft posterior to the detrusor covering the repairs.

With the VVF repair completed, a suprapubic catheter and urethral Foley catheter are placed with 5-mL balloon inflation each. In patients with long-term, large fistula, the bladder capacity is reduced due to the constant drainage. Therefore, the placement of two fully inflated balloons in combination with irritation from the incisions may lead to intensification of bladder spasms. Therefore, a Malecot-type catheter without a balloon is another option to reduce irritative symptoms. The vertical bladder incision is closed in two layers with 2-0 polyglycolic acid sutures. A closed pelvic drain is also placed. Postoperative care is similar to that after transvaginal VVF repair.

An alternative to the previously described intra-abdominal technique is the standard O'Conor technique. The bladder is bivalved posteriorly from the dome to the level of the VVF. Then, the VVF is excised entirely (Figs. 24.11 through 24.13). After further dissection of the bladder from the vagina, the vaginal defect is closed in two nonopposing layers with interrupted absorbable sutures (Fig. 24.14). An interposition flap is tacked over the vaginal closure and the bladder is closed. The first technique is slightly more difficult in that the fistula is approached posteriorly and transected between the bladder and vagina. However, the advantages are that the smaller cystotomy is separated from the repair.

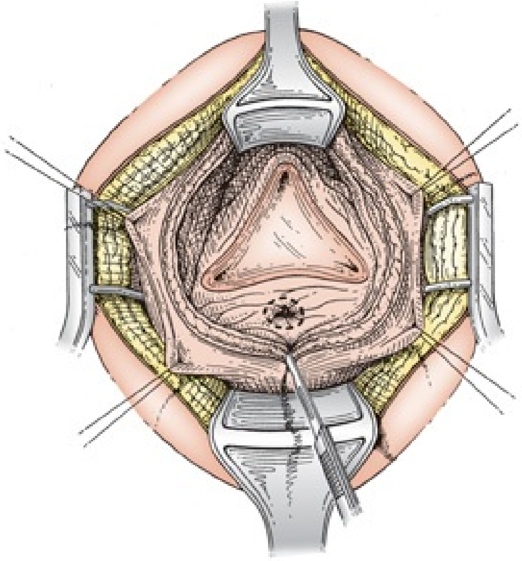

FIGURE 24.11 Cystotomy extended down to the fistula site.

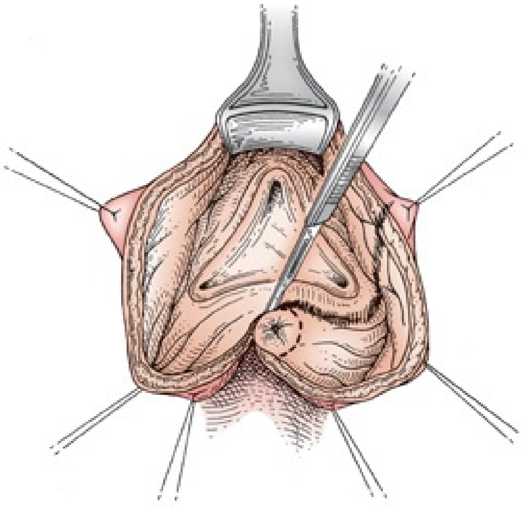

FIGURE 24.12 Circumscribing incision around the fistula.

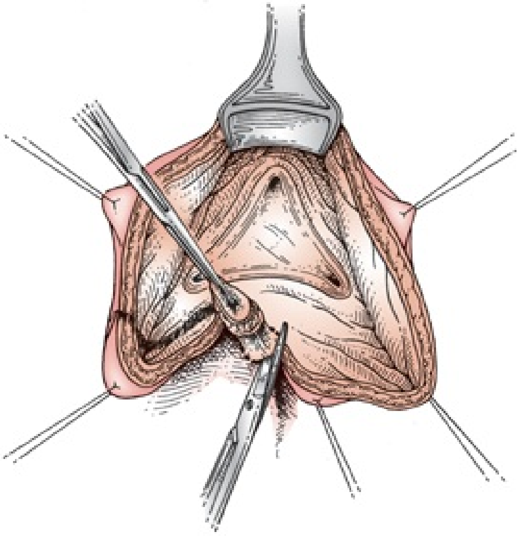

FIGURE 24.13 Sharp excision of the fistula tract.

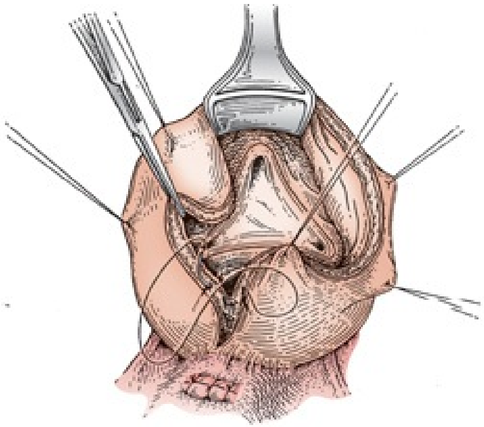

FIGURE 24.14 Relation of the cystotomy to the vaginal closure.

Transvesical (Extraperitoneal) Approach

The advantage of this approach is that one can avoid entering the peritoneal cavity. Through a midline infraumbilical incision, the bladder is identified and opened with a midline vertical incision. The VVF is located and the ureteral orifices are cannulated with stents. The fistulous opening is circumscribed carefully with a scalpel, incising only the thickness of the bladder mucosa and staying out of the vagina. This is performed to leave the fistula tract intact, along with a 2- to 3-mm ring of bladder mucosa. With sharp dissection directed radially away from the VVF for 1 to 2 cm, the bladder is mobilized away from the vagina (Fig. 24.15). To help with exposure, a Foley catheter may be placed transvesically in the VVF for upward traction.

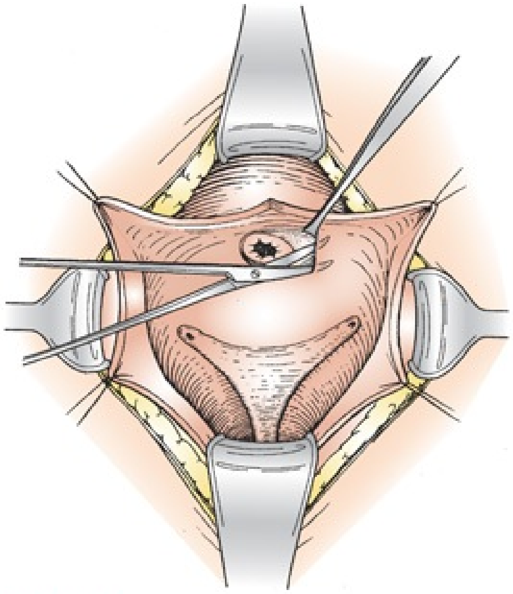

FIGURE 24.15 Transvesical development of the plane between the bladder and vaginal walls.

With interrupted 3-0 polyglycolic acid sutures, the fistula and vagina are closed together. Next, the bladder muscle is closed perpendicular to the fistula and vaginal closure, also with 3-0 polyglycolic acid sutures. Finally, the bladder mucosa is closed with running 4-0 polyglycolic acid sutures. A suprapubic cystotomy catheter and a urethral Foley catheter are placed followed by closure of the bladder in two layers with 2-0 polyglycolic acid sutures. Postoperative care is similar to that previously described.

Laparoscopic and Robot-Assisted Repair of Vesicovaginal Fistulas

With the high success of the transvaginal approach, the decision to repair a VVF using a transabdominal approach requires some justification based on the characteristics of the fistula, inciting etiologic factors and history of prior repair. High VVFs, fistulas situated close to the ureteric orifices, or those with failed vaginal repair, may be better served by using a transabdominal approach because of its higher success rate. An abdominal incision, however, is associated with a higher morbidity risk and longer recovery time for the patient. The development of minimally invasive surgical techniques led to the application of laparoscopic techniques for the repair of VVF. Nezhat et al. (22) was the first to report correction of a VVF using a laparoscopic approach in 1994. Its limitations have centered on dissection of adhesions and fibrosis around the fistula and application of sutures in a tension-free manner. Recent studies show a 100% success rate by several authors, but this remains in a small number of patients with primary fistulas. Table 24.2 summarizes the most recent studies comparing laparoscopic, robot-assisted, transvaginal, and open abdominal approaches in VVF repair. The development of the robot-assisted laparoscopic approach has reduced many of the challenges faced in the surgical repair of the VVF.

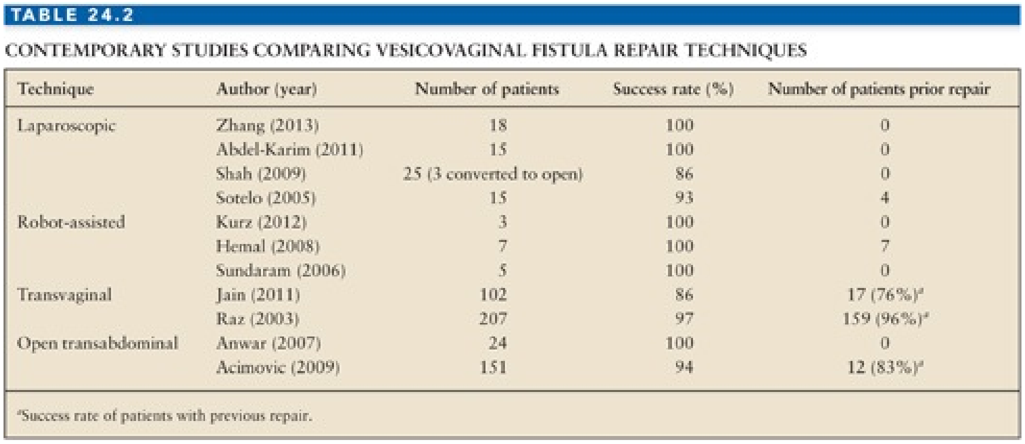

TABLE 24.2

CONTEMPORARY STUDIES COMPARING VESICOVAGINAL FISTULA REPAIR TECHNIQUES

Technique	Author (year)	Number of patients	Success rate (%)	Number of patients prior repair
Laparoscopic	Zhang (2013)	18	100	0
	Abdel-Karim (2011)	15	100	0
	Shah (2009)	25 (3 converted to open)	86	0
	Sotelo (2005)	15	93	4
Robot-assisted	Kurz (2012)	3	100	0
	Hemal (2008)	7	100	7
	Sundaram (2006)	5	100	0
Transvaginal	Jain (2011)	102	86	17 (76%)[a]
	Raz (2003)	207	97	159 (96%)[a]
Open transabdominal	Anwar (2007)	24	100	0
	Acimovic (2009)	151	94	12 (83%)[a]

[a] Success rate of patients with previous repair.

The potential benefits offered by laparoscopic and robotic repair of VVFs include shorter recovery time, reduced morbidity, less blood loss, better cosmesis, and improved visualization of the fistula and adjacent tissues, facilitating more precise extensive dissection around the fistula. The surgeon is also able to perform other concomitant procedures such as ureteral reimplantation or augmentation cystoplasty, if necessary. As the operation is traditionally performed using a transperitoneal approach, it is easily amenable to laparoscopic techniques. The first complete transabdominal laparoscopic and robotic repairs of a VVF were performed in 1994 and 2005, respectively. Evidence for the efficacy and safety of this approach is based on few small series of nonrandomized reports and case reports. In Sotelo's series, 14 out of 15 patients were cured using the laparoscopic approach at a mean follow-up of 26 months (23).

Gupta et al. (24) in 2010 compared the outcomes between recurrent VVF repaired in either open or robotic fashion. Twelve patients in the robotic arm were matched based on patient demographics, fistula etiology, prior repairs, and fistula size to 20 patients in the open arm. The resultant success rates were 100% in the robotically managed group versus 90% in the open group; however, it was not statistically significant due to sample size. Nonetheless, mean blood loss (88 versus 170 mL) and hospital stay (3.1 versus 5.6 days) were significantly less with a *P* value <.05 when comparing between robotic and open groups, respectively (24).

The technical advances afforded by the laparoscopic technique include the need for a minimal cystotomy, often in a reverse tennis racquet fashion with minimal bladder mobilization and magnified anatomy enhancing visualization of the fistula margins. Robotic assistance has decreased the fatigue factor of the surgeon, minimized the technical difficulty associated with placement of tension-free sutures to the bladder and vagina, and improves the surgeon's depth perception.

Either a four- or five-port system is used for laparoscopic or robotic approach, respectively. The fistula may be catheterized to reduce loss of pneumoperitoneum, and the bladder is catheterized with a Foley catheter after careful localization of the fistula using vaginoscopy and cystoscopy. If the fistula is close to the ureteric orifices, the ureters are cannulated to allow easier localization. Minimal cystotomy is performed around the fistula, and the fistula is repaired in the usual fashion via the mini-O'Conor approach (25). Tissue interpositioning can also be applied, usually using omentum. Average operation times run around 140 to 233 minutes, with an average length of stay of approximately 4 days. The Foley catheter is removed on days 10 to 14, preceded by cystography.

Laparoscopic and robotic techniques can be applied safely and effectively in the treatment of supratrigonal and large VVFs. This technique offers many potential benefits to the patient; however, there remains a paucity of randomized studies to quantitate its true effectiveness. It is also an evolving area, with the potential for further advances in surgical technique.

Technique Controversies

Tissue Interposition

Tissue interposition has been advocated historically, especially in recurrent VVF. However, recent evidence by Flynn et al. (26) suggests that there is no added benefit in the success rate of benign VVFs. The patients were in two groups: 25 patients with primary VVF and 24 patients with recurrent VVF. Hysterectomy was the etiology of the fistula in most patients being 88% in group 1 and 95% in group 2. The mean fistula size was 7.1 ± 4.8 mm in group 1 and 6.7 ± 8.6 mm in group 2. All repairs were done transvaginally and patients were discharged with only a suprapubic catheter for drainage that was typically left for 3 weeks. The authors, however, state that tissue interposition should be used in the face of lack of local tissue after fistula excision and/or poor tissue quality resulting from chronic infection or steroids. As such, the decision for tissue interposition should not be based on recurrence but rather individualized based on fistula etiology and integrity of local tissue (26).

Excision of Fistula Edges

Another technical point that has been questioned is the classical teaching of trimming the edges of the fistula to obtain bleeding, well-vascularized tissue. Mourad (27) studied 64 women randomized into two groups with no difference in fistulae characteristics. The cure rates were not statistically different based on trimming of the fistulous tract edges versus inclusion of the original fistulous edges. Anecdotally, however, the authors did note in the event of recurrence, the fistulous tract was larger when the edges were trimmed. This led to the conclusion that there is no added benefit to trimming the edges with a potential negative effect in patients with subsequent recurrence (27).

OUTCOMES

Complications

Clearly, the most problematic complication is recurrent or persistent fistula. The catheter is replaced for several weeks and the cystogram repeated. If the fistula fails to resolve or improve, then endoscopic evaluation—vesical and vaginal—is performed in preparation for a second procedure. For recurrent fistulas complicated by prior pelvic irradiation, a conservative approach is wise, waiting 6 to 12 months before attempting repair. Frequency, urgency, and urge incontinence in the early preoperative period are treated symptomatically with anticholinergic therapy. These, however, are expected due to bladder decompensation and trigonal/suture line irritation. Residual incontinence must be evaluated with physical examination and fluoroscopic urodynamics. Occult or de novo stress urinary incontinence occurring in 10% to 12% of patients requires separate treatment after recovery from the VVF repair. Ureteral obstruction, prolonged ileus, and bowel obstruction are uncommon.

Results

A review of the VVF series from the last two decades demonstrates the success rate of transvaginal and transabdominal repairs to be 92.5% to 96% and 85% to 100%, respectively (10,11,17,28). Laparoscopic and robot-assisted VVF is still growing with very small series reporting results comparable to conventional techniques. Therefore, when the appropriate approach is selected based on the etiology, location, concomitant pathologies, and surgeon experience, excellent results can be expected in the great majority of patients. However, in those who have failed multiple repairs due to severe tissue compromise secondary to radiation or who have developed the end-stage detrusor, diversion may be the only alternative.

CHAPTER 25 INTESTINOURINARY FISTULAS

RYAN L. MORI, ERIC A. KLEIN, AND KENNETH W. ANGERMEIER

An intestinourinary fistula is a pathologic extra-anatomic epithelialized connection that can be described based on the respective intestinal and urologic segments involved (i.e., enterovesical, colovesical, rectovesical, rectourethral). This chapter will describe the etiology, evaluation, and management of intestinourinary fistulas with special emphasis on intestinovesical and rectourethral fistulas.

INTESTINOVESICAL FISTULAS

Etiology

The etiology of enterovesical and colovesical fistulas can be divided into three broad categories: inflammatory, neoplastic, and traumatic (Table 25.1). In modern series, diverticular disease is the most common etiology representing 67% of cases, followed by malignancy in 15% and Crohn disease in 9% (1,2). A history of pelvic irradiation increases susceptibility and complexity. Men are affected twice as commonly as women due to the presence of the uterus and broad ligament as a protective barrier. Up to 50% of women with colovesical fistulas have undergone previous hysterectomy (3).

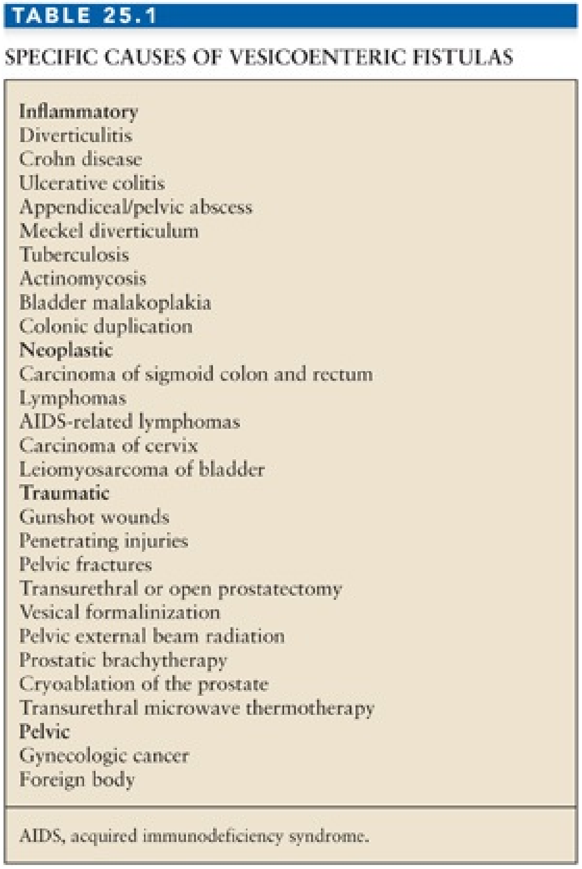

TABLE 25.1

SPECIFIC CAUSES OF VESICOENTERIC FISTULAS

Inflammatory
Diverticulitis
Crohn disease
Ulcerative colitis
Appendiceal/pelvic abscess
Meckel diverticulum
Tuberculosis
Actinomycosis
Bladder malakoplakia
Colonic duplication
Neoplastic
Carcinoma of sigmoid colon and rectum
Lymphomas
AIDS-related lymphomas
Carcinoma of cervix
Leiomyosarcoma of bladder
Traumatic
Gunshot wounds
Penetrating injuries
Pelvic fractures
Transurethral or open prostatectomy
Vesical formalinization
Pelvic external beam radiation
Prostatic brachytherapy
Cryoablation of the prostate
Transurethral microwave thermotherapy
Pelvic
Gynecologic cancer
Foreign body

AIDS, acquired immunodeficiency syndrome.

Diagnosis

Although the inciting pathology is usually intestinal, the presenting symptoms are often urinary in nature. The most common presenting complaints are pneumaturia reported in 57% to 91% and fecaluria in 42% to 76%. Recurrent urinary tract infections, irritative voiding symptoms, and abdominal pain are also common, whereas passage of urine per rectum is not typical (1–4). Physical signs suggestive of enterovesical fistulas are often subtle or absent but may include a palpable mass or abdominal tenderness with or without local peritonitis. Associated physical findings are more commonly associated with fistulas secondary to inflammatory bowel disease (5). In patients with rectal disease, a rectal abnormality or tenderness may be present. Urinalysis usually reveals pyuria with or without hematuria, and urine cultures are positive in the majority of patients with the most common growth patterns being multiple organisms or isolated *Escherichia coli* (2).

Given the symptomatic nature of enterovesical and colovesical fistulas, the diagnosis is typically a clinical one. The goal of assessment is not only to diagnose and localize the fistula but also to identify and develop a treatment strategy for the underlying intestinal or urinary pathology. Radiographic assessment is used as an adjunct and may assist with anatomic localization and surgical planning. Traditionally, barium enema has been used as a first study, but more recent series have demonstrated fistula identification rates of only 20% to 42% (1–4). Other imaging modalities including computerized tomography (CT) and magnetic resonance imaging (MRI) have mixed results in the literature in terms of diagnosis. However, although axial imaging may fail to demonstrate the fistula, it may aid in surgical planning and identification of etiology and may be diagnostic based on the associated indirect findings of the fistula including air in the bladder or focal bladder or bowel wall thickening. In our institution, the use of CT cystography has replaced other anatomic and functional studies including standard cystography, CT urogram, and MRI.

Functional studies have been described for the diagnosis of enterovesical fistula and include the charcoal test, urinary or rectal visualization of administered dyes, the poppy seed test in which the urine is evaluated for orally consumed poppy seeds, or the Bourne test where urine is examined for barium following a nondiagnostic barium enema. Although the sensitivities of these tests may approach 100% in the literature (4), they are seldom performed because they often fail to provide anatomic detail and the diagnosis of fistula is usually self-evident based on the clinical picture.

Direct visualization with colonoscopy and cystoscopy is a key component of the analysis. Colonoscopy rarely identifies a fistula tract but is recommended for its importance in evaluating the etiology and extent of the intestinal disease (1–4). Cystoscopy is the most common abnormal investigation. Although fistula identification rates are reported to be from 10% to 60% (1,3), up to 90% of cystoscopies may show indirect evidence of the fistula including bullous edema or inflammatory bladder wall abnormalities (2).

Management

Given the symptomatic nature, the potential for morbidity, and the associated underlying bowel pathology, most intestinovesical fistulas should be addressed surgically. The principles of surgical management include removal of the diseased segment of intestine as well as the fistula tract with or without defunctionalization of the affected bowel segment with a proximal diversion. Typically, the bladder can be managed with 7 to 10 days of catheter drainage with minimal need for resection or repair especially in the setting of benign bowel disease (6). Larger bladder injuries are typically managed with two-layered closures. For this reason, surgery is often directed by the colorectal surgeon with assistance from the urologist when necessary.

A one-stage approach with bowel resection and reanastomosis has become the standard because it is associated with fewer complications and lower mortality, but management must be based on the underlying pathology on a case-by-case basis. Even in the setting of abscess or purulent peritonitis, a one-stage approach can still be safely performed given that the inflammatory focus is resectable and the bowel anastomosis can be “quarantined from any inflammatory nest” (3). A two-stage approach should be considered in patients with bowel obstruction or when there is concern for a healthy anastomosis such as in the setting of extensive locoregional abdominal sepsis, significant inflammation, or in the setting of prior radiation. The two stages may consist of bowel resection with a Hartmann procedure followed by reanastomosis, or resection with anastomosis and proximal diversion followed by delayed restoration of bowel continuity. Some patients, especially those with a history of radiation, may require permanent bowel and/or bladder diversion.

Nonoperative or minimally invasive management may be considered in patients who are deemed unfit for surgery. Spontaneous closure is rare but may occur especially in the setting of traumatic rather than inflammatory fistulas. Evaluation of several series of patients with intestinovesical fistula provides some information on patients who refuse or are unfit for surgery. Although Amin et al. (7) demonstrate that patients with diverticular colovesical fistulas may get by without significant complications in some circumstances, Thomas et al. (1) demonstrate a high rate of mortality without intervention.

Surgical Technique

One-Stage Surgery

On the day prior to surgery, a mechanical bowel preparation is administered and the patient is maintained on a clear liquid diet. Gram-negative and anaerobic coverage is provided by administering a third-generation cephalosporin and metronidazole within 1 hour of surgical incision.

The majority of fistulas can be best approached by a midline laparotomy incision extending from the pubic ramus to the umbilicus (Fig. 25.1), with cranial extension as needed. The peritoneum is entered, adhesiolysis is performed as needed, and the site of the fistula is identified. The remainder of the procedure is determined by the underlying disease causing the fistula and any associated complications. Patients with Crohn disease often have multifocal fistulas not involving the urinary tract and may require multiple resections or strictureplasties. In malignant fistulas, the requisite oncologic procedure is performed with resection of the fistula tract.

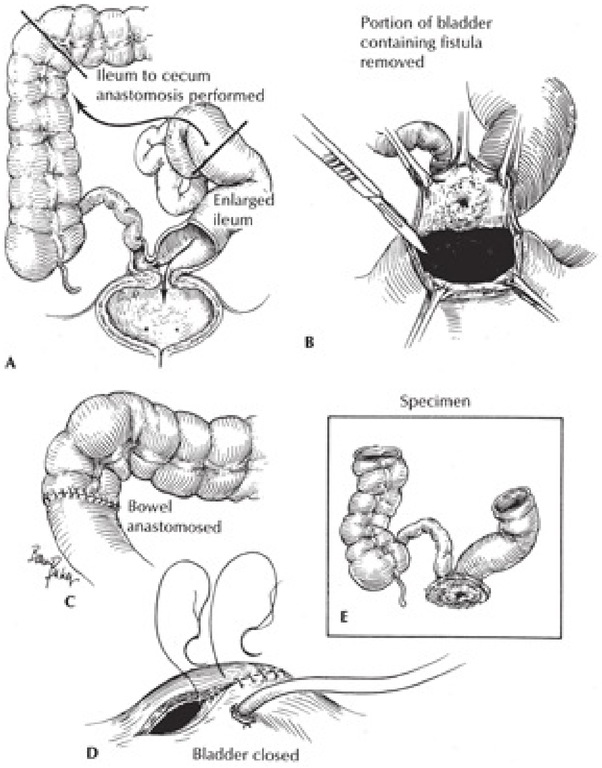

FIGURE 25.1 Management of an enterovesical fistula using bowel resection and restitution with primary bladder closure.

Fistulas associated with malignancy or large cystotomies may require partial cystectomy. Closure of small or unidentified cystotomies is not essential. Larger bladder defects should be closed in two layers with absorbable suture. A large or difficult to access bladder defect may require a midline anterior cystotomy. In the setting of ureteral involvement, ureteroneocystostomy may be required. Whenever possible, healthy tissue such as an omental or peritoneal flap should be interposed between the bowel and the bladder repairs, especially in the setting of radiation or poor tissue quality. Extraperitoneal drainage should be conducted, especially in the setting of a large bladder repair. A urethral catheter should be maintained for at least 7 days postoperatively, and in the setting of a more involved bladder repair, suprapubic catheter drainage may be used as well. A laparoscopic approach has also been described with good success (8).

Outcomes

The overall complication rate from intestinovesical fistula surgery has been reported to range between 6.4% and 49% (1). Major complications of the surgical management of intestinovesical fistula include death (0% to 3.5%), cardiopulmonary event (1.3% to 6.7%), deep venous thrombosis (0% to 1.2%), anastomotic leak (1.1% to 5.3%), prolonged ileus (0% to 4.8%), enterocutaneous fistula (0% to 1.2%), and wound infection (10% to 20%). Fistulas secondary to radiation and malignancy are associated with greater morbidity (9–11).

The results of the one-stage procedure for enterovesical fistula are dependent on the etiology of the fistula. The fistula recurrence rate in the setting of diverticular disease is virtually nonexistent (1,3). However, fistula recurrence in the setting of Crohn’s disease or malignancy can occur in up to 13% and 15% of patients, respectively (9,12). Urinary leak rates are very low but have approached 8% in small series (12) of fistulas in Crohn patients.

RECTOURETHRAL FISTULAS

Background

Over the past decade, there have been some changes in the surgical approach to rectourethral fistulas (RUFs). This has corresponded with a number of new therapies for prostate cancer and the transition of management toward the urologic surgeon. There are several surgical approaches that are acceptable. The management of each case is unique and must consider fistula etiology, complexity, associated urinary or bowel dysfunction, associated urethral or bladder neck stricture, and patient performance status.

The urologic surgeon should be familiar with the transperineal approach because it offers excellent exposure to both the urinary and rectal components of the fistula, allows for multiple potential interposition flaps, and is applicable to the repair of both simple and complex fistulas.

Etiology

RUFs have long been considered a rare clinical entity, but the incidence is increasing in tandem with the increase in treatment for prostate cancer. The etiology of the majority of RUFs is iatrogenic secondary to surgical, ablative, or radiation therapy to the prostate for prostate adenocarcinoma with combination therapy further increasing the risk. The overall risk for surgical RUF during radical prostatectomy may be as high as 0.53% according to one large contemporary series and is threefold higher following perineal prostatectomies (1.04%) compared to retropubic prostatectomies (0.34%) (13). Radiation-induced fistulas accounted for only 3.8% of all reported cases of RUF prior to 1997 (14), but recent series suggest that radiation or ablative energy are involved in up to 64% of rectourethral fistulas (10,15,16) with a steadily increasing incidence over the past decade. Brachytherapy can result in rectourinary fistula in 0.6% to 2.4% (17–19), and in cases of combined brachytherapy and external beam radiotherapy, the incidence is as high as 2.9% (19). Salvage therapies following primary surgery or radiation for prostatic carcinoma can have an even higher incidence of RUF (20,21). Fistulas can occur anytime following radiation ranging from several months to many years (14). Historically, RUF has also occurred in the absence of malignancy in the setting of congenital defects, trauma, pelvic surgery, and inflammatory bowel disease (22) as illustrated in Table 25.1.

Diagnosis

Similar to other intestinourinary fistulas, the diagnosis of RUF is clinical and is suggested by any combination of fecaluria, pneumaturia, or the passage of urine per rectum in a patient with risk factors for RUF. Unlike intestinovesical fistulas, passage of urine per rectum is the most common observance and occurs more frequently than pneumaturia and fecaluria (6). Patients may also present with infectious sequelae including recurrent urinary tract infections or sepsis. Rectal pain may be an early sign before other manifestations occur. In a patient with a history of radiation and an ulcerative anterior rectal lesion, rectal biopsy is cautioned against because there is an increased risk of subsequent fistula formation (23).

Diagnosis of rectourethral fistula is driven by the combination of endoscopy, radiographic imaging, and combined examination under anesthesia by both the colorectal and urologic teams. Digital rectal examination and proctoscopy help to assess the size and the location of the fistula relative to the dentate line as well as the integrity of the rectal mucosa and the anal sphincter. Cystoscopy allows for identification of the likely fistula site as urethral or vesicular as well as assessment of the bladder for capacity, radiation cystitis, and proximity of the fistula tract to the ureteral orifices. Presence of a urethral stricture, typically within the membranous urethra, should also be noted. Radiographic tests of importance include retrograde urethrogram, voiding cystourethrogram, and computerized tomography of the pelvis.

It is imperative during the workup to differentiate between complex and simple rectourethral fistulas. We consider simple fistulas to be small in size and secondary to surgery or trauma in the absence of radiation, ablative energy, or local tissue destruction. Surgical fistulas that are very large, or those that occur in the setting of local tissue damage or radiation effect, are considered to be complex (24,25). This distinction is important because the surgical management and expected outcomes differ for simple fistulas compared to complex ones.

Management

Rectourethral fistula represents a surgical problem in the majority of patients. Spontaneous closure is a rare event, especially in the setting of complex fistulas. However, up to 33% spontaneous closure rate has been described in cases of small surgical fistulas with urinary and fecal diversion alone (13) and has rarely been seen in cases of complex fistulas as well (26). The majority of patients with a complex RUF will require a combination of urinary or bowel diversion, and often both. In the setting of a simple RUF, this may not always be required and is done on a case-by-case basis. Urinary diversion can be achieved with a urethral catheter or a suprapubic catheter. Fecal diversion can be done laparoscopically, and the choice of a temporary versus a permanent diversion is based on the integrity of the anorectal function as well as the size of the fistula and the integrity of the surrounding tissues.

Typically, we perform combined exam under anesthesia, cystoscopy, proctoscopy, and laparoscopic fecal diversion if necessary as the first step in management. Some argue that in the absence of significant infections or sepsis, diversion can be delayed until the time of definitive repair (21). However, in the presence of radiation or ablative energy, or larger fistulas with poor local tissue quality, combination urinary and fecal diversion is recommended. Typically, we allow 3 to 6 months of diversion prior to repair in the case of complex fistulas.

Surgical management of RUF requires an individualized management strategy. Often multiple stages are required and the patient should be counseled appropriately. There are five key factors which must be considered in each case.

1. Sphincteric function
2. Presence of urethral stricture or bladder neck contracture
3. Status of the adjacent tissue
4. Size and location of the fistula
5. Overall condition and life expectancy of the patient

Sphincteric Function

In the setting of presurgical anorectal sphincteric incompetence, permanent fecal diversion should be offered in place of complex anal sphincter-sparing surgery. In the setting of urinary sphincteric deficiency, the patient must be counseled on the options of supravesical diversion or fistula repair followed by delayed implantation of an artificial urinary sphincter.

Presence of Urethral Stricture or Bladder Neck Contracture

Concurrent urethral strictures can occur in up to 11% of nonradiated RUF patients and up to 28% of those with fistulas secondary to radiation/ablation (15). Obstruction distal to the site of fistula repair may compromise an otherwise adequate repair and thus should be corrected prior to or simultaneously with RUF repair.

Status of Adjacent Tissue

Fistulas following pelvic radiation or ablative energy are often large and more complex. Radiation causes damage to endothelial cells, connective tissue, and vasculature, and these ischemic changes may compromise surgical repair. Even with healthy tissue interposition, failure rates in the setting of radiation and ablation are higher (16,19). Further, patients with radiation/ablation are more likely to require permanent fecal or urinary diversion (27).

Size and Location of the Fistula

Small and distal fistulas in the absence of radiation or ablative energy may be repaired through a transanal or transsphincteric approach. Larger fistulas and those associated with tissue damage secondary to radiation often require a transperineal, abdominal, or combined approach. Some patients with very large fistulas or troublesome sepsis or bleeding may require permanent urinary and fecal diversion and pelvic exenteration.

Overall Condition and Life Expectancy of the Patient

Poor surgical candidates may be best managed by a combination of permanent fecal and/or urinary diversion.

The panacea of surgical therapy for rectourethral fistula consists of fistula closure, interposition of healthy well-vascularized tissue, and preservation of orthotopic bowel and bladder function. Even the most complex fistulas (multiple ablative therapies, complicated surgical repair, or prior failed repair) are potentially amenable to repair with preservation of both orthotopic bowel and bladder function (28,29).

Surgical Approaches

Multiple surgical approaches exist for the treatment of RUF. Historically, the transanal and transanosphincteric approaches have dominated the literature. A more recent analysis of the literature shows transperineal repair in 66% of cases followed by transsphincteric (15.7%), transabdominal (12.5%), and transanal (5.9%) (30). Due to the relative rarity of occurrence and the shared surgical obligation of colorectal and urologic surgeons, there is limited data on the best approach for repair. The distinction between simple and complex RUF is of paramount importance because the surgical management and expected outcomes differ. As the burden of care shifts toward urologic surgeons, the transperineal approach has become the favored one in our hands for both simple and complex fistulas because it provides excellent exposure to both the urethral and rectal sides of the fistula and allows for the simultaneous management of urethral stricture and allows options for tissue interposition.

Surgical Approaches for Simple Rectourethral Fistulas

Those fistulas that are small and postsurgical can be approached in several ways depending on their location. Although the transanal and transanosphincteric approaches have been successful historically, we feel that the transperineal approach is well suited for all RUFs. Typically, prior or concomitant fecal diversion is at the discretion of the surgeon, and failure rates are acceptably low when diversion is omitted in selected cases.

Transanal Approach. This approach is well suited for small and distal postsurgical fistulas not associated with prior radiation, ablation, or poor local tissue quality. The patient is placed in a jackknife position. A speculum is inserted transanally to expose the fistula. If appropriate exposure is not possible then another technique should be chosen. If exposure allows, a full-thickness U flap of rectal wall is elevated, mobilized, and advanced over the fistula in a two-layer closure (Fig. 25.2). Alternatively, the fistula tract may be excised circumferentially with the adjacent rectal mucosa and the rectal wall muscle and mucosa closed separately. The use of this approach is decreasing as the incidence of radiation induced fistulas rises, but it is well tolerated and has success rates ranging upward of 70% to 100% (31–33). Typically, a urinary catheter is left indwelling for 2 to 3 weeks postoperatively.

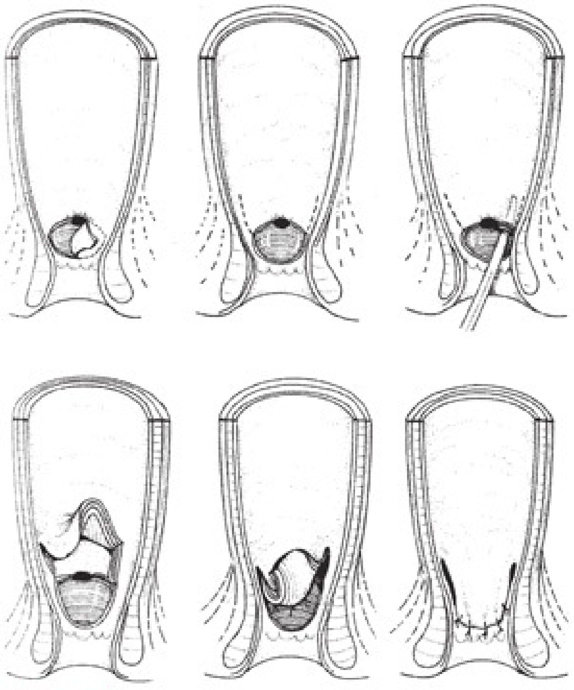

FIGURE 25.2 Through the anal canal, an ellipse of rectal mucosa is removed. A full-thickness U-shaped flap of rectal wall is elevated above the fistula. The full-thickness flap of rectal wall is brought down over the fistula and sutured in two layers to the rectal wall. (Reprinted with permission from Tiptaft RC, Motson RW, Costello AJ, et al. Fistulae involving rectum and urethra: the place of Parks' operations. *Br J Urol* 1983;55:711–715. Copyright © 2008, John Wiley and Sons.)

York–Mason Approach. Historically, this transanosphincteric approach has been the most widely used surgical approach for RUF repair, and the efficacy and success has been well established (34,35). This approach is best suited for small postsurgical fistulas that are too proximal to be treated by the transanal approach. Previous radiation or ablative therapy makes this approach less desirable because it limits the options for healthy tissue interposition.

The patient is placed in the prone jackknife position and the buttocks are separated with adhesive tape. An incision is made in the midline from the tip of the coccyx to the anal verge. The sphincter is divided in the midline after marking sutures are placed on each side to ensure precise reapproximation. The rectal mucosa is then opened along the entire length of the incision to expose the fistula tract (Fig. 25.3). The fistula tract is excised and the plane between the rectal wall and the urinary tract is dissected. The urethra and the rectum are then closed in multiple layers using absorbable suture followed by closure of the rectal mucosa and finally the sphincter. Avoidance of overlapping suture lines is done where possible. A Foley catheter is placed and left indwelling for 2 to 3 weeks. A voiding cystourethrogram confirms the absence of leak. Typically, the fecal incontinence rates are acceptably low if adequate attention is given to proper sphincteric closure.

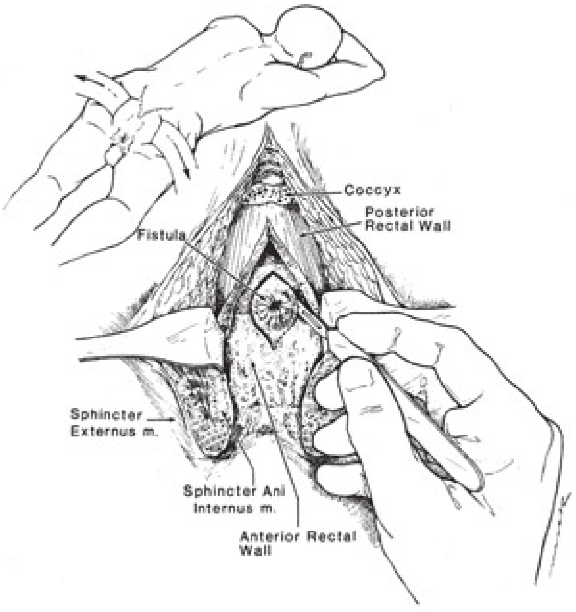

FIGURE 25.3 Posterior sagittal, transanorectal (York–Mason) approach for repair of rectourinary fistulas. The patient is placed in the prone jackknife position with tape used to displace the buttocks laterally. After division of the posterior anus and rectum, the fistula is easily identified with ample room for excision and repair. (Reprinted with permission from Stephenson RA, Middleton RG. Repair of rectourinary fistulas using a posterior sagittal transanal transrectal (modified York–Mason) approach: an update. *J Urol* 1996;155:1989–1991. Surgical Approaches for Complex Rectourethral Fistulas

Presurgical evaluation of continence and functionality of the fecal and urinary systems as well as the functional class of the patient is necessary to determine the best treatment approach. We feel that complex rectourethral fistula repair with the goal of preservation of both fecal and urinary continence is best carried out through a transperineal approach. In the setting of adequate potential urinary function with a damaged anal sphincter, the transperineal approach with gracilis interposition is combined with an abdominal approach for permanent fecal diversion. In the setting of multiple complex fistulas or marked destruction of both the fecal and urinary systems, the abdominal approach with pelvic exenteration and supravesical diversion with permanent fecal diversion is preferred (36).

Our typical approach to a complex rectourethral fistula would involve three steps. First, an examination under anesthesia as described previously is conducted with placement of a suprapubic catheter and a fecal diversion. Often the fecal diversion can be done laparoscopically, decreasing the morbidity to the patient. Second, after 3 to 6 months of diversion, a transperineal repair with gracilis muscle interposition is performed. Concomitant urethral stricture can be addressed simultaneously with a transperineal approach with either an excision with primary reanastomosis or a buccal mucosa onlay graft. Finally, restoration of bowel continuity is staged to follow. A fourth step may be required to place an artificial urinary sphincter if urinary continence is compromised.

Transperineal Approach. The patient is first placed in the high lithotomy position. If possible, a urethral catheter is inserted. An inverted U incision is made in the perineum extending from one ischial tuberosity to the other and located just above the level of the anal sphincter (Fig. 25.4A). If needed, a short midline vertical limb can be added for exposure. After bluntly developing the ischiorectal space bilaterally, the perineal dissection begins in the plane between the anal sphincter and the bulbospongiosus muscle taking care to avoid injury to the sphincter mechanism if possible. The dissection is continued along the anterior surface of the rectum until the fistula is encountered. The rectum is sufficiently mobilized laterally into the perirectal fat to allow a tension-free closure of the fistula from the rectal side. The urethra and/or prostate if applicable are then dissected off of the rectum proximal to the fistula, and it is important to carry this dissection to near the level of the peritoneal reflection to aid closure of the rectum and secure placement of the gracilis flap. Assessment is made at this point of the degree of rectal injury as well as urethral injury (Fig. 25.4B). Flexible cystoscopy aids in localizing and planning the repair for the urethral side of the fistula. The rectum is closed in two layers with the assistance of the colorectal team. If buccal mucosa is required for closure of a large fixed urethral defect, graft harvest can be done during this time. The urethral defect is closed by suturing the buccal graft with absorbable suture. If the defect does not require grafting, it is closed primarily with interrupted absorbable suture. We typically use polydioxanone suture for its tensile strength, and make all attempts to keep the knots outside of the urothelium.

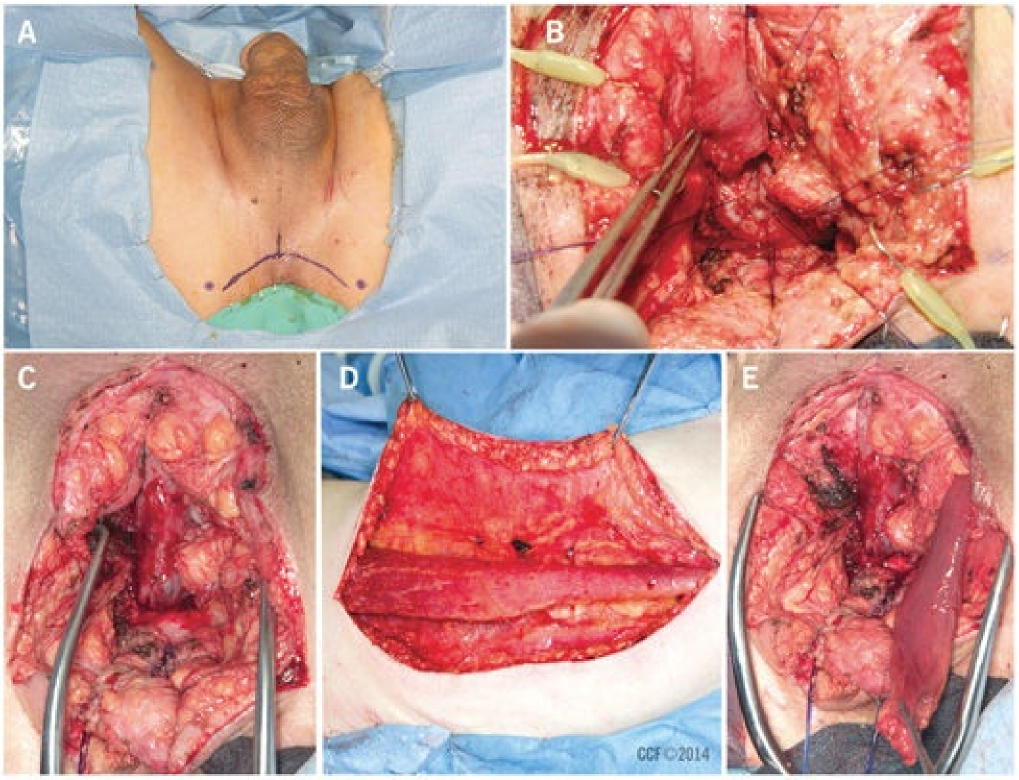

FIGURE 25.4 Transperineal repair with excision and primary anastomosis for urethral stricture. A: Positioning and skin incision. The ischial tuberosities are marked with dots. B: Anastomotic sutures in the prostatic urethra for anastomotic repair. C: Closure of the rectum and anastomosis of the urethra is complete. D: The gracilis muscle is isolated and taken off of its distal insertion. E: Gracilis is rotated into the wound as an interposition flap. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2002–2014. All rights reserved.)

If an associated bulbomembranous urethral stricture is present, a urethrotomy incision may be initiated at the fistula site and extending through the membranous stricture and 1 cm into healthy urethra. The buccal mucosa graft is then laid into this entire defect. In the setting of a posterior urethral stricture and associated cavitation and tissue destruction, buccal mucosa onlay is not possible, and we then proceed with excision of the cavitated tissue (“partial prostatectomy”) to a level where the prostatic urethra or bladder neck appears to be sufficient to support an anastomotic repair. The distal urethra is then mobilized and the intercrural space developed to allow a tension free anastomosis to the proximal bulbar urethra (Fig. 25.4C).

Gracilis Interposition Flap. The gracilis muscle offers a versatile option for healthy tissue interposition in both the prone and lithotomy positions as first described by Ryan et al. (37) in 1979. The patient’s legs are lowered into a low lithotomy position, and a linear incision is made along the course of the gracilis muscle (Fig. 25.4D). The anatomic marker is the palpable adductor longus muscle, and the incision should be two fingerbreadths inferior to this line along its axis. The proximal sites of insertion of the gracilis tendon are the symphysis pubis, inferior pubic ramus, and ischium and the distal insertion is onto the medial condyle of the knee. The muscle is mobilized, taking care to preserve the primary vascular pedicle, which is derived primarily from the medial circumflex branch of the profunda femoral artery, although one to two other smaller pedicles may be encountered. The primary pedicle is usually located approximately 9 cm from the pubic tubercle. The muscle is released from its distal tendinous insertion and routed through a large tunnel into the perineal incision (Fig. 25.4E). It is interposed between the two repairs and sutured in place proximally and laterally with absorbable suture. Typically, there are minimal functional losses as the adducting function of the leg is maintained by the adductor magnus and adductor longus; however, it is our preference to harvest the left muscle if possible because it is less likely to interfere with the subsequent operation of a motor vehicle. Drains are left both in the perineum and along the gracilis harvest site.

In the setting of a simple RUF, a gracilis interposition may still be used at the discretion of the surgeon if the repair seems to be tenuous for some reason. Alternatively, a flap of scrotal dartos can be rotated into the defect to serve as an interposition in selected patients (38).

Transabdominal Approach. The transabdominal approach may be used in the setting of a diseased rectum and a higher order fistula to the bladder neck or posterior bladder. It provides good exposure to a proximal fistula and allows simultaneous permanent colostomy as well as access to omentum or the rectus muscle for use as interposition flaps. The abdominal approach is not well suited for fistulas to the urethra because access via the pelvis is limited.

Although some have demonstrated the feasibility of transperitoneal laparoscopic repair in select cases of RUF because it may facilitate simultaneous colostomy and interposition, efficacy data is limited compared to more conventional methods.

Abdominoperineal Approach. In the setting of severe damage to the rectum and a preserved anal sphincter as may be seen at times following radiation therapy, repair of the rectal side of the RUF may not be possible. In this situation, proctectomy with a staged Turnbull–Cutait coloanal pull through procedure may be feasible with the goal of preserving fecal continence and function as well as urinary function. The proctectomy in combination with urethral repair is done in the prone jackknife position followed by repositioning the patient supine for laparotomy and coloanal pull through. Rotation of the sigmoid mesentery anteriorly during the pull through can provide coverage for the urethral repair or a buccal graft when needed.

Outcomes

There is a high degree of fistula closure and preservation of urinary and bowel continuity and function even in complex cases of RUF following transperineal repair with gracilis muscle interposition. Mild urinary incontinence is a common occurrence, and more clinical significant incontinence occurs in 12% to 16% (15,16,28) and can be managed with a staged artificial urinary sphincter implantation staged 6 to 12 months after the repair. Recurrent urethral stricture or bladder neck contracture can occur in 10% to 25% (21,28) and is typically managed endoscopically. Subsequent permanent urinary diversion may be required in up to 10% (15). Fecal incontinence rates range from 8% to 23% (16,39), and permanent diversion is necessary in 16% to 31% (15,16). Quality of life outcomes tend to be acceptable, and fecal outcome measures are typically better than urinary (39).

CHAPTER 26 VESICAL TRAUMA AND HEMORRHAGE

CHAD M. GRIDLEY AND CHRISTOPHER D. MCCLUNG

BLADDER TRAUMA

Trauma is the most common cause of bladder injury; however, only 1.6% of trauma victims will have a bladder laceration (1). Blunt trauma, such as high-impact motor vehicle collisions or falls, is the cause of 80% to 85% of bladder injuries (2–4). The mechanisms through which these injuries typically occur are either by a direct blow to the abdomen with a full bladder (classically causing rupture at the dome) or by an injury associated with a pelvic fracture. Pelvic fracture is associated with 80% of bladder injuries and accounts for almost all extraperitoneal injuries (3). These fracture-related injuries occur due to shearing from disruption of fascial attachments to the bladder or due to direct lacerations by bone fragments. The latter is more rare. Penetrating injuries to the bladder are less common in the civilian literature. Bladder injury has been cited to be present in 3.6% of abdominal gunshot wounds, 13% of penetrating injuries to the rectum, and 20% of penetrating injuries to the buttocks (5–8). The bladder can also be injured iatrogenically. Common iatrogenic causes include gynecologic surgery (52% to 61%), urologic surgery (12% to 39%), and general surgical procedures (9% to 26%) (9,10).

Presentation and Diagnosis

In the classical clinical presentation of a bladder injury, patients complain of suprapubic fullness and an inability to void. Hematuria is the hallmark of a bladder laceration. Swelling of the perineum and scrotum is also common when significant urinary extravasation or pelvic bleeding has occurred. Gross hematuria is present in 95% of patients.

According to the 2004 consensus statement on bladder injuries, the absolute indication for bladder imaging is a pelvic fracture associated with gross hematuria (11). Relative indications for imaging include clinical situations where there is a high index of suspicion of bladder injury. These include microscopic hematuria associated with a pelvic fracture and gross hematuria without a pelvic fracture. Specific pelvic fracture patterns have been shown to be predictive of injury. In a review of 37 patients, Avey et al. (12) showed that pubic symphysis diastasis and obturator ring fractures with displacement greater than 1 cm were predictors of bladder laceration. Acetabular fractures were not predictive of injury.

Static and computerized tomography (CT) cystography are the current studies recommended to diagnose bladder injuries. A recent study showed that noncontrast CT scan failed to detect or misdiagnosed the location of bladder injuries in 13% of patients (13). Although both static and CT cystography have equal sensitivities and specificities, a CT cystogram is the most common test performed in modern trauma centers. Patients with bladder trauma generally have coexisting injuries requiring a CT scan for other reasons. A CT cystogram can be performed quickly in this clinical situation where many centers have CT scanners in close proximity to the trauma bay. The sensitivity and specificity of CT cystography to detect bladder injury are 95% and 100%, respectively. Furthermore, CT cystography has the ability to determine the location of the bladder laceration with 82% accuracy (14). If static cystography is performed, it is important to obtain drainage phase images because up to 10% of lacerations can be missed if these images are not taken (15). Drainage phase images are not required for CT cystography.

Static and CT cystography require a Foley catheter for imaging. It is important to remember that 10% to 29% of bladder injuries will have a coexisting urethral injury (16). If blood at the meatus is present on initial exam, the urethra should be assessed with a retrograde urethrogram prior to inserting the catheter. Once the urethra is cleared, a Foley catheter may be placed. The bladder is then filled under gravity in a retrograde fashion through the Foley catheter with 350 mL of contrast in an intubated patient or until tolerated in an awake patient. Capping the Foley catheter and allowing renal secretion of intravenous (IV) contrast to fill the bladder is not an appropriate way to perform bladder imaging (17).

The initial diagnostic element is to define the location of injury: extraperitoneal (EP), intraperitoneal (IP), or both. These occur with frequencies of 60%, 30%, and 10%, respectively (2,4,15). The hallmark of an IP injury is the presence of contrast that outlines loop of bowel (Fig. 26.1). Isolated EP injuries have no communication with the peritoneum and will classically have a “flame” or “molar tooth” appearance on imaging (Fig. 26.2). A fine diagnostic detail is to assess the status of the bladder neck. Bladder neck lacerations can be seen as areas of extravasation low on the bladder near the Foley balloon (Fig. 26.3).

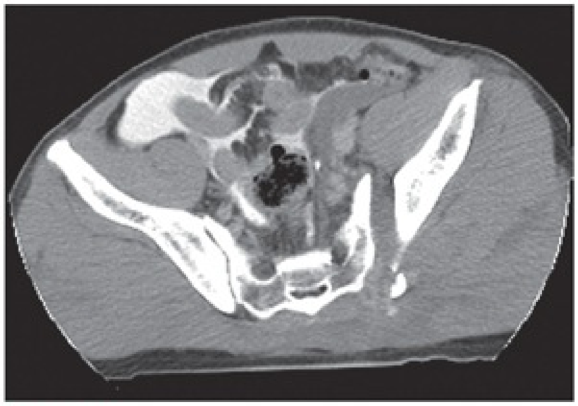

FIGURE 26.1 A CT cystogram demonstrating an IP injury with contrast outlining loops of bowel.

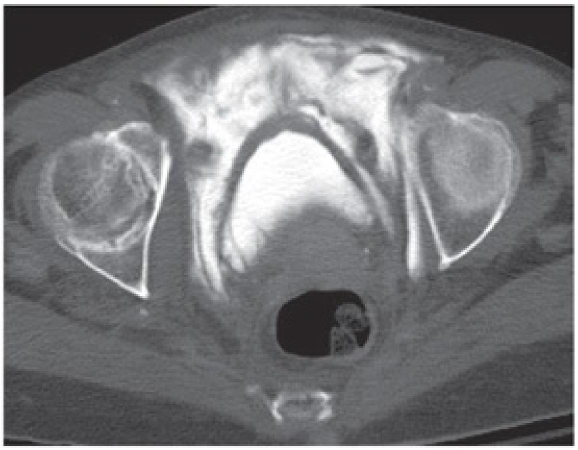

FIGURE 26.2 A CT cystogram revealing an EP injury. This image depicts the “molar tooth” sign common in many EP injuries.

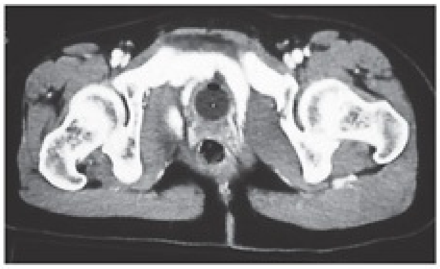

FIGURE 26.3 A CT cystogram image imaging revealing a bladder neck injury, with contrast extravasation at the bladder neck.

The American Association for the Surgery of Trauma (AAST) has established a grading system for organ injuries due to trauma. Most urologists are familiar with this grading system for renal trauma, but they are less familiar with the system for bladder trauma. In brief, the AAST grades injuries on a scale from 1 to 5, with grade I being a low-grade injury and V being a severe injury. This scale is shown in Table 26.1. The classification becomes easy to remember if one thinks of contusions or small EP lacerations as low-grade injuries and combined EP/IP injuries or bladder neck lacerations as high grade.

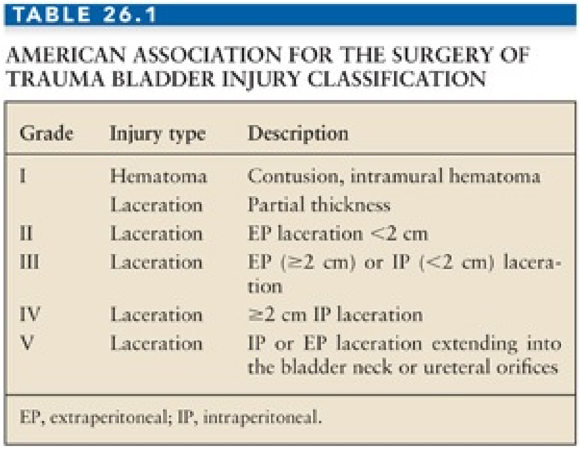

TABLE 26.1

AMERICAN ASSOCIATION FOR THE SURGERY OF TRAUMA BLADDER INJURY CLASSIFICATION

Grade	Injury type	Description
I	Hematoma	Contusion, intramural hematoma
	Laceration	Partial thickness
II	Laceration	EP laceration <2 cm
III	Laceration	EP (≥2 cm) or IP (<2 cm) laceration
IV	Laceration	≥2 cm IP laceration
V	Laceration	IP or EP laceration extending into the bladder neck or ureteral orifices

EP, extraperitoneal; IP, intraperitoneal.

Management

The management of bladder lacerations depends on injury location. The two options are conservative management with Foley catheter alone or primary surgical repair (cystorrhaphy). In general, EP injuries without bladder neck involvement may be managed with a Foley catheter alone. Healing occurs within 10 to 14 days in 74% of cases, and almost all heal within 3 weeks (18,19). However, complications have been cited to occur such as delayed healing, vesicocutaneous fistula formation, septic events, and bladder calculi (18). Prior research does suggest that complications are lower for EP lacerations repaired primarily relative to conservative management with a Foley catheter alone (19).

IP injuries and bladder neck injuries require formal surgical repair. Although bladder neck injuries are by definition EP, resolution with Foley catheter alone is marginal at best. Persistent leaks are common in this situation.

Penetrating injuries should be managed with exploration. These patients are commonly explored for nonurologic indications to manage other injuries because up to 80% of penetrating bladder injuries also have gastrointestinal injuries. Concomitant rectal and bladder injuries can result in fistula formation if not surgically repaired. Repair is encouraged in this setting along with the use of an omental flap as tissue interposition to avoid overlapping suture lines between bladder and rectal repairs. In the largest penetrating lower urinary tract study to date, 90% of patients had dual entrance and exit wounds (20). All lacerations should be repaired, and gastrointestinal injuries should be addressed.

A unique consideration is the coexisting vaginal laceration and bladder laceration. All female patients presenting with a pelvic fracture require a manual vaginal exam to rule out vaginal laceration and open pelvic fracture. If not surgically addressed, hematoma infection and fistula formation may occur (21). The bladder and vagina require suture repair. As with rectal injuries, the use of an omental flap for tissue interposition between the bladder laceration and vaginal laceration repair sites is suggested.

Surgical repair of bladder lacerations should be done during the index admission. If the patient is having exploratory laparotomy shortly after admission for other intra-abdominal injuries and is hemodynamically stable, the repair should be done at this time. A trauma patient will not infrequently require resuscitation and pelvic angioembolization for pelvic bleeding immediately after presentation. In this setting, resuscitation takes precedent, and surgical repair should be done as soon as the patient is hemodynamically stable.

Cystorrhaphy can be accomplished by two separate approaches: transabdominally or retropubically. In an acute setting, the benefit of a transabdominal approach is to avoid a pelvic hematoma associated with a pelvic fracture. The space of Retzius should not be opened in this situation because significant bleeding can ensue. EP and bladder neck lacerations can be repaired from within the bladder through an abdominal incision.

Primary surgical closure of EP repairs is most commonly done at the time of open reduction and internal fixation of a pelvic fracture. This commonly occurs several days after admission when the patient has been resuscitated and bleeding has resolved. It is the authors’ practice to repair all EP injuries primarily at the time of open reduction and internal fixation for the pelvic fracture. Although more studies are needed to document superiority of primary suture repair over conservative management with a Foley for EP injuries, older data does suggest that complication rates are higher with Foley treatment alone (19).

In summary, EP lacerations may be managed solely with Foley catheter decompression. Indications for open surgical repair are the following:

1. IP bladder rupture
2. Bladder neck laceration
3. Penetrating bladder injury
4. Inadequate drainage with a Foley catheter
5. Concomitant rectal or vaginal injury
6. Hemodynamic stability and undergoing laparotomy for other indications
7. EP repair at time of open fixation for a pelvic fracture

Rarer indications for surgical intervention include the presence of bone fragments protruding into the bladder and bladder entrapment into a pelvic fracture site. Bladder entrapment into a pelvic fracture site can occur during the injury itself, or at the time of internal or external fixation of the pelvis (22,23). Failure to treat these early after injury can result in persistent urinary leaks, lower urinary tract symptoms, and dyspareunia (24). Examples of radiographic and intraoperative findings of bladder entrapment after pelvic fracture are shown in Figures 26.4 and 26.5.

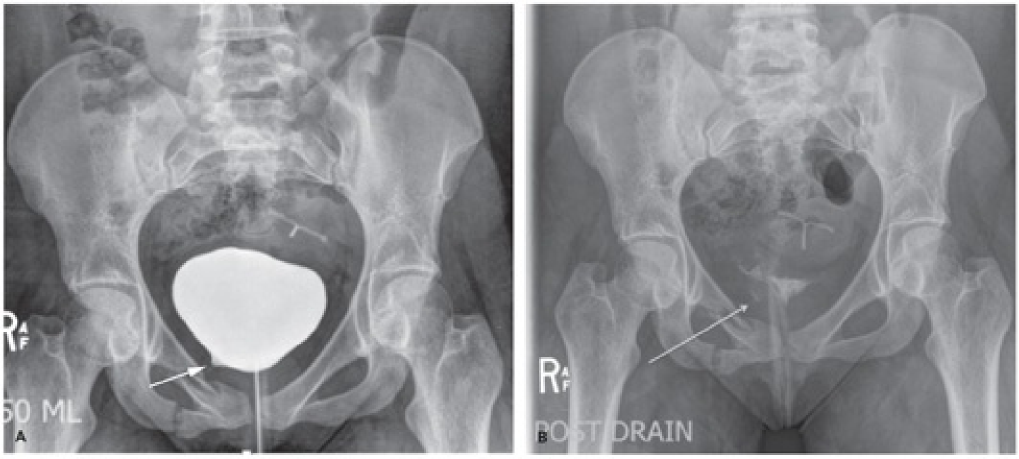

FIGURE 26.4 A: The filling phase of a static cystogram in a patient with bladder entrapment from a pelvic fracture. The *arrow* demonstrates the site of bladder entrapment. B: The drainage phase of a static cystogram in a patient with bladder entrapment from a pelvic fracture. The *arrow* demonstrates the site of persistent extravasation.

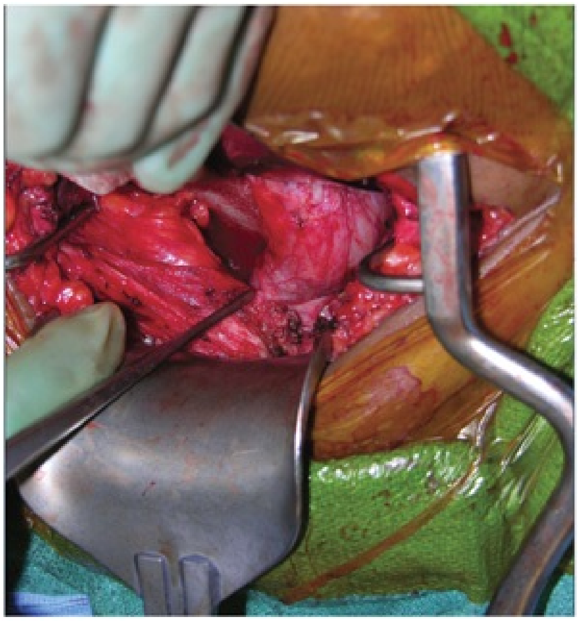

FIGURE 26.5 Intraoperative findings on the patient in Figure 26.4. The forceps are pointing toward the site of bladder entrapment.

Description of Repair

Transabdominal (Fig. 26.6A and B): A vertical, midline incision is made. The skin and rectus fascia are opened. The peritoneum is entered. Urine and abdominal fluid are evacuated. The abdominal is serially examined to rule out other organ injuries. The location of the IP laceration is identified, and the bladder is evacuated of any residual hematoma. Bony spicules, if present, are removed at this time. The bladder is thoroughly investigated transvesically through the laceration. If the laceration is small, the cystotomy is extended to improve visualization. The presence of concomitant EP lacerations and bladder neck injuries are ruled out. If nonviable tissue is present, laceration edges are gently debrided. Exposure of the bladder neck can be facilitated with the use of a long nose nasal speculum. If a bladder neck laceration is present, it is repaired with interrupted 2-0 polyglycolic acid sutures from within the bladder. If a separate EP injury is identified, it is repaired in two layers with a running 3-0 polyglycolic acid suture from within the bladder. During the acute setting of a pelvic fracture, it is important to do repairs within the bladder and to avoid the space of Retzius. Opening up the space of Retzius will disturb the pelvic hematoma and significant bleeding may follow.

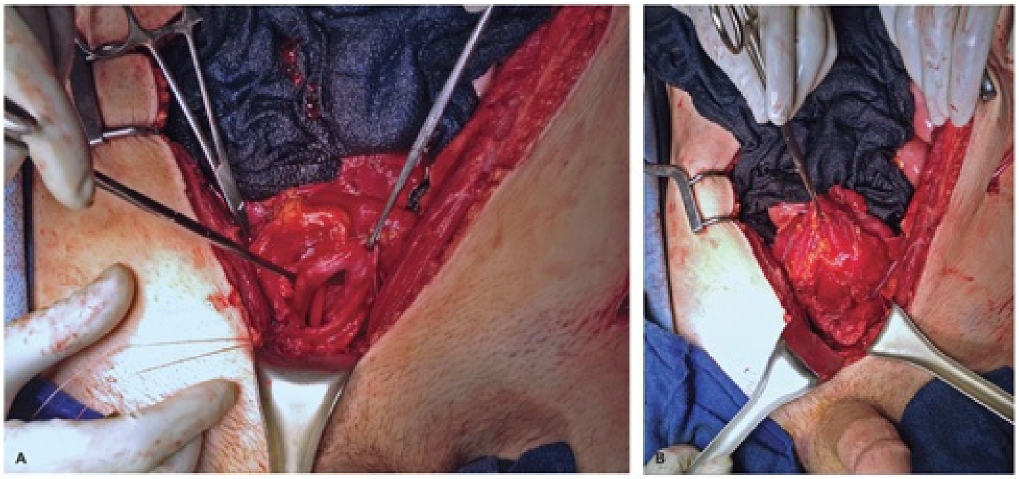

FIGURE 26.6 A: Intraoperative finding of a combined EP and IP bladder laceration. B: Image after cystorrhaphy of the same patient in Figure 26.6A. (Images courtesy of Thomas Smith, MD, Baylor College of Medicine.)

The ureteral orifices are systematically identified. If no efflux of urine is seen or if bloody efflux is present, the ureters are explored to rule out a concomitant ureteral injury. The management of ureteral injuries is described elsewhere within this text.

Once the transvesical investigation is complete, nonviable edges of the IP laceration are debrided, and the bladder is closed in two layers. The mucosal layer is closed with a running 3-0 polyglycolic acid suture, and the muscular layer is closed with a running 3-0 polyglycolic acid suture. Placement of a suprapubic tube is not required. Small case series have shown no benefit to leaving a suprapubic tube in addition to a Foley catheter (25,26). The bladder is filled through the Foley with sterile saline to assess the watertightness of closure, and interrupted sutures are placed to insure watertightness of closure if needed. Drains are generally not necessary but may be used for the tenuous repair. The abdominal contents are irrigated with copious amounts of saline. The abdomen and skin are closed in routine fashion.

Extraperitoneal Repair

Most orthopedic surgeons use a Pfannenstiel incision to accomplish an open reduction and internal fixation of the pelvis. If other abdominal urologic surgery is required, or if an abdominal washout is required for IP repair, the authors advise the urologist to discuss the plans with the orthopedic team prior to surgery. A mutually beneficial midline incision can be used. In general, primary bladder repair for EP injuries can be amply managed through a Pfannenstiel incision.

After completion of the open reduction and internal fixation per orthopedics, the bladder is exposed within the space of Retzius. After repair of pelvic fractures, the bleeding from the fracture site is minimal to nonexistent. The laceration is identified, and the bladder is explored through the laceration as described earlier. The lacerated edges are minimally debrided, and the bladder is closed in two layers. The mucosal layer is closed with a running 3-0 polyglycolic acid suture, and the muscular layer is closed with a running 3-0 polyglycolic acid suture. A suprapubic tube is not necessary. The fascia and skin are then closed in standard fashion.

Postoperative Care

A static cystogram is obtained 7 to 10 days after cystorrhaphy. If no evidence of extravasation is seen, the Foley catheter may be removed. It is the authors' preference to perform a static cystogram over CT cystography to prevent unneeded radiation exposure. Although most practitioners perform postoperative imaging, recent evidence suggests that routine imaging may not be necessary. In a recent case series of 127 patients, only 1 patient had persistent extravasation on postoperative imaging (27). This was a patient with a complex trigone injury requiring ureteral reimplantation. From this work, the authors concluded that postoperative imaging is not required for simple or low-grade injuries.

Complications

In general, complications are rare after primary suture repair of bladder injuries. In one large series, no urologic complications were cited after primary closure of the bladder (18). Complications that are cited to occur include hematuria with clot retention, sepsis, urinary urgency, and urinary frequency (19).

Complications are more common in patients with an EP rupture managed with a Foley catheter alone. In a review of a 10-year experience in managing bladder lacerations, Kotkin and Koch (18) cited a 26% complication rate in EP lacerations managed with Foley catheter alone. Cited complications included persistent extravasation on imaging, bladder calculi, pseudodiverticulum formation, pelvic hematoma infection, sepsis, and death (18,19).

VESICAL HEMORRHAGE

Significant bleeding from the bladder can occur in the absence of trauma. The most common cause of refractory hematuria is hemorrhagic cystitis (HC). HC is defined by diffuse inflammation to the bladder causing bleeding from the mucosa. This can be a significant challenge for the urologist to manage. The causes of HC include infection (viral and bacterial), chemical exposure (including chemotherapy), and pelvic radiation. The possible etiologic factors for HC are listed in Table 26.2.

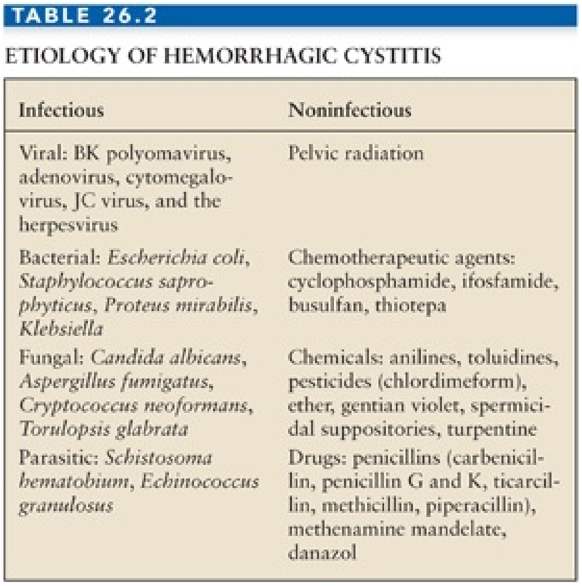

TABLE 26.2

ETIOLOGY OF HEMORRHAGIC CYSTITIS

Infectious	Noninfectious
Viral: BK polyomavirus, adenovirus, cytomegalovirus, JC virus, and the herpesvirus	Pelvic radiation
Bacterial: *Escherichia coli*, *Staphylococcus saprophyticus*, *Proteus mirabilis*, *Klebsiella*	Chemotherapeutic agents: cyclophosphamide, ifosfamide, busulfan, thiotepa
Fungal: *Candida albicans*, *Aspergillus fumigatus*, *Cryptococcus neoformans*, *Torulopsis glabrata*	Chemicals: anilines, toluidines, pesticides (chlordimeform), ether, gentian violet, spermicidal suppositories, turpentine
Parasitic: *Schistosoma hematobium*, *Echinococcus granulosus*	Drugs: penicillins (carbenicillin, penicillin G and K, ticarcillin, methicillin, piperacillin), methenamine mandelate, danazol

Bacterial infections are the most common cause of HC. Due to the effectiveness of antibiotic therapy, refractory hemorrhage is rarely seen and the disease has a limited course after treatment with appropriate antibiotics. The most common organisms associated with bacterial HC include *Escherichia coli*, *Staphylococcus saprophyticus*, *Proteus mirabilis*, and *Klebsiella* (28). Fungal organisms that have been cited to cause HC include *Candida albicans*, *Cryptococcus neoformans*, *Aspergillus fumigatus*, and *Torulopsis glabrata* (28). Viral infections are a less common cause of HC and are more common in children and immunosuppressed adults. Specific viral etiologies include the

BK polyomavirus, adenovirus, cytomegalovirus, JC virus, and the herpesvirus (29).

Unlike the limited course of bacterial induced HC, other etiologies can have a chronic course. The most common cause of chronic HC is due to use of chemotherapeutic oxazaphosphorines (30). Included within this class of medications are cyclophosphamide and ifosfamide. Acrolein, a liver metabolite of oxazaphosphorines, is the principal inciting agent and acts by direct contact with the bladder mucosa. It is thought to have a pathologic affect by increasing intracellular reactive oxygen, nitrogen species, and proinflammatory cytokines (31). Histologic changes that occur in the bladder are similar to those seen with radiation and include edema, ulceration, neovascularization, hemorrhage, and necrosis. Animal studies have shown that direct cytotoxic effects occur as early as 2 hours after exposure (32). The incidence of cyclophosphamide-associated HC ranges from 2% to 40%, with mortality rates as high as 4% (30). Busulfan and thiotepa are also associated with HC (30). HC is dose-dependent and related to the route of administration of the chemotherapeutic agent (higher with IV administration). Furthermore, it is more severe in dehydrated patients. Efforts to prevent the development of agents causing acrolein-induced HC have focused on expedient bladder drainage (with or without a Foley catheter), hydration, and the use of medications to inhibit direct acrolein cytotoxicity (mesna and Mucomyst) (33). Current research suggests that none of these treatment options are clearly superior to one another (34,35).

Radiation therapy to the prostate, bladder, or other pelvic organs can result in HC. This can occur as late as 10 years after radiotherapy. The median time to development of HC after radiation therapy is 4 years (35,36). Initially, there is mucosal edema with submucosal hemorrhage. In the long term, radiation causes progressive endarteritis whereby tissue becomes hypoxic. The urothelium is then unable to replace collagen and normal cellular loss resulting in eventual tissue breakdown (37).

A wide range of drugs and industrial toxins can also give rise to HC. The most common are aniline dyes. Conservative treatment with adequate hydration, bladder irrigation, and removal of the causative agent will suffice as treatment in most cases.

Management of Hemorrhagic Cystitis

A practical list and algorithm for the management of HC is outlined in Table 26.3 and Figure 26.7. Initial attempts at treating significant HC should be focused on patient presentation and clinical symptoms. If the patient is significantly anemic, tachycardiac, and hypotensive, IV hydration should be started immediately, and blood transfusions should be given as indicated. If the patient is in clot retention, a large (24Fr) three-way catheter should be placed. The patient's bladder should then be manually irrigated until free of clots and continuous bladder irrigation then started. If the patient denies passing clots, is able to void, and is not severely anemic, conservative management with hydration alone is not unreasonable. If the cause of hematuria is thought to be of infectious etiology, treat with appropriate antibiotic therapy as indicated.

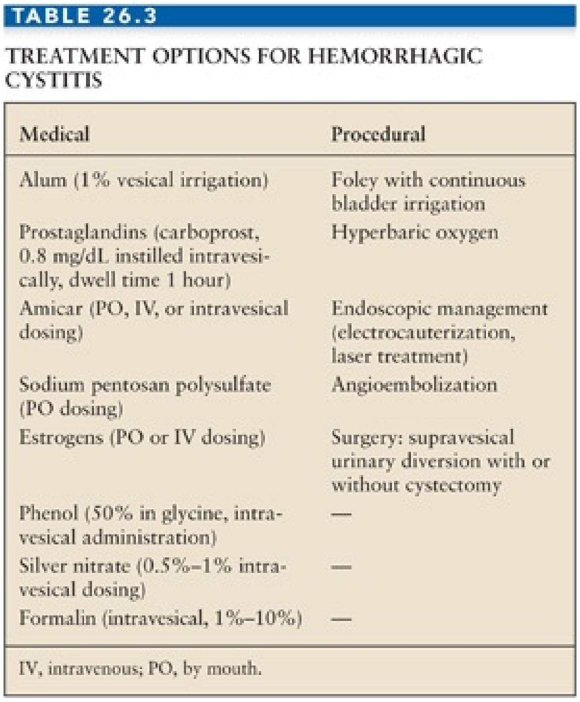

TABLE 26.3

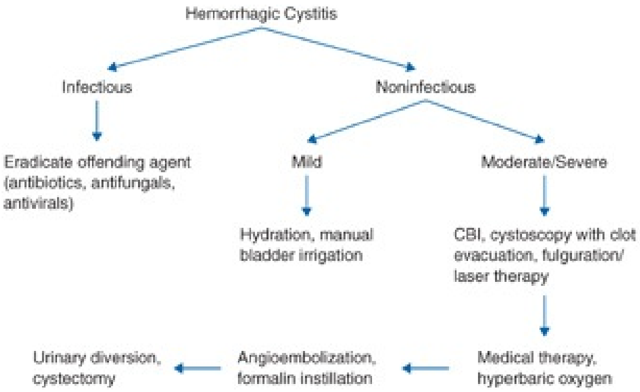
TREATMENT OPTIONS FOR HEMORRHAGIC CYSTITIS

Medical	Procedural
Alum (1% vesical irrigation)	Foley with continuous bladder irrigation
Prostaglandins (carboprost, 0.8 mg/dL instilled intravesically, dwell time 1 hour)	Hyperbaric oxygen
Amicar (PO, IV, or intravesical dosing)	Endoscopic management (electrocauterization, laser treatment)
Sodium pentosan polysulfate (PO dosing)	Angioembolization
Estrogens (PO or IV dosing)	Surgery: supravesical urinary diversion with or without cystectomy
Phenol (50% in glycine, intravesical administration)	—
Silver nitrate (0.5%–1% intravesical dosing)	—
Formalin (intravesical, 1%–10%)	—

IV, intravenous; PO, by mouth.



Hemorrhagic Cystitis
Infectious
Noninfectious
Eradicate offending agent (antibiotics, antifungals, antivirals)
Mild
Moderate/Severe
Hydration, manual bladder irrigation
CBI, cystoscopy with clot evacuation, fulguration/ laser therapy
Medical therapy, hyperbaric oxygen
Angioembolization, formalin instillation
Urinary diversion, cystectomy

FIGURE 26.7 Algorithm for the treatment of HC.

Moderate hematuria can be treated with continuous saline irrigation through a three-way Foley catheter. If the hematuria fails to resolve, endoscopic management of HC can be attempted. Various methods have been used to control bleeding. These methods include electrocauterization, Nd:YAG laser coagulation, green light KTP laser, and 980-nm diode lasers (38–40).

If hematuria persists, intravesical medications can be given with or without the use of continuous bladder irrigation (CBI). One percent alum (potassium or ammonium aluminum sulfate) is often used in this situation. The alum acts as an astringent and precipitates the surface proteins. The bladder should be completely irrigated free of clots prior to starting alum because gelatinous clots can be difficult to irrigate after therapy has begun. Aluminum levels must be monitored, particularly in patients with renal insufficiency. Severe acidosis and encephalopathy can occur in such patients as a result of high aluminum levels.

Another intravesical agent that has been used for HC is the periodic installation of prostaglandins (PGE_2, $PGF_{2\alpha}$) and $PGF_{2\alpha}$ analogs (carboprost) (41–43). Although the exact mechanism by which these work is unknown, they are thought to cause smooth muscle contraction of the blood vessels in the mucosa or submucosa as well as to cause platelet aggregation (44). They can be used prophylactically or therapeutically. PGE_2 has been used in a dose of 0.75 mg in 200 mL of normal saline instilled for 4 hours. The effective dose of $PGF_{2\alpha}$ has been 1.4 mg in 200 mL of normal saline. Carboprost has been used in a dose of 0.8 mg per dL diluted in normal saline and instilled for 1 hour at 6-hour intervals; good results occurred in 62% of patients in one study (43).

Intravesical instillation of silver nitrate (0.5% to 1% solution) for short periods of time (10 to 20 minutes) followed by saline irrigation of the bladder to remove residual silver nitrate is also an effective technique. Reflux should be ruled out by cystography prior to dosing with silver nitrate because upper tract obstruction may occur (45). Instillation of silver nitrate is painful and should be conducted under anesthesia.

E-aminocaproic acid (Amicar) can be given orally, parenterally, or intravesically by CBI. Amicar prevents the activation of plasminogen to plasmin, inhibiting fibrinolysis. It is now U.S. Food and Drug Administration–approved for the use of refractory hematuria. Caution should be used when dosing this medication because thromboembolic complications may occur. It is contraindicated in patients with thromboembolic disorders such as coronary artery disease, history of ischemic strokes, and deep vein thromboses. When used, it does appear to be efficacious. In a case series of 37 patients, Singh and Laungani (46) reported a success rate of 92%.

Sodium pentosan polysulfate (SPPS), a semisynthetic polysaccharide, has been studied as an agent in the treatment of HC secondary to radiation. SPPS replaces the surface glycosaminoglycans that have been injured. In a review of 14 patients, Hampson and Woodhouse (47) reported a complete or partial response in 79% of patients.

Estrogens are believe to control hematuria by strengthening the capillary walls within the mucosa of the bladder (48). They have been used to treat HC secondary to radiation and cyclophosphamide exposure. Conjugated estrogens can be administered through oral or IV routes. Success rates vary between 60% and 80% (49).

Phenol has been used to treat HC (50). Phenol is instilled in a dose of 30 mL of a 100% solution mixed with an equal volume of glycine for a dwell time of 1 minute. The solution is washed out with 95% ethanol (60 mL) and saline to prevent methemoglobinemia. Limited data exists in the literature to compare it efficacy to other known treatments.

Hyperbaric oxygen (HBO) therapy has been demonstrated to show efficacy in treating radiation-induced HC (5). HBO therapy is believed to promote angiogenesis at the site of the irradiated tissues through an increased oxygen gradient (37). The usual course of HBO treatment includes 100% oxygen levels at 2 to 2.5 atm of pressure, 5 days a week for a total of 30 treatment sessions. Complete response rates range between 59% and 96%, with relapse rates of 16% to 24% (36,51–54).

Persistent severe hemorrhage that has not subsided despite the aforementioned measures can be treated with intravesical instillation of 1% formalin. Formalin fixes bladder mucosa through protein cross-linking. Due to defunctionalization of the bladder, this is reserved as a last resort. As formalin instillation is painful, general anesthesia is required. It is necessary to first rule out vesicoureteral reflux by performing a cystogram before using formalin because it can cause fibrosis and scarring of the ureters and renal pelvis. If need be, the ureters can be occluded with Fogarty balloon catheters to prevent reflux while formalin is instilled. Fifty milliliters of 1% formalin (0.37% formaldehyde) diluted with saline should be instilled for 4 to 10 minutes. This should then be washed out with saline, and the saline irrigation continued for 24 hours. The external genitalia are covered with towels or Vaseline to prevent irritation. Formalin instillation may be repeated, and dose escalations up to a concentration of 10% have been documented. Success rates in radiation-induced HC range between 75% and 89%, with relapse rates in 23% (55,56).

Open ligation of the hypogastric arteries is rarely performed in the modern era. Embolization of the hypogastric arteries with autologous clot, gel foam, coils, or ethanol via interventional radiologic techniques is more common and has evolved over time. Originally, these were “nonselective” because both internal iliac arteries were embolized. Nonselective embolization not uncommonly resulted in temporary gluteal claudication. However, selective embolization of the vesical arteries is now possible, with significantly less complications. Based on the present authors’ review, 13 cases of superselective angioembolization for HC have been published in the literature. Durable success was achieved in 11 patients in the follow-up period. Bilateral embolization was required for complete resolution in all cases (57–59).

Supravesical diversion is the last resort in the management of HC. The goal of supravesical diversion is to divert urokinase away from the lower urinary tract. This can be accomplished by the following techniques: nephrostomy tube placement with ureteral occlusion, cystotomy with externalized ureteral catheters, cutaneous ureterostomies, and formal diversion with an ileal conduit. In general, the complication rates are high when diversions are done without a cystectomy. In a series of 40 patients who had diversions without a cystectomy, 80% had bladder-related complications (60). A cystectomy should be strongly considered if a urinary diversion is performed.

CHAPTER 27 INTERSTITIAL CYSTITIS/BLADDER PAIN SYNDROME

MICHAEL J. EHLERT AND KENNETH M. PETERS

Interstitial cystitis/bladder pain syndrome (IC/BPS) is a chronic, unrelenting condition with considerable morbidity. The symptoms were first described in the early 20th century associated with a distinct ulcer within the bladder (1). IC/BPS continues to be one of the most commonly missed diagnoses in urology (2). Patients are often seen by multiple providers and offered outdated and ineffective treatments for years. Recently, the evolution of thought around this condition and how to best treat it has changed from primarily bladder-centered to one of systemic neurosensitization often resulting in pelvic floor spasm leading to a voiding and pain syndrome. It is imperative that the patient complaining of IC/BPS symptoms is carefully phenotyped to determine the best mode of treatment. This chapter will describe various procedures to improve the symptoms of voiding dysfunction and pelvic pain.

Although the etiology of IC/BPS has not been clearly identified, much more is now known about its characteristics and natural history. The presentation may be variable; however, the more common symptoms are urinary frequency, urgency, and pelvic pain. Until recently, IC/BPS has been considered a disease predominantly affecting women; however, more men are now being diagnosed with this disease (3). Men presenting with symptoms of genital or perineal pain, frequency, or dysuria are often labeled as having chronic, abacterial prostatitis; in fact, many of them suffer from IC/BPS. The astute clinician should aim to accurately diagnose this condition and offer treatments which have shown benefit to alleviate the most bothersome symptoms for each patient.

DIAGNOSIS

Because patient presentation and symptoms vary widely, all other etiologies must be excluded. The most worrisome would be that of a malignancy or other systemic condition for which treatment would be needed. IC/BPS thus remains a diagnosis of exclusion. Investigations should routinely be directed to exclude bacterial cystitis, neurogenic and nonneurogenic overactive bladder (OAB), endometriosis, bladder cancer, urethral diverticulum, and pelvic floor dysfunction. Defining IC/BPS has been extremely controversial, and to date, there remains considerable disagreement among experts. In 1987 and 1988, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) developed a research definition for IC/BPS in order to provide homogenous groups of patients that may be compared to one another in clinical studies. However, experts in female urology and urogynecology have found this definition to be far too restrictive, and as many as 60% of patients with IC/BPS were being excluded (2). According to the International Continence Society, IC/BPS should be suspected in anyone with symptoms of suprapubic pain related to bladder filling, accompanied by urinary frequency and urgency, in the absence of urinary infection or other pathology (4). A similar definition was adopted by the American Urological Association (AUA) in their recent guidelines, although a more general “unpleasant sensation (pain, pressure, discomfort)” relating to the bladder was included (5). The European Society for the Study of IC/BPS (ESSIC) has developed specific diagnostic criteria that are based on a combination of urinary symptoms and bladder findings during cystoscopic evaluation. Although the vague inclusion criteria and overlapping taxonomy may be confusing, treatment should generally be directed toward the patient’s symptoms and any other coexisting conditions. Epidemiologic studies have shown increased rates of irritable bowel syndrome, fibromyalgia, migraine headaches, and anxiety (6).

Symptoms of IC/BPS are extremely variable and may present as mild irritative symptoms to severe symptoms refractory to all standard therapies. Acknowledging and treating the disease early often leads to rapid improvement in symptoms; thus, recognizing IC/BPS early so that therapy can be initiated is extremely important.

The diagnosis of IC/BPS begins with a complete and thorough history. Onset of symptoms may be days, weeks, or even months. Often patients have been clinically diagnosed with urinary tract infections despite negative cultures. Other misdiagnoses include endometriosis, fibroids, or other pelvic disorders, and some have even undergone surgery for them (7). A full dietary and fluid history is useful, as certain foods and drinks may exacerbate IC/BPS symptoms (8). A voiding diary provides objective evidence of daytime and nighttime frequency, and pain symptoms can be recorded with these as well. Baseline and sequential voiding diaries and symptom questionnaires allow one to determine the impact of various treatments for IC/BPS. The O’Leary-Sant Interstitial Cystitis Symptoms Index/Interstitial Cystitis Problem Index (ICSI/ICPI) and Pain, Urgency, Frequency scales (PUF) are commonly used (Table 27.1). For the pain component, a 10-point visual analog scale (VAS) and brief descriptor of pain location and quality is often all that is needed. It must be emphasized that these questionnaires assess baseline symptoms and treatment response but do not diagnose IC/BPS per se.

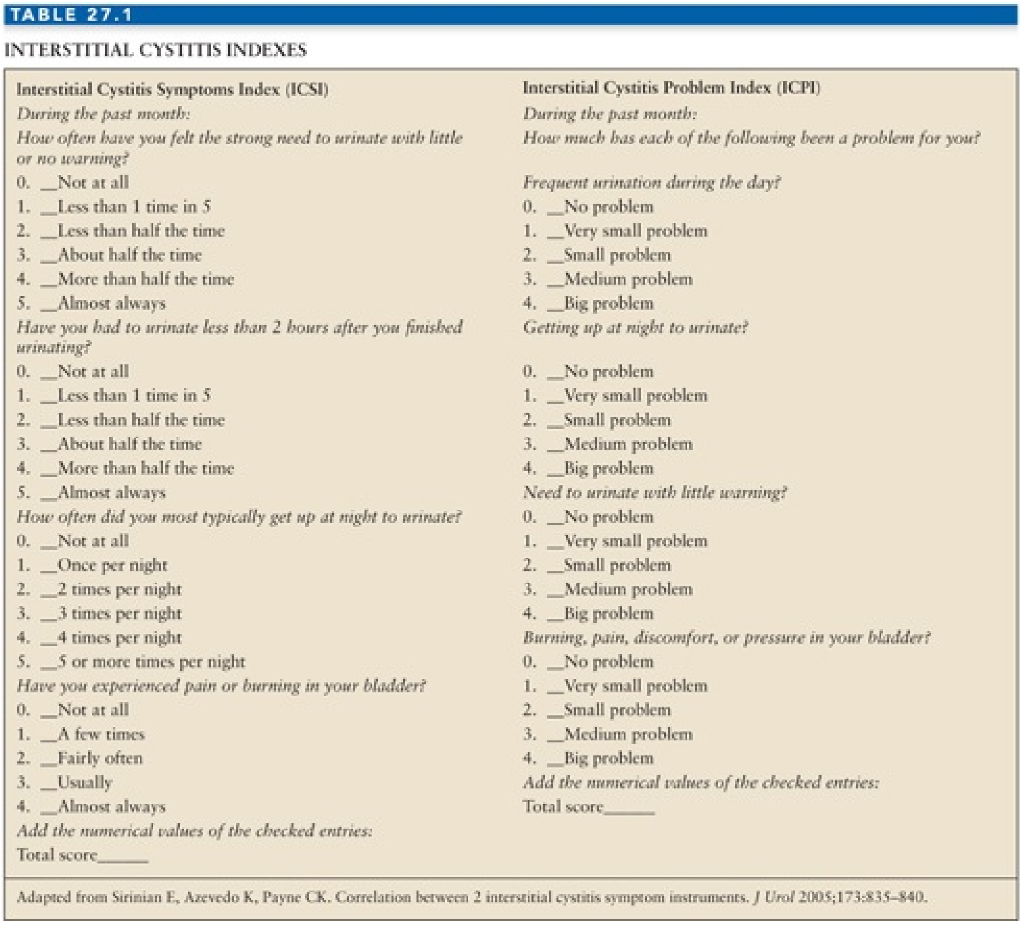

TABLE 27.1

INTERSTITIAL CYSTITIS INDEXES

Interstitial Cystitis Symptoms Index (ICSI)

During the past month:

How often have you felt the strong need to urinate with little or no warning?

0. _Not at all
1. _Less than 1 time in 5
2. _Less than half the time
3. _About half the time
4. _More than half the time
5. _Almost always

Have you had to urinate less than 2 hours after you finished urinating?

0. _Not at all
1. _Less than 1 time in 5
2. _Less than half the time
3. _About half the time
4. _More than half the time
5. _Almost always

How often did you most typically get up at night to urinate?

0. _Not at all
1. _Once per night
2. _2 times per night
3. _3 times per night
4. _4 times per night
5. _5 or more times per night

Have you experienced pain or burning in your bladder?

0. _Not at all
1. _A few times
2. _Fairly often
3. _Usually
4. _Almost always

Add the numerical values of the checked entries:

Total score_____

Interstitial Cystitis Problem Index (ICPI)

During the past month:

How much has each of the following been a problem for you?

Frequent urination during the day?

0. _No problem
1. _Very small problem
2. _Small problem
3. _Medium problem
4. _Big problem

Getting up at night to urinate?

0. _No problem
1. _Very small problem
2. _Small problem
3. _Medium problem
4. _Big problem

Need to urinate with little warning?

0. _No problem
1. _Very small problem
2. _Small problem
3. _Medium problem
4. _Big problem

Burning, pain, discomfort, or pressure in your bladder?

0. _No problem
1. _Very small problem
2. _Small problem
3. _Medium problem
4. _Big problem

A physical examination that includes a thorough pelvic and neurologic examination should be performed. The female pelvic examination should include evaluation for tenderness of the anterior vaginal wall and levator muscles, the ability to contract and relax the pelvic floor muscles, and the degree of pelvic relaxation. A high-tone pelvic floor can contribute to a large portion of patient symptomatology (9). Urethral fullness, tenderness, or expression of pus may suggest a urethral diverticulum requiring further workup. Vaginal pH and wet-mount microscopic exam is beneficial in ruling out vaginitis or infectious etiology. Careful attention should be paid to vulvar or vestibular sensitivity, herpetic vesicles, atrophic vaginal mucosa, and any other cutaneous findings. A rectal examination can rule out any rectal abnormalities or masses, and in men, not only should the prostate be palpated but the tenderness or spasm of the pelvic floor muscles should also be assessed because this is a common cause of pelvic pain and voiding dysfunction. A urinalysis and urine culture should be performed to exclude active infection. Sterile pyuria should prompt staining for acid-fast bacilli to rule out genitourinary tuberculosis. If microscopic or gross hematuria is present, an initial workup including computerized tomography (CT) urography and cystoscopy is required in order to evaluate for bladder cancer or stone disease.

In patients with primarily urinary urgency, frequency, or incontinence, a trial of anticholinergics may cause symptoms to subside supporting the diagnosis of OAB. If symptoms persist, if pelvic pain worsens with bladder filling, or if severe dysuria is present, a cystoscopic evaluation is warranted. IC was first described as a distinct ulcer seen on cystoscopic examination (1). This lesion is typically red, raised, and friable and can be seen during cystoscopy without hydrodistention. The lesion is difficult to distinguish from carcinoma in situ, and a biopsy with cauterization of the lesion is required to confirm its benign nature. Although less than 15% of patients diagnosed with IC/BPS have an ulcer in their bladder, symptom improvement with fulguration can be remarkable (10). Ulcerative patients are typically older and have more severe bladder-associated pain and a smaller anesthetic bladder capacity (11).

In patients in whom a diagnosis of IC/BPS is highly suspected clinically, cystoscopy with hydrodistention under anesthesia may reveal petechial hemorrhages and glomerulations, which are found in over 90% of women with the syndrome. However, the presence of petechial hemorrhages alone is not diagnostic, as they can also be seen in normal men and women (12). A computerized cystometrogram may also be performed to look for uninhibited contractions and to determine the functional bladder capacity. Some investigators have suggested the use of the potassium sensitivity test (PST) to diagnose IC/BPS (13). The PST is based on the hypothesis that there is increased epithelial permeability in the bladder of IC patients and potassium is very irritating to the exposed tissue. However, a significant false-positive rate exists, and many patients will eventually be diagnosed with a normal bladder (14). Additionally, 17% of women with IC/BPS may have a negative test (15). For these reasons, PST is not currently recommended during evaluation and diagnosis.

INDICATIONS FOR SURGERY

Any patient with significant tenderness of the pelvic floor muscles on exam should undergo transvaginal/transrectal myofascial release. This may be augmented with trigger point injections into these muscles. Patients with unexplained urinary urgency, frequency, and pelvic pain who are refractory to conservative therapies are candidates for an operative hydrodistention, which may be not only diagnostic but also therapeutic. Patients with ulcerative disease may benefit from ablation of the ulcers with cautery or laser (10,16). This procedure also evaluates the maximum anesthetic bladder capacity, which may predict symptom severity and treatment failures (17).

Radical surgery for IC/BPS is rarely indicated and should be used as a last resort. However, in carefully selected patients, this can be a viable and well-tolerated treatment. Magnetic resonance imaging (MRI) of the pelvis may demonstrate a thickened, end-stage bladder that may be amenable to radical surgery (Fig. 27.1). Maximum anesthetic bladder capacity is often <200 mL. Patients who undergo bladder augmentation or continent diversion need to be willing and able to perform clean intermittent catheterization. Additionally, patients must accept that frequency symptoms may improve but that pain may persist. Diverting the urine without removing the diseased bladder is not always sufficient to relieve the symptoms of IC/BPS. Therefore, any diversion procedure for pain should be accompanied by cystectomy (18). Finally, neuromodulation has been effective in treating refractory urinary urgency and frequency (19). It has also recently shown to be effective in IC/BPS patients, although not officially indicated for pelvic pain syndromes. Because IC/BPS is a syndrome of urgency, frequency, and pain, patients who are refractory to standard therapies would be candidates for nerve stimulation.

NONSURGICAL THERAPY

Establishing a diagnosis of IC/BPS in itself is usually therapeutic and alleviates patient frustrations. A multimodality approach along with patient education is the most effective means of treating IC/BPS. Behavioral therapies must be stressed, such as fluid management, pelvic floor physical therapy, dietary restrictions, and relaxation therapy (20). Many patients suffer from pelvic floor spasm, which causes pelvic pain, dyspareunia, and urinary hesitancy. Treatment by a therapist knowledgeable in myofascial release techniques may be of benefit (9,21). Once behavioral therapy and education are optimized, oral medication is a reasonable first-line treatment for IC/BPS.

At the present time, the only oral therapy approved by the U.S. Food and Drug Administration (FDA) for IC/BPS is pentosan polysulfate sodium (Elmiron, Janssen Pharmaceuticals, Inc), a glycosaminoglycan that binds tightly to the bladder mucosa. Pentosan polysulfate may be considered after behavioral and symptom management therapy for IC/BPS. Because it may require several months before any clinical improvement is seen, it should not be used as a single agent for the treatment of IC/BPS. Hydroxyzine has antihistaminic and antianxiety properties and affects mast-cell degranulation, which may play a role in symptoms of IC/BPS. Treatment is started at 10 mg orally daily and can be titrated up based on sedation side effects. However, neither pentosan polysulfate nor hydroxyzine showed high response rates in recent clinical trials (22). Muscle relaxants such as diazepam or low-dose baclofen may be useful in women with accompanying pelvic floor spasm, although study outcomes have been mixed (23,24).

Tricyclic antidepressants such as amitriptyline or imipramine may improve symptoms due to their anticholinergic and antipain effects (16). Recent meta-analysis showed that amitriptyline had a large treatment effect on pain, urgency, frequency, and ICSI scores (25). Finally, chronic pain is recognized as a legitimate complaint and should be treated aggressively. Various narcotics and anti-inflammatories can be tried, along with nerve blocks or implantable pain pumps, to treat the severe pain that can be associated with IC/BPS. The enlistment of a pain specialist may be helpful for specific blocks or for management of long-term narcotic contracts. With increasing scrutiny of opioid abuse and diversion, this treatment is becoming more complex. Urinary analgesics (phenazopyridine, methenamine, and other combination formulations) may also be effective as part of combination therapy. Cyclosporine has been used in some clinical trials, but when applied to the general population of IC/BPS patients, the results are inconclusive. For patients with the ulcerative form and symptom improvement after ulcer fulguration, treatment with a potent immunologic modifier such as cyclosporine has shown to be effective (26).

Intravesical therapies have been a mainstay in treatment for many years due to the prior belief that this was a disease limited to the bladder. Dimethyl sulfoxide (DMSO) is the only FDA-approved intravesical therapy for this disease. DMSO is a product derived from paper pulp and is mainly used as an industrial solvent. It is given in the office setting as a 50% solution in 50 mL of sterile saline. Patients rarely have side effects, although they may complain of transient urethral pain or irritation after the first instillation or a garliclike odor from their mouth. If effective, symptoms may resolve for months to even years (27).

Bacille Calmette-Guérin (BCG) is prepared from an attenuated strain of bovine tuberculosis bacillus, *Mycobacterium bovis*, and is given intravesically as a 50-mg dose in 50-mL saline solution. While traditionally used for treating carcinoma in situ of the bladder or low-stage urothelial carcinoma, it appeared to show promise as an intravesical agent in treating IC/BPS. In a randomized placebo-controlled clinical trial, 21% of patients responded to BCG, compared to 12% of placebo. However, the difference was not statistically significant ($P = .062$), and therefore, this should not be offered outside of the research setting.

Other second-line agents that have been used include capsaicin, heparin, sodium oxychlorosene, and silver nitrate. The most commonly described “cocktails” include heparin, lidocaine, and sodium bicarbonate. Side effects of these bladder instillations seem minor, and some patients gain significant improvements in symptoms. They are generally listed as second-line treatments, although their duration of effects is limited and require repeat and scheduled instillations (28,29).

Because many patients present with high-tone pelvic floor and myofascial tenderness, transvaginal trigger point injections can also be offered. On exam, the levator muscles are palpated, and areas of discreet tenderness and bands can be felt. Injections usually consist of a local anesthetic, although techniques of dry needling and Botox have also been described. The underlying mechanism is thought to include disruption of the positive-feedback cycle of pain/spasm as well as local release of inflammatory and vasodilatory mediators. Our technique involves a mixture of ropivacaine 0.5% and triamcinolone (40 mg) injected transvaginally using a curved stylet (Fig. 27.2). Others may prefer the straight Iowa Trumpet; however, the long spinal needles employed easily curve in the stylet and enter the muscles perpendicularly. A 7-inch 22-gauge spinal needle is used to infiltrate the muscles, aspirating first to avoid intravascular injections. Each trigger point is injected with 2 to 5 mL, although multiple injections along the levator group on the side of spasms are also effective. A tampon is placed for 5 minutes after the injections to tamponade any mucosal bleeding. The response to injections should be immediate and can be quantified with a VAS (0 to 10) pre- and postprocedure. Some patients experience a brief flair of symptoms after the anesthetic wears off and before the anti-inflammatory response from local steroid injections occurs. Complications from trigger point injections include vaginal bleeding, leg weakness, perineal numbness, vaginal hematoma, stress urinary incontinence, and systemic reactions to local anesthetic. These are usually minor events and of short duration. The clinician must also be aware of the maximum dose for whichever anesthetic chosen to avoid systemic effects. Injections can be repeated every 4 to 6 weeks in an attempt to break the pain/spasm cycle.

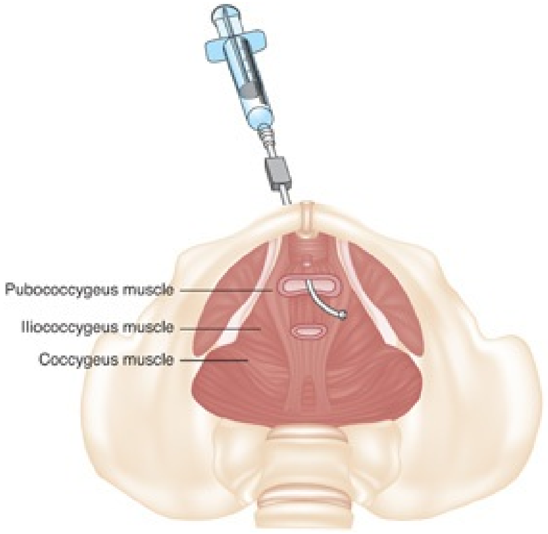

FIGURE 27.2 Technique of transvaginal trigger point injection. A curved cannula is used to advance a 7-inch spinal needle into the levator muscles.

SURGICAL TECHNIQUE

Bladder Hydrodistention

A complete cystoscopy is performed to assess the urethra and bladder for any masses, stones, or diverticula (Fig. 27.3). After careful inspection, the bladder is filled by gravity drainage under anesthesia at 100 cm H_2O pressure to its capacity. Upward pressure with a finger along each side of the urethra is often needed to maximally distend the bladder to prevent leakage around the cystoscope. The bladder is distended until no further water will run into the bladder, and this is allowed to dwell for 2 minutes. The bladder is drained and the volume measured. The procedure is then repeated a second time.

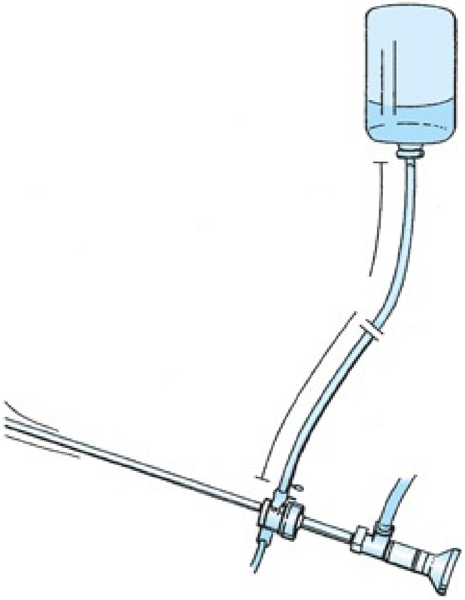

FIGURE 27.3 Hydrodistention is carried out with the irrigation bag hung 100 cm above the level of the bladder. Bladder capacity is reached when irrigant flow stops. During filling, the bladder mucosa is typically normal-appearing. After 2 minutes of distention, the bladder is drained and the capacity is measured. At the termination of bladder emptying, the irrigant fluid is often blood-tinged or grossly hemorrhagic in patients with interstitial cystitis (IC). Repeat cystoscopy will demonstrate diffuse glomerulations in all sectors of the bladder consistent with IC. Repeat hydrodistention is performed to maximally distend the bladder.

A normal bladder will accommodate up to (or over) 1 L under a general anesthetic. On the other hand, the bladder of a patient with the ulcerative form of IC/BPS will be less compliant, often stretching to <350 mL. Typically with IC/BPS, there is terminal hematuria noted when the bladder is drained. Upon reinspecting the bladder, the vast majority of patients will have glomerulations seen in all sectors of the bladder, suggestive of IC. Patients having the ulcerative form will have distinct inflammatory lesions on cystoscopy called Hunner lesions, and with hydrodistention, deep cracks in their bladder at the site of ulcers may occur (1) (Fig. 27.4).

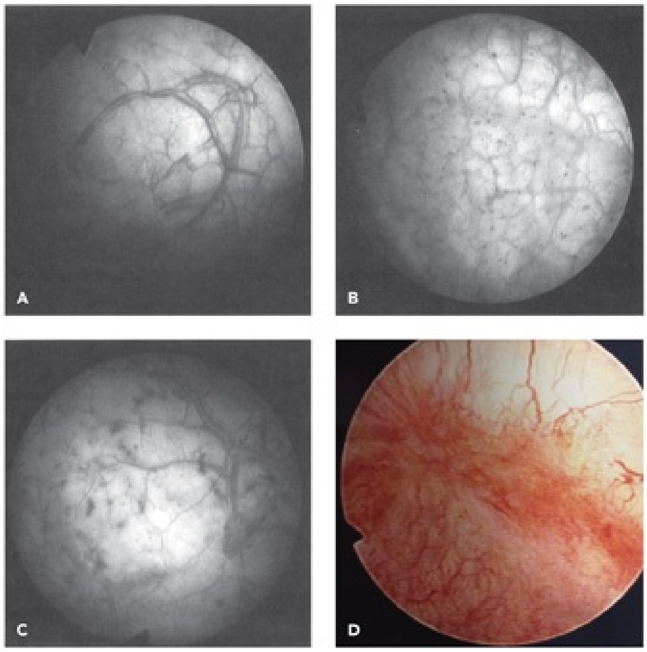

FIGURE 27.4 **A:** Normal appearance of the bladder urothelium before hydrodistention in a patient with symptoms consistent with interstitial cystitis. **B:** Same patient following hydrodistention. The urothelium is abnormal, revealing minimal to moderate glomerulation. **C:** Cystoscopic appearance of a patient with moderate glomerulations and submucosal hemorrhage. **D:** Hunner lesions with marked hemorrhage surrounding the ulcer. This patient was successfully treated with neodymium:YAG laser ablation therapy.

Endoscopic Resection or Fulguration of Ulcers

Approximately 15% of IC/BPS patients comprise the ulcerative subset, and they generally have worse pain and frequency symptoms. A resectoscope with loop electrocautery can be used to resect these lesions and cauterize the base (30). Alternatively, the involved areas can be cauterized with a Bugbee electrode, ball electrode, or neodymium:YAG laser. The laser is set at 15 W with a firing duration of 1 to 3 seconds. The laser fiber is maintained in constant motion over the target, and the procedure is completed when the ulcer is completely blanched (16). At the first treatment session, it is imperative to biopsy the lesions to avoid confusion with more devastating carcinoma in situ. Further biopsy is unnecessary because there is no established pathway from ulcerative IC to bladder carcinoma.

Augmentation Cystoplasty

Simple augmentation of the bladder should only be performed if one has an operative bladder capacity with hydrodistention of <300 mL and symptoms of severe urgency/frequency. The bladder is isolated transabdominally, and a posterior-based U-shaped incision is created on the anterior bladder (Fig. 27.5). A 30-cm segment of distal ileum is isolated in the standard fashion and opened along its antimesenteric border. The ileal segment is folded to create a nonperistaltic ileal patch. This is secured to the anterior bladder with running absorbable suture, effectively increasing the functional capacity of the bladder. Care must be taken to open the bladder widely to avoid creating a poorly draining diverticulum. Patients with known inflammatory bowel disease or prior ileocecectomy are not candidates for this approach. Recent advances in pediatric reconstruction and robotic-assisted technology have shown that ileocystoplasty can also be approached using minimally invasive techniques (31,32). More in-depth discussion is available elsewhere in this text. Patients undergoing an augmentation must understand that their pelvic pain symptoms may not resolve from augmentation alone. Additionally, because the detrusor is incised, the emptying mechanism of the bladder is altered, and patients may need to perform intermittent straight catheterization to effectively empty their bladder. Mucous production, stone formation, and bladder rupture are known complications from the addition of bowel to the bladder wall, and patients should be followed accordingly.

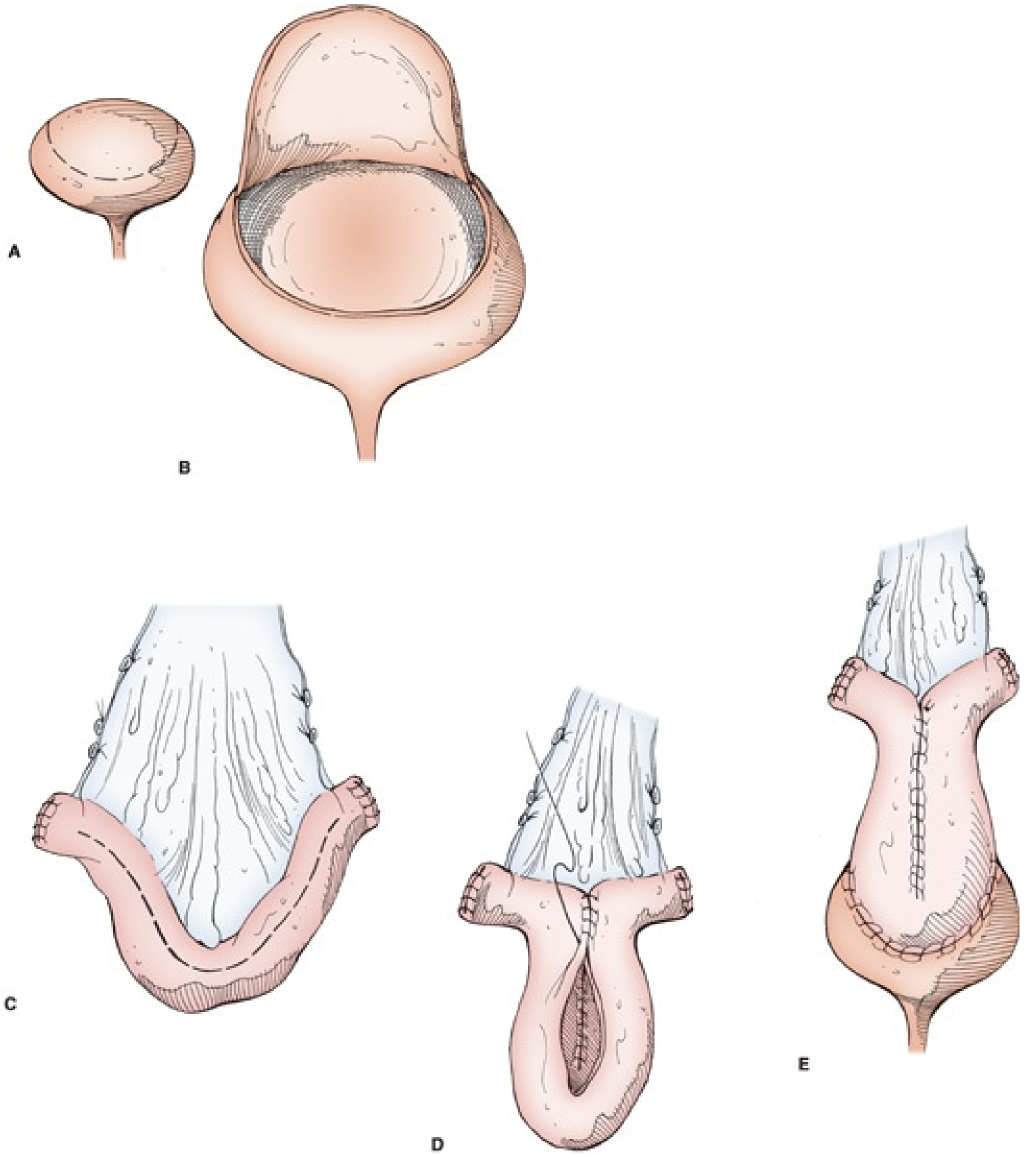

FIGURE 27.5 Ileal augmentation cystoplasty. **A:** A posterior-based U-shaped incision is created on the anterior bladder. **B:** Completion of the posterior-based bladder flap. **C:** A 30-cm segment of the distal ileum is isolated and divided along the antimesenteric border. **D:** The ileal segment is then folded and the posterior surface is closed completely with a running absorbable suture. The anterior segment is partially closed. **E:** Completed ileal bladder anastomosis.

Partial Cystectomy and Substitution Cystoplasty

Supratrigonal cystectomy with enterocystoplasty is preferred over simple augmentation cystoplasty because most of the diseased bladder is removed (33) (Fig. 27.6). This technique should be reserved for patients with small bladder capacity found on hydrodistention under an anesthetic (<300 mL). Patients with a primary pain complaint are not good candidates for supratrigonal cystectomy, particularly if the pain is urethral in nature. In addition, patients should be able to perform intermittent straight catheterization and bladder irrigation in case of poor emptying or mucus formation.

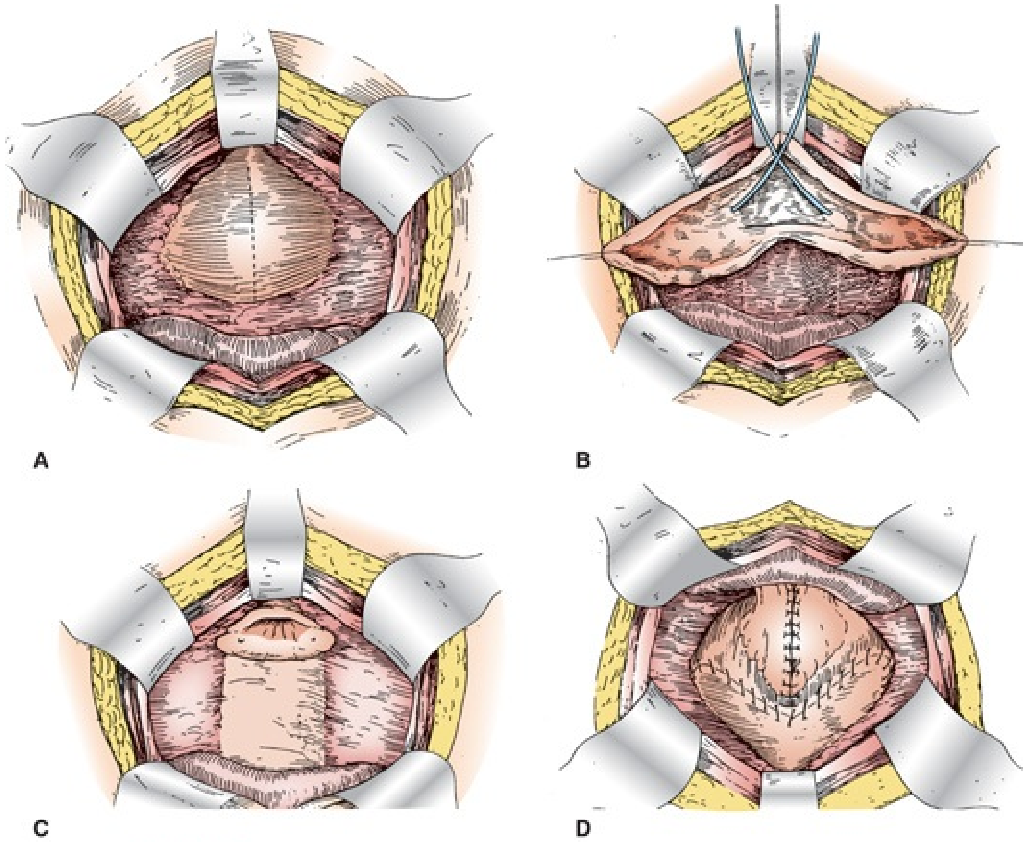

FIGURE 27.6 Technique of subtotal cystectomy and substitution cystoplasty. A: The bladder is being bivalved with electrocautery. B: View of the bladder with both ureteral orifices cannulated with ureteral catheters to avoid injury to ureters during bladder resection. C: Completion of subtotal cystectomy with only a small cuff of bladder remaining, which consists of the urethra, bladder neck, and trigone. D: Completed anastomosis of the bowel onto the bladder cuff. A Foley catheter (not shown) and a suprapubic tube are placed to ensure adequate drainage during the immediate postoperative period.

The patient is placed in a supine position and a Foley catheter is placed sterilely in the bladder. The peritoneal cavity is entered through a vertical midline incision, and an appropriate segment of either large or small bowel with a mesentery long enough to reach down to the bladder is selected. The preferred bowel segments are the cecum, sigmoid colon, or ileum. The bladder is filled via the Foley catheter and divided using a clamshell technique, exposing the trigone. Ureteral catheters are placed before resection of the bladder to avoid injury to the ureters. Using electrocautery, a supratrigonal cystectomy is performed, resecting all but a 1- to 2-cm cuff of bladder that includes the trigone and bladder neck. Placing Allis clamps on the edges of the remaining bladder controls hemostasis. The vesicoenteric anastomosis is completed using a single-layer running closure of 3-0 absorbable polyglactin or polydioxanone suture. A 22Fr Foley catheter is placed through the bowel segment and used as a suprapubic tube. Both tubes are kept to dependent drainage for 21 days, when a cystogram is performed to ensure the integrity of the anastomosis. Many women are able to empty with a Credé maneuver, but a regimen of intermittent catheterization is imperative to evacuate mucus and assure complete emptying.

Total Cystectomy with Orthotopic Neobladder or Urinary Diversion

A total cystectomy has the benefit of removing the entire diseased bladder and may be the treatment of choice for the patient with an “end-stage” bladder. The choice of performing a continent versus incontinent diversion is based mainly on patient preference. If a patient has significant urethral symptoms, an orthotopic neobladder may not be the preferred conduit. The benefits of continent diversions are obvious; however, there have been conflicting reports of IC/BPS developing in the continent bowel segments (34–36). An informed and motivated patient would be the best candidate for a continent diversion. The techniques of cystectomy and urinary diversion, including complications, are described elsewhere.

Sacral Nerve Stimulation

Chronic inflammation in a pelvic organ may lead to nerve upregulation to the spinal cord, affecting all pelvic structures. Sacral nerve modulation (InterStim, Medtronic, Inc, Minneapolis, MN) is approved by the FDA for urinary urgency, frequency, urge incontinence, idiopathic urinary retention, and fecal incontinence. Preoperatively, the efficacy of sacral nerve stimulation is determined by a test performed prior to placing a permanent generator. If a patient experiences at least a 50% improvement in the symptoms and desires a permanent implant, an implantable generator can be placed permanently in a subcutaneous pocket in the upper buttocks. Patients have an external programmer to control the degree and frequency of stimulation and multiple programs can be stored on one device. The complete procedure and description of technique is described elsewhere in this edition.

Currently, a smaller generator is available that may be easier to implant and more comfortable for patients. Battery life on this smaller device is 4 years, compared to 8 years for the larger generator. Regardless, patients must be aware that they will require replacement of their generator later in life. Long-term complications have been minimal with the device. Most commonly revision or explants are for device failure, battery replacement, or loss of efficacy. Reported rates vary, with revisions ranging from 16% to 20% and explantation 10% to 24% (37,38). Future limitations need also be discussed with the patient, including chest or body MRI, future pregnancy, and underwater diving activities.

Pudendal Neuromodulation

Stimulation of the pudendal nerve is not FDA-approved but may offer an alternative to sacral nerve stimulation. Multiple studies have shown inhibition of the micturition reflex with afferent pudendal stimulation, which also results in an increase in bladder capacity and a decrease in uninhibited bladder contractions (39,40). Because afferent signaling is thought to be the primary driver of neuromodulation, using the pudendal nerve spreads the signal more broadly across the sacral nerve roots leading to an enhanced signal being delivered to the central nervous system. Studies have shown promise in using the pudendal nerve as a site of stimulation in patients with urinary urgency, frequency, and pelvic pain (41,42).

Similar to sacral lead placement, the patient is placed prone with the buttocks and posterior thighs prepped and draped. Electromyography (EMG) monitoring must be used to confirm nerve stimulation because the bellows response can be confused with cross-stimulation of motor branches of the proximal sacral nerve roots adjacent to the pudendal nerve. Electrodes are placed at 3 and 9 o'clock in the external anal sphincter and the ischial tuberosity palpated and marked. The skin 1 cm medial at the level of the anus is marked and infiltrated with local anesthetic. The 5-inch foramen needle is advanced medial to lateral toward to ischial spine while stimulating at 5 V per 5 Hz (Fig. 27.7). Fluoroscopy is used to confirm the correct trajectory and continuous EMG monitoring assesses for compound muscle action potentials (C map) at the anal sphincter. Leg rotation or other gluteal nerve stimulation should be assessed and avoided because this will limit the patient's ability to activate and use the device. After a small skin incision is made, the directional guide wire is placed and the blunt-tip lead introducer is advanced again while being stimulated. Once C map is confirmed, the longer 41-cm quadripolar lead is placed and tested for response. We find that optimal placement results in nerve stimulation between 1 and 2.5 V on at least three of the four leads. Withdrawal of the lead introducer will deploy the tines and secure the lead in place. A small subcutaneous pocket is created just below the ipsilateral iliac crest for a future pulse generator similar to the sacral technique. The tunneling device is then used to bring the lead to this pocket, and connections are made to the cutaneous extension wire. This wire is then tunneled to the contralateral side for a 2-week stage I trial period (Fig. 27.8).

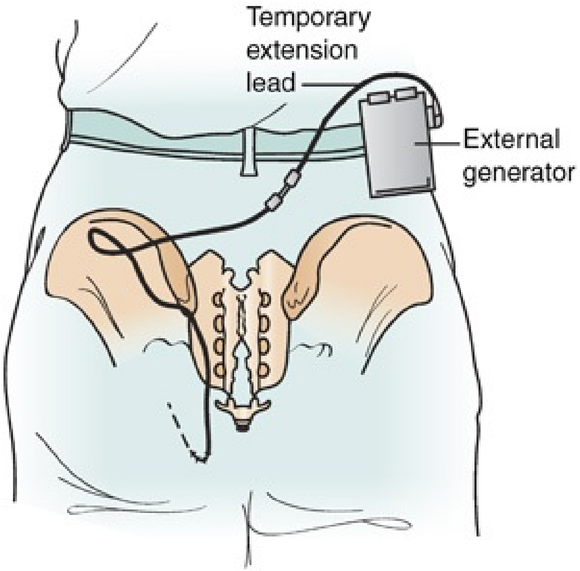

FIGURE 27.8 Stage I implant. The lead is tunneled to a small, subcutaneous pocket on the ipsilateral side. The lead is then connected to a temporary extension lead, which is tunneled to the contralateral side and externalized. The external generator is then connected to the extension lead. The patient is discharged to home, and sacral nerve stimulation is tested over a 14- to 21-day period. Voiding logs and pain scores are maintained, and the program is changed as needed to maximize the clinical response.

In a recent single-blind crossover trial, 22 patients had both sacral and pudendal tined leads placed. Each was stimulated in random order. In responders (>50% improvement in their symptoms), the “better” lead was chosen by the patient (Fig. 27.9). Pudendal lead placement took a mean of 19.6 minutes compared to 27.4 minutes for sacral leads ($P = .039$). Seventy-seven percent had a permanent generator placed after the trial period. The mean ICSI score decreased from 14.3 preoperatively to 10.7 at 6 months postoperatively in the sacral nerve stimulation group ($P = .03$) and decreased from 15.7 to 8.6 in the pudendal group ($P = .009$). The decrease in the ICPI was statistically significant only for the pudendal group, with a decrease from 12.9 to 7.5 at 6 months ($P = .002$). Average preoperative frequency was 24.07 per 24 hours for both groups. At 6 months, the mean total 24-hour voids decreased to 13.94 in the sacral group ($P = .001$) and to 12.84 in the pudendal group ($P = .001$). Mean voided volume increased from the preoperative value of 81.8 mL to 152.8 mL in the sacral group ($P = .001$) and to 158.0 mL in the pudendal group ($P = .001$). Of patients having a permanent generator placed, the majority (77%) chose to have the pudendal lead permanently implanted. A follow-up of 55 pudendal lead patients showed significant improvement in urgency, frequency, and pelvic and bladder pain. Nevertheless, further studies with larger numbers are needed to determine if pudendal nerve stimulation is as effective as or better at reducing urgency, frequency, and pain symptoms than sacral stimulation.

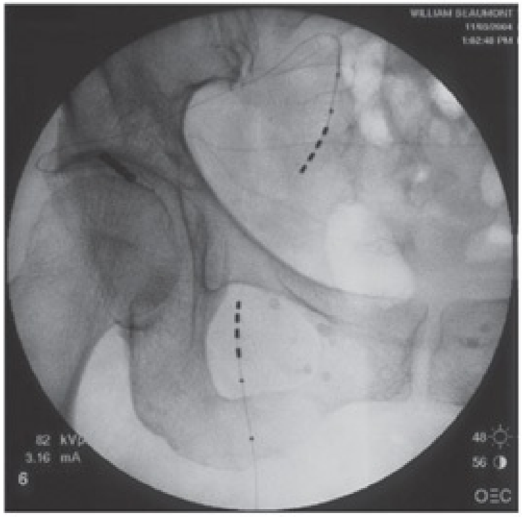

FIGURE 27.9 Postoperative photograph showing both sacral and pudendal leads in place. The pudendal lead was chosen by the majority of patients in a randomized, single-blind crossover study.

Posterior Tibial Nerve Stimulation

The tibial nerve arises from L4 through S3 and is a branch of the sciatic nerve. As with sacral and pudendal stimulation, it is possible to stimulate the posterior tibial nerve and modulate the innervation to the bladder, urinary sphincter, and pelvic floor (43,44) (Fig. 27.10). The technique stimulates the posterior tibial nerve with a 34-gauge needle placed bilaterally at SP-6. The needles are placed approximately 4 cm deep at a 30-degree angle cephalad. An adhesive grounding electrode is applied on each side near the medial calcaneus. Stimulation of the posterior tibial nerve is done with amplitude of 0.5 to 10.0 mA using a fixed pulse width (200 μs) and frequency (20 Hz). Stimulation is applied for 30 minutes. The stimulation needs to be done on a weekly basis for 12 weeks, after which an attempt to wean treatments to once a month is tried. Efficacy for posterior tibial nerve stimulation (PTNS) has been shown in a randomized sham-controlled trial for OAB symptoms (45) and is comparable to pharmacotherapy (46). No trials have directly compared PTNS response for patients with primary IC/BPS on pain symptoms. The limitation of this therapy is the repeated treatments and office visits over time.

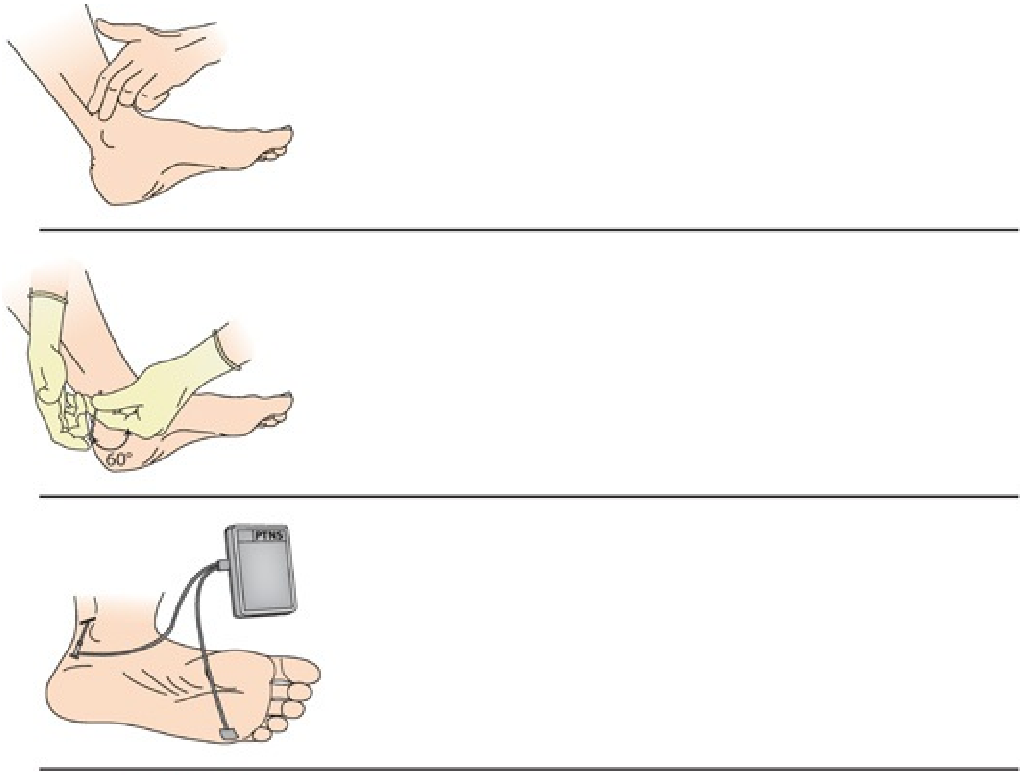

FIGURE 27.10 Neuromodulation of the posterior tibial nerve. A 34-gauge acupuncturelike needle is inserted approximately 3 to 4 cm deep to the tibial nerve for stimulation.

Denervation

Bladder denervation procedures have been reported in the treatment of patients with intractable bladder pain and urinary frequency and urgency. Division of the posterior sacral roots, posterior rhizotomy, or division of the inferior vesical neurovascular pedicle may result in temporary improvement in urinary frequency, urgency, and pain. Ingelman-Sundberg (47) described a more selective denervation in which a transvaginal approach is used to resect the inferior hypogastric plexus, dividing both the sympathetic and parasympathetic fibers. Candidates for the transvaginal denervation are selected by first performing a subtrigonal injection of bupivacaine, which, if successful, results in significant relief of their irritative symptoms. However, with the advent of more oral therapies, along with neuromodulation, denervation is mainly mentioned in this section for its historical significance.

More recently, the introduction of intradetrusor injections of botulinum toxin for neurogenic and nonneurogenic OAB has translated into studies for patients with IC/BPS. Well-designed studies have led to the approval of onabotulinumtoxinA (Botox, Allergan Inc, Irvine, CA) for OAB. Using 100 U of toxin, investigators showed improvement in maximum bladder capacity, ICSI, ICPI, and pain VAS scores, alone and combined with hydrodistention (48,49). Treatments require repeat injections every 3 to 12 months and expose the patients to the risks of urinary retention and urinary tract infections. These small studies support this use of botulinum toxin, although results have generally been limited to small, nonrandomized samples. Response rates were also poor in those with ulcerative forms of IC/BPS (50).

OUTCOMES

Complications

Complications of hydrodistention with or without fulguration are listed in Table 27.2. The most serious complication is bladder rupture, which should be considered if there is resumption of fluid inflow after maximally distending the bladder, return of significantly less fluid than what was instilled upon bladder drainage, or severe suprapubic or abdominal pain or distention. If a bladder rupture is suspected, an immediate cystogram should be performed. If the rupture is extraperitoneal, prolonged Foley catheter drainage is usually all that is needed to allow the rupture to heal spontaneously. If intraperitoneal leakage of contrast is seen, however, immediate exploration and repair are warranted to prevent peritonitis from urine leakage in the peritoneal cavity.

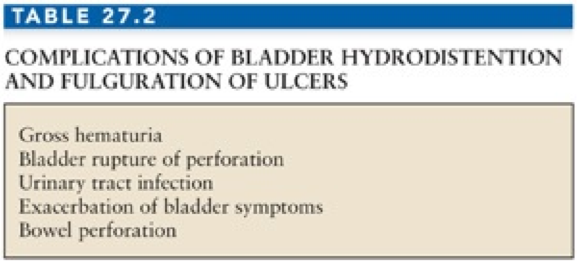

TABLE 27.2

COMPLICATIONS OF BLADDER HYDRODISTENTION AND FULGURATION OF ULCERS

Gross hematuria
Bladder rupture of perforation
Urinary tract infection
Exacerbation of bladder symptoms
Bowel perforation

Early and late complications secondary to major bladder reconstruction are listed in Table 27.3. Persistence of IC/BPS symptoms is probably the most common and disheartening outcome for both the patient and surgeon.

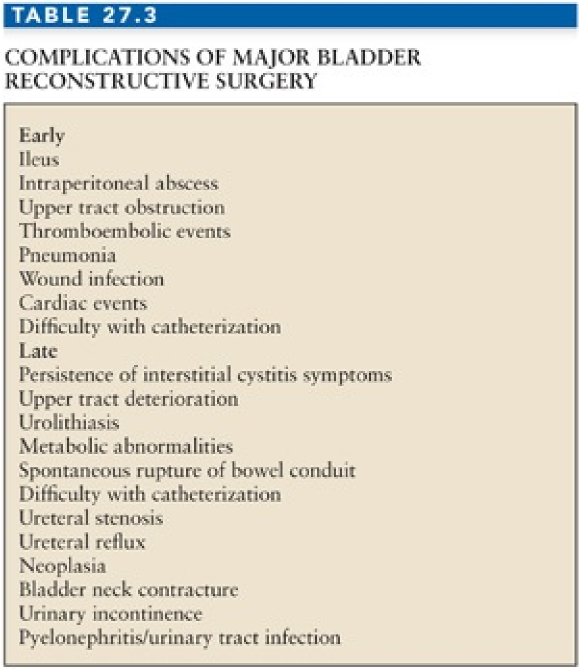

TABLE 27.3

COMPLICATIONS OF MAJOR BLADDER RECONSTRUCTIVE SURGERY

Early
Ileus
Intraperitoneal abscess
Upper tract obstruction
Thromboembolic events
Pneumonia
Wound infection
Cardiac events
Difficulty with catheterization
Late
Persistence of interstitial cystitis symptoms
Upper tract deterioration
Urolithiasis
Metabolic abnormalities
Spontaneous rupture of bowel conduit
Difficulty with catheterization
Ureteral stenosis
Ureteral reflux
Neoplasia
Bladder neck contracture
Urinary incontinence
Pyelonephritis/urinary tract infection

The major risk of selective denervation cystolysis is ureteral injury during the vaginal dissection and is avoidable by placing ureteral catheters.

No serious, irreversible, adverse events have been reported with sacral nerve stimulation. Complications associated with InterStim are listed in Table 27.4. Reoperation occurs in approximately 25% of patients undergoing sacral nerve implantation. Causes for reoperation include sensory discomfort, lead migration, device failure, pocket revision, and infection. Infection of the device requiring explantation occurs infrequently, in 5% of patients in a recent review of a large series (37). Others have described perioperative cephalosporin use as a risk factor for infection, specifically for methicillin-resistant *Staphylococcus aureus* (51). Perioperative, broad-spectrum antibiotic coverage during implantation of the lead and generator should be administered to decrease the rate of infection.

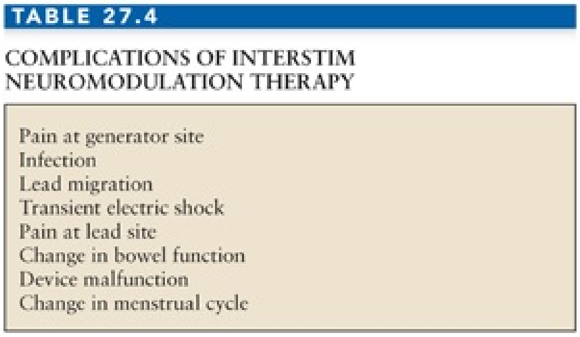

TABLE 27.4

COMPLICATIONS OF INTERSTIM NEUROMODULATION THERAPY

Pain at generator site
Infection
Lead migration
Transient electric shock
Pain at lead site
Change in bowel function
Device malfunction
Change in menstrual cycle

Results

Symptoms of IC/BPS may worsen for 2 to 3 weeks after a hydrodistention. Approximately 40% to 50% of IC/BPS patients undergoing a hydrodistention will have prolonged symptom improvement. If symptoms improve significantly for at least 4 to 6 months, repeat bladder hydrodistention may be indicated. Fulguration of Hunner lesions improves symptoms in over 80% of patients undergoing this therapy. The improvement in pain is usually seen in the first 2 to 3 days and may be long-lasting (16). For those who relapse, repeat fulguration of ulcers usually yields a similar response, 57% undergoing repeat procedure at 48 months (10).

The more aggressive, open surgical approaches have shown good results in carefully selected patients. Relief of symptoms in patients undergoing reconstructive surgery ranges between 60% and 90%. Long-term follow-up studies have shown durable responses in these highly selected patients. In one study, 41 patients underwent cystectomy, augmentation, or diversion only. Thirteen patients with intact or augmented bladder ultimately underwent cystectomy. Seventy-four percent reported pain-free status, and 68% were satisfied with the end result (52). Patients with ulcerative disease have been reported to have better results (53), although they have required completion cystectomy or ulcer fulguration at the trigonal remnant. Although a significant percentage of this highly select group of patients who undergo cystectomy will experience significant relief, there are reports of patients having persistent pelvic pain despite having no pelvic organs. This belies the importance of patient selection and expectations preoperatively.

We reviewed our experience with sacral nerve modulation for refractory IC/BPS (54). When a traditional test was performed with a temporary lead, we had a test-to-implant rate of 52% versus a 94% test-to-implant rate in the staged approach. The benefit of the staged test is that the permanent lead is more programmable and can be tested for an extended period of time. If a response is found, the lead does not need to be removed prior to placing the generator, and the settings that worked on the temporary generator can be programmed into the permanent implanted neurostimulator so that there is no interruption in therapy. Twenty-six patients with refractory IC/BPS who had failed six previous treatments for their disease were implanted with a permanent generator. With a mean follow-up of 5.6 months, 96% of patients said they would undergo the implant again and would recommend the therapy to a friend. Significant improvements were seen in the number of day voids (47%) and nocturia (60%). The majority of patients reported at least a 50% improvement in frequency (72%), urgency (68%), pelvic pain (71%), pelvic pressure (67%), quality of life (76%), incontinence (69%), and vaginal pain (60%). No patients showed a >50% worsening in any symptom. The overall reoperation rate was 11.5% (3 of 26). An objective measurement of pain improvement was reported. Twenty IC/BPS patients with pelvic pain had a permanent implant placed with a median follow-up of 272 days. Seventeen of 20 (85%) used chronic narcotics prior to implant. Nineteen of 20 (95%) reported moderate or marked improvement in pain after implantation of a permanent generator. Morphine dose equivalents (MDEs) decreased from 86 mg per day to 56 mg per day (34%) ($P = .015$)

after implant, and 24% stopped all narcotics.

A prospective study in patients with symptoms of IC/BPS refractory to more conservative treatments was performed after having InterStim implanted. At 14 months follow-up, mean voided volume increased from 111 mL to 264 mL, mean daytime frequency decreased from 17.1 to 8.7, and mean nighttime voids decreased from 4.5 to 1.1. Additionally, pain and symptom scores, measured using the Interstitial Cystitis Symptom and Problem Indices, all improved. Overall, 16 of 17 patients who underwent permanent implantation (94%) had improvement in all parameters at their most recent postoperative visit (55). Another literature review found the response rates for pain ranged from 51% to 77% in those with chronic pelvic pain (56).

CHAPTER 28 MINIMALLY INVASIVE BLADDER PROCEDURES: RADICAL CYSTECTOMY, PARTIAL CYSTECTOMY, URACHAL EXCISION, DIVERTICULECTOMY

ANDRE LUIS DE CASTRO ABREU, SAMEER CHOPRA, AND INDERBIR S. GILL

It is estimated that 72,570 new cases of bladder cancer (BCa) with 15,210 deaths due to this disease occurred in the United States during 2013. Excluding dermatologic malignancies, BCa is the fourth most common cancer and eighth most common cause of death in American men (1). Radical cystectomy (RC) remains the gold standard for treatment of muscle-invasive or refractory non–muscle-invasive BCa (2). It provides satisfactory long-term oncologic outcomes, as it is curative for most patients who have localized disease, with 5- and 10-year recurrence-free survival rates approaching 70% (3). Minimally invasive RC has emerged as an alternative to open radical cystectomy (ORC). It successfully duplicates all technical aspects of the open approach and achieves similar functional and oncologic outcomes while minimizing blood loss, transfusion rates, and potentially, procedural morbidity.

The first laparoscopic radical cystectomy (LRC) with extracorporeal ileal conduit was reported in 1995 (4). Gill et al. (5,6) reported the first cases of LRC with ileal conduit and orthotopic ileal neobladder performed completely intracorporeally in 2000 and 2002, respectively. The first robot-assisted radical cystectomy (RARC) was performed in Germany in 2002, and in 2003, Menon et al. published the first case series of RARC (7,8). Like other robot-assisted surgeries, RARC is gaining popularity. In fact, the proportion of RARCs has consistently increased from 0.6% in 2004 to 12.8% in 2010, and more than 2,101 RCs were performed with robotic assistance to date (9,10). We perform RARC and urinary diversion routinely at our institution and herein present our step-by-step technique.

DIAGNOSIS

The diagnosis and staging of muscle-invasive BCa are addressed elsewhere in this book.

INDICATIONS

The indications for RARC are similar to ORC; therefore, patients with refractory high-risk non–muscle-invasive or muscle-invasive BCa are candidates for RARC. Our current contraindications include fixation of the bladder to surrounding structures and pelvic wall on bimanual palpation, bulky lymphadenopathy, and uncorrected bleeding diathesis. At this writing, the following conditions are no longer contraindications for RARC at our institution: bulky organ-confined primary tumors, history of pelvic surgery or radiation, history of neoadjuvant chemotherapy, morbid obesity, advanced age, aortoiliac vascular surgery, or endovascular stenting; these situations make the procedure challenging yet still feasible (11–13). In fact, RARC has been performed in locally advanced BCa (pT4) and in octogenarians with multiple comorbidities with acceptable outcomes (14,15).

ALTERNATIVE THERAPY

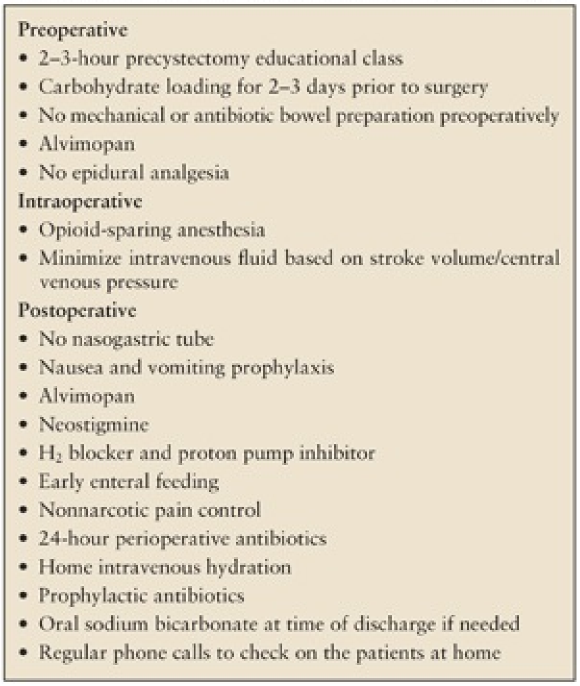
Bladder-preserving protocols using external beam and chemotherapy are available for those who may not be considered for radical cystectomy.

ENHANCED RECOVERY AFTER SURGERY PROTOCOL

Table 28.1 emphasizes part of our Enhanced Recovery after Surgery (ERAS) protocol.

TABLE 28.1

ENHANCED RECOVERY AFTER SURGERY PROTOCOL



Preoperative
- 2–3-hour precystectomy educational class
- Carbohydrate loading for 2–3 days prior to surgery
- No mechanical or antibiotic bowel preparation preoperatively
- Alvimopan
- No epidural analgesia

Intraoperative
- Opioid-sparing anesthesia
- Minimize intravenous fluid based on stroke volume/central venous pressure

Postoperative
- No nasogastric tube
- Nausea and vomiting prophylaxis
- Alvimopan
- Neostigmine
- H_2 blocker and proton pump inhibitor
- Early enteral feeding
- Nonnarcotic pain control
- 24-hour perioperative antibiotics
- Home intravenous hydration
- Prophylactic antibiotics
- Oral sodium bicarbonate at time of discharge if needed
- Regular phone calls to check on the patients at home

RADICAL CYSTECTOMY

Thorough preoperative evaluation is necessary, including cardiac and medical clearance. The patient starts with a clear liquid diet the day prior to surgery. A stoma site is marked before RARC for all patients by an enterostomal therapist. Heparin is administered 1 hour prior to surgery and intravenous antibiotic (typically cefoxitin) is administered at induction until 24 hours postoperatively. As such, the patient preparation is similar as for ORC.

Patient Positioning and Port Placement

Under general anesthesia, the patient is placed in supine position with abducted legs in the appropriate securely fashioned leggings (Fig. 28.1A). All pressure points are meticulously padded and the patient is secured to the surgical table. Sequential compression stockings are applied prior to induction. The patient is prepared from the nipples down to the midthighs, including the genitalia. A warming blanket covers the upper chest and shoulders. After sterile preparation and draping of the patient, a 20Fr Foley urethral catheter is inserted.

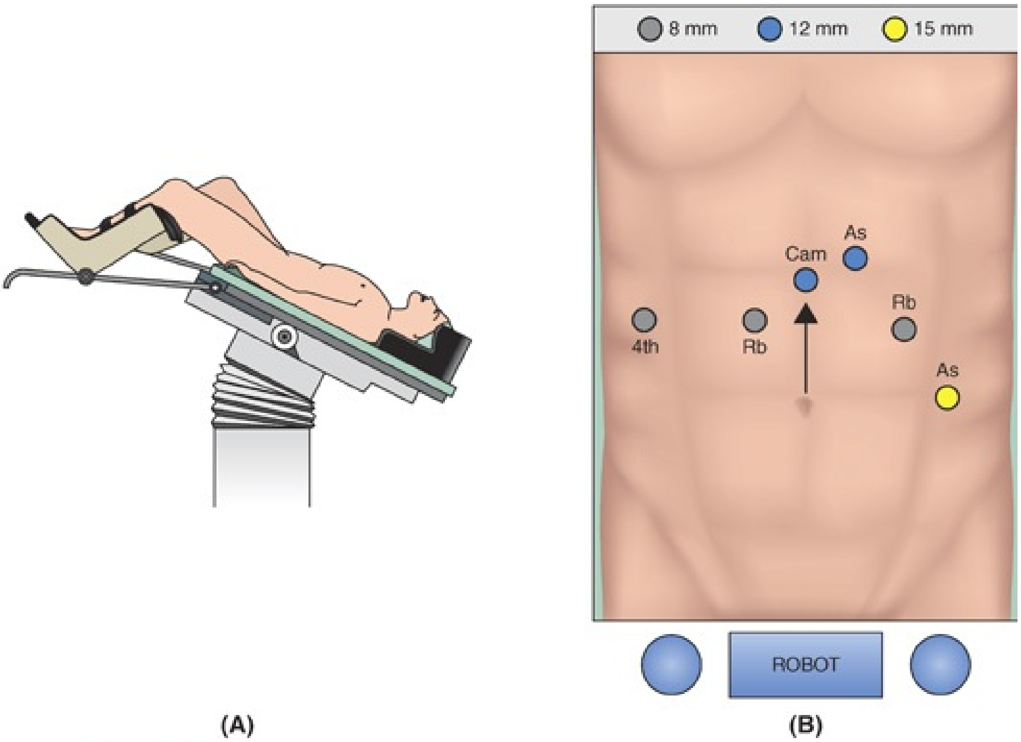


FIGURE 28.1 **A:** Patient is placed in supine position with abducted legs in steep Trendelenburg. **B:** Port placement for RARC is similar to robot-assisted radical prostatectomy; however, the ports are placed more cephalad and an additional 15-mm port is placed in the left inferior quadrant. *4th*, fourth robotic arm; *As*, assistant port; *Cam*, camera; *Rb*, robotic arm.

A 15 mm Hg pneumoperitoneum is created with a 2-mm MiniPort and is maintained at this pressure, even during active suction, by a high-flow insufflator. Six transperitoneal ports (four ports of 8 mm for the robot) are placed more cephalad than the port position commonly used for robotic prostatectomy, with the camera port placed in the midline, 5 to 10 cm above the umbilicus (Fig. 28.1B). A 15-mm port is placed in the left iliac fossa and a 12-mm port is placed in the upper left quadrant; the positioning of these two ports is important for allowing a favorable angle for the staplers during small bowel transection and reconstruction, as well as for the removal of lymph nodes in packets, according to node templates dissection. This configuration allows for the dissection of the urachus, extended or superextended lymphadenectomy (if necessary), and adequate intestinal mobilization. With the patient placed in steep Trendelenburg, the robotic platform da Vinci Si Surgical System is then positioned between the patient's legs and the robot is docked. The first assistant stands on the left side of the patient.

Anatomic Orientation

Upon initial inspection, the surgeon must identify five important landmarks:

1. The medial umbilical ligaments
2. The peritoneal folds overlying the ureters close to the bladder
3. The vasa on each side
4. The posterior cul-de-sac of the rectovesical pouch

5. The iliac vessels

Identification of these landmarks is essential because it allows for precise orientation throughout the procedure and expeditious dissection.

Mobilization and Division of the Ureters

The ureters are identified at the level where they cross the iliac vessels and the posterior peritoneum is incised. The ureters, along with their surrounding fat, are dissected distally until their insertion into the bladder. It is important to maintain an adequate cover of periureteric fatty tissue. Close to the vesicoureteric junction, the superior vesical artery and the vas deferens are visualized crossing the ureter. These are mobilized away from the ureteric surface to obtain maximum ureteric length. The ureters are then divided just before they enter the bladder (prior to the ureteral orifice) between Hem-O-Lok clips and a sample of each proximal portion is sent for pathologic assessment. The Hem-O-Lok clips on the bladder side of the transected ureter serve as critical landmarks during the subsequent dissection, as they provide a readily identifiable visual clue during transection of the lateral pedicles. The ureters remain clipped throughout the procedure to create proximal ureteral hydrodistention, which facilitates later ureteroenteric anastomosis.

Retrovesical Dissection

With the robotic arm retracting the bladder anteriorly, the lateral peritoneotomies of the rectovesical pouch that were previously performed are now joined across the midline. It is important that the peritoneotomy across the cul-de-sac be created distally, such that it is only 1 to 2 cm anterior to the surface of the rectum. Often, there is a subtle transverse peritoneal fold at this location (we refer to it as the “second peritoneal fold”). This plane is now developed between the vasa and seminal vesicles anteriorly and the anterior surface of the rectum posteriorly. The vessels supplying the seminal vesicles are controlled, and bilateral vasa and vesicles are maintained en bloc with the bladder. Continued dissection brings the posterior layer of Denonvilliers fascia into view, which is incised with cold Shears (monopolar curved scissors) to reveal the yellow prerectal fat posterior to the prostate. This is an important landmark guiding the posterior dissection; the plane must remain between the prostate anteriorly and the prerectal fat posteriorly toward to the prostate apex, thus minimizing chance of rectal injury (Fig. 28.2).

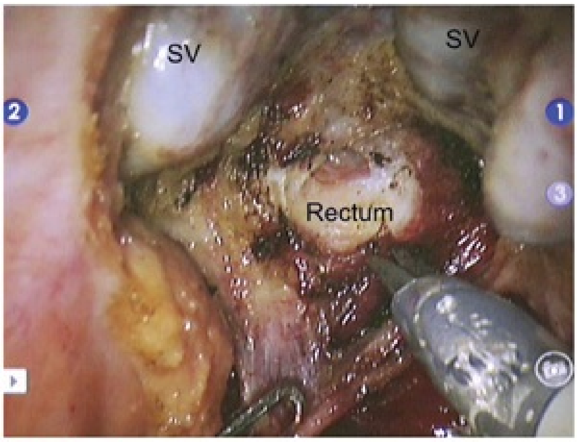

FIGURE 28.2 Dissection of the rectovesical space. The bladder is retracted anteriorly by the fourth arm, and a plane between the prostate (anterior) and prerectal fat (posterior) is developed toward the apex of the prostate. *SV*, seminal vesicles.

Lateral Dissection of the Bladder and Control of Vascular Pedicles

The parietal peritoneum lateral to the medial umbilical ligaments is incised from the vas deferens as it crosses the pelvic brim toward the peritoneotomy across the rectovesical cul-de-sac. The vasa are clipped and divided at the pelvic brim. The space between the bladder and the lateral pelvic wall is now developed bluntly, retracting the bladder medially away from the iliac vessels and the obturator nerve. As the bladder is still anteriorly attached to the abdominal wall, this allows the lateral pedicles to be clearly identified bilaterally. The lateral pedicles are now divided with 60-mm laparoscopic vascular staplers (Fig. 28.3). Once again, the two clips on the bladder end of the transected juxtavesical ureters serve as critical landmarks for the anteromedial limit of resection; the laparoscopic stapler is deployed just posterolateral to these clips. Usually, two or three stapler cartridge firings are necessary on each side to control the entire width of the lateral pedicles down to the endopelvic fascia on either side.

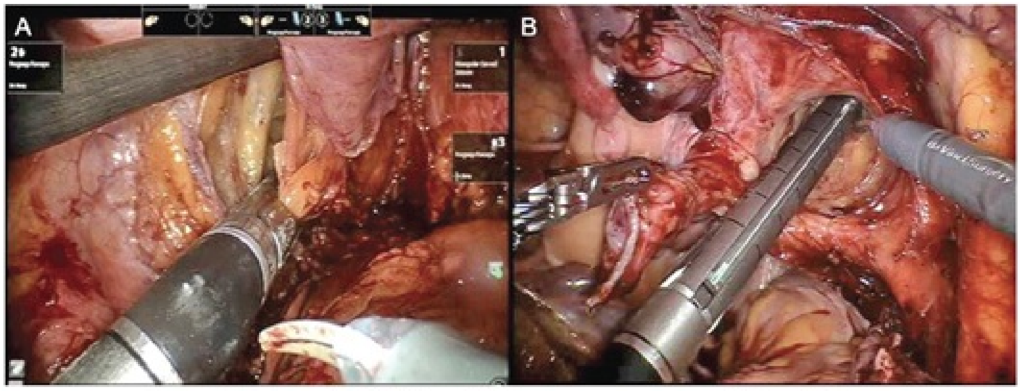

FIGURE 28.3 Ligation of the left bladder pedicle during cystoprostatectomy (A) and of the right bladder pedicle during anterior pelvic exenteration (B), with the use of a vascular stapler.

The posterior pedicles are now visualized coursing from just lateral to the rectum toward the urinary bladder. These are controlled with the stapler or divided between sequentially applied Hem-O-Lok clips. Usually, only the cephalad part of the posterior pedicles can be controlled at this stage; the caudal aspect is addressed after releasing the bladder from the anterior abdominal wall and completing the anterior dissection. At this point, the dissection is within proximity to the anterolateral surface of the rectum.

Anterior Dissection

A liberal inverted U incision is made with the hot Shears electrocautery, starting lateral to each medial umbilical ligament, with the limbs of the U joined anteriorly across the midline at the umbilicus. The urachus and medial umbilical ligaments are divided just caudal to the umbilicus. The bladder is dynamically pulled posteriorly, an avascular plane between the muscles aponeurosis and prevesical fat is dissected caudally toward the pubic bone and endopelvic fascia. The bladder is then released from the anterior abdominal wall; care is taken to protect the inferior epigastric vessels as they course up from the external iliac vessels to enter the posterior rectus sheath.

The space of Retzius is developed behind the pubic bone. Areolar tissue is dissected away to expose the anterior surface of the prostate and the endopelvic fascia on each side. The endopelvic fascia is incised down to the region of the dorsal venous complex. The superficial dorsal vein is coagulated and the fat overlying the anterior surface of the prostate is cleared off with the bipolar forceps. The puboprostatic ligaments are divided with cold Shears.

Transection of Dorsal Vein Complex and Membranous Urethra and Specimen Entrapment

The dorsal vein complex (DVC) is now ligated, using a 0-Vicryl on a CT-1 needle and carefully transected with cold scissors toward the anterior surface of the urethra. The remaining posterior pedicles are then clipped and divided. If an orthotopic neobladder reconstruction is planned, a long urethral stump is required. Thus, a meticulous dissection with small cuts surrounding the urethra is performed, releasing the urethra from the prostate apex. An anterior urethrotomy is performed, and the Foley catheter is then divided between Hem-O-Lok clips to avoid local spillage of urine. The urethra is now transected just proximal to the verumontanum and biopsies of the proximal and distal urethra are sent for frozen section evaluation. The free specimen is entrapped in an Endo Catch bag (II Endo Catch bag 15 mm) and parked in one side within the abdomen for later retrieval.

MODIFICATIONS FOR NERVE-SPARING CYSTECTOMY IN MEN

Once the ureters are divided and posterior dissection commences, care is taken to stay closely along the surface of the seminal vesicles, as the neurovascular bundles run lateral to the apical tip of the vesicles distally toward the prostate-vesicular junction. Thermal energy is avoided in the vicinity of the bundles. The plane of dissection is closer to the bladder and further away from the rectum. The bundle on either side is dissected away with cold Shears, and hemostasis is secured with Hem-O-Lok clips. This is in contrast to the non–nerve-sparing technique, in which a laparoscopic stapler is used for en masse transection of the lateral pedicle more posterolaterally, closer to the rectum, and at a considerable distance from the bladder. During the anterior dissection, the endopelvic fascia is maintained intact, and the lateral pelvic fascia is incised high on the prostate to drop the bundles posteriorly. The DVC is then divided as previously described. The bundles on either side are released from the prostate apex using cold Shears, and the urethra is divided. The remainder of the operation proceeds in the usual fashion.

MODIFICATIONS FOR CYSTECTOMY IN WOMEN

Pelvic Exenteration

For cystectomy in women, the procedure begins with the dissection of the ureters as previously described. The uterus is pulled proximally by the fourth robotic arm and Endo GIA staplers transect the infundibulopelvic ligaments and the uterine arteries. An incision is made in the posterior peritoneum near the uterine cervix. A stick sponge previously inserted into the vagina facilitates visualization of the vaginal fornix (Fig. 28.4). The remaining posterior dissection and the vaginal incision are made after preparing the DVC. The lateral pedicles are transected with laparoscopic staplers and the bladder is dropped in the usual fashion as described earlier. The DVC is suture-ligated with a 2-0 polyglactin suture on a CT-1 needle.

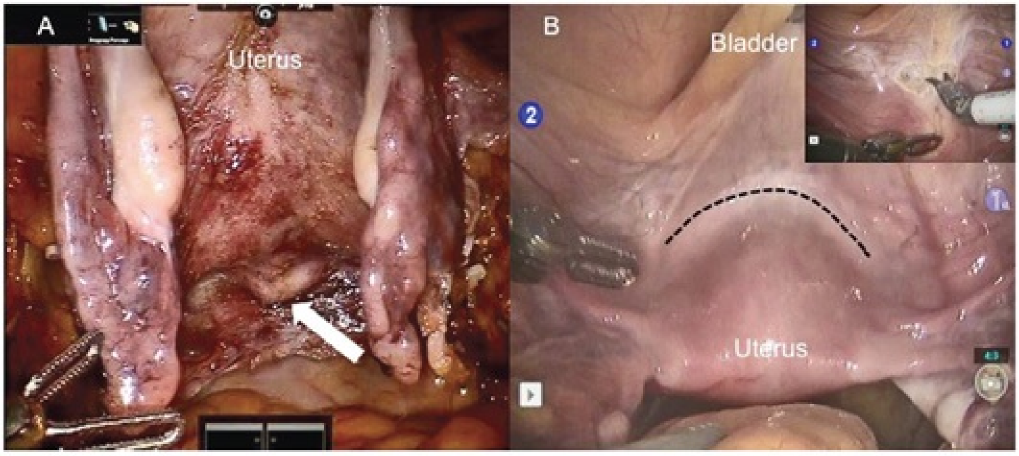

FIGURE 28.4 Cystectomy in women. **A:** During anterior pelvic exenteration, gauze is inserted in the vulva to help identify the vagina (*arrow*). **B:** In reproductive organ–sparing cystectomy, the dissection is created between the bladder and the uterus (*dotted line* and *insert*).

Attention is now returned to the posterior dissection. With the uterus anteverted, a transverse incision of the posterior vaginal fornix is completed at the previously scored site. The vaginal incision is extended distally on either side of the urethra, excising a narrow central strip of vagina en bloc with the bladder specimen. Using a perineal approach, the external meatus and distal urethra are circumferentially cored out using electrocautery. The urethra is then resected along with the bladder, the anterior two-third portion of the vagina, the uterus, and the ovaries. The specimen is entrapped in an Endo Catch bag and extracted through the vulva (Fig. 28.5). A minipad is placed in the vulva to minimize the loss of CO_2 and the pneumoperitoneum is maintained by a high-flow insufflator. These allow for vaginal reconstruction using 2-0 V-Loc sutures on a CT-1 needle via robotic technique before proceeding with urinary diversion.

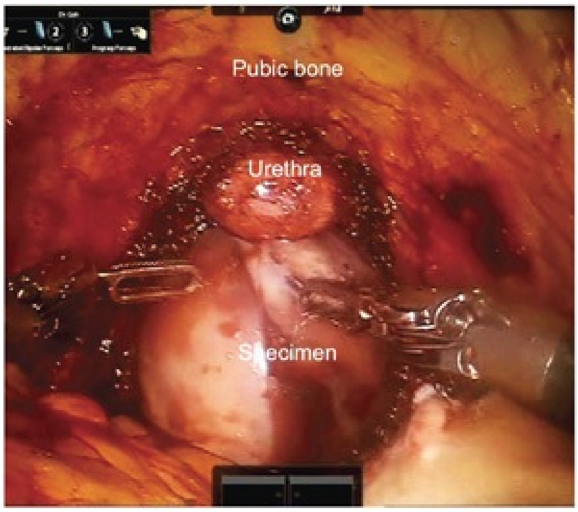

FIGURE 28.5 In women, an excellent choice for extraction of the surgical specimen is through the vagina. If an orthotopic neobladder is planned for UD, an adequate urethral stump is preserved.

If a urinary orthotopic neobladder reconstruction is planned, the distal urethra must be preserved (Fig. 28.5). Thus, the urethra must be carefully dissected and sectioned allowing for a sufficiently long stump for neobladder-urethral anastomosis. In these cases, it is recommended to pad the remainder of the vagina with the omental patch positioned between the neobladder and the vagina to prevent urinary fistula formation.

REPRODUCTIVE ORGAN–SPARING CYSTECTOMY

In carefully selected, sexually active women with less aggressive organ-confined disease, a reproductive organ–sparing cystectomy can be an option. In these cases, the suspensory ligaments of the ovaries and the uterine arteries and ligaments are preserved. Precise dissection of the bladder away from the uterus and vagina is critically important. With a stick sponge inserted through the vulva, the vagina is pulled posteriorly and the uterus is retroverted using the robotic fourth arm. The bladder is identified, and the peritoneum on the anterior surface of the uterus is incised transversely using hot scissors (Fig. 28.4). With the bladder now retracted anteriorly, dissection is performed along and close to the anterior surface of the uterus, developing this avascular plane. Typically, dissection proceeds smoothly until the cervix is reached, where adhesions are often dense. At this point, care is taken not to thin the vaginal wall or enter the bladder. This dissection is carried distally down to the bladder neck, which is the landmark of posterior dissection. Anterior dissection is now performed and the lateral pedicles are divided with a stapler. The urethra is prepared in the usual fashion and the rest of the procedure is followed as previously described. As the vagina is not opened, the specimen is entrapped in an Endo Catch II bag for later retrieval.

EXTENDED AND SUPEREXTENDED LYMPHADENECTOMY

Surgical Technique

Although the extent of lymphadenectomy is debatable, it is noteworthy that not only the lymph node yield but also the quality of resection, including skeletonization of the arteries is important (16). Also relevant is the ligation of the larger lymphatic vessels to prevent formation of lymphocele or chylous ascites, and care must be taken to avoid cutting into any enlarged lymph nodes to minimize the risk of tumor spillage. We perform lymph node dissection after the robotic cystectomy. The landmarks (template) for superextended lymphadenectomy are distally the lymph nodes of Cloquet, laterally the genitofemoral nerve, medially the perivesical fat, and proximally the inferior mesenteric artery (IMA). Therefore, the anterior surface of the aorta and vena cava up to the IMA, along with the para-aortic, preaortic, interaortocaval, precaval, and pericaval lymphatic fatty tissue/nodes, are excised. The aortic bifurcation and the presacral area are also dissected (17). The technique mimics the “split-and-roll” technique used during ORC. Right lymphadenectomy is performed first. Using the 30-degree camera lens, the lymphadenectomy begins distally with the dissection of the lymph nodes of Cloquet. It then continues proximally toward the bifurcation of the aorta up to the IMA (Fig. 28.6A). To obtain a good dissection of the obturator fossa, lateral dissection is necessary up to the external iliac vessels allowing for direct visualization of the obturator nerve (Fig. 28.6B). The right ureter should be dissected cranially to avoid inadvertent proximal damage. The lymphadenectomy then continues in the left pelvic region, which is initially performed from proximal to distal (aorta to iliac vessels), as opposed to the technique on the right side. The mesosigmoid is retracted laterally to the left allowing lymphadenectomy of the left internal iliac vessels and presacral region. This maneuver facilitates the creation of a “window” below the sigmoid colon for later transposition of the left ureter to right during ureteral bowel anastomosis (Fig. 28.7). The remainder of the left pelvic lymphadenectomy is performed in the same fashion as the right lymphadenectomy. The sigmoid colon is now retracted to the right and the dissection begins distally and continues proximally toward the already skeletonized internal iliac vessels. The removal of the lymph nodes occurs in packets, according to the templates, and the nodes are placed in the appropriate bag at the time that each region is dissected, as this may influence the number of lymph nodes removed (18).

URINARY DIVERSION

Surgical Technique

Intracorporeal Orthotopic Ileal Neobladder

In order to create a spherical orthotopic ileal neobladder (OIN) with a good filling capacity while maintaining a low pressure, the principles of ORC should be replicated and applied to the robotic approach (19,20). Here, we describe our updated technique for OIN (20). For the urinary diversion (UD), the use of atraumatic Cadiere forceps instead of a ProGrasp Forceps is essential to avoid intestinal injury during bowel manipulation.

Isolation of the Small Bowel Intestine

A total of 65 cm of small bowel segment is isolated as follows: 44 cm of the reservoir, 16 cm of the chimney, and 5 additional cm are discarded ("discarded segment") during the small bowel anastomosis (Fig. 28.8). Using the 30-degree camera lens, the first step in creating the neobladder is to identify a loop of ileum that reaches the urethra without tension, which is usually located 25 to 30 cm proximal to the ileocecal valve. This point is marked with a 3-0 V-Loc barbed stitch in the antimesenteric edge of the bowel and it will be the site of neobladder-urethral anastomosis. This is a major step of the UD because it saves time and ensures the feasibility of performing neobladder-urethral anastomosis without tension. From this point, we measure 11 cm distally (toward to the ileocecal valve) and 11 cm proximally (total 22 cm). The use of a previously metered Penrose is important because it ensures accurate measuring and, because it is malleable, it facilitates intracorporeal manipulation. This point (22 cm) is marked with an undyed 2-0 Vicryl and is pulled distally toward the pelvis by the fourth arm (denoting the apex of the posterior plate). An additional 22 cm is measured proximally to this point (total 44 cm) and is also marked with an undyed 2-0 Vicryl to signify the end of the reservoir and beginning of the chimney. An additional 16 cm (total: 60 cm) is measured proximal to this point (44 cm) for the chimney. Finally, 5 cm (total: 65 cm) of proximal ileum ("discarded segment") is resected and discarded. This discarded segment helps "keeping out" the neobladder, preventing neobladder-bowel fistula, and ensuring good vascularization to the ends of the bowel during the intestine reconstruction (anastomosis). To avoid confusion during the intestine reconstruction, the ends of the intestine are marked with undyed Vicryl for the UD (*u*ndyed for *U*D) part and with dyed Vicryl for the gastrointestinal part.

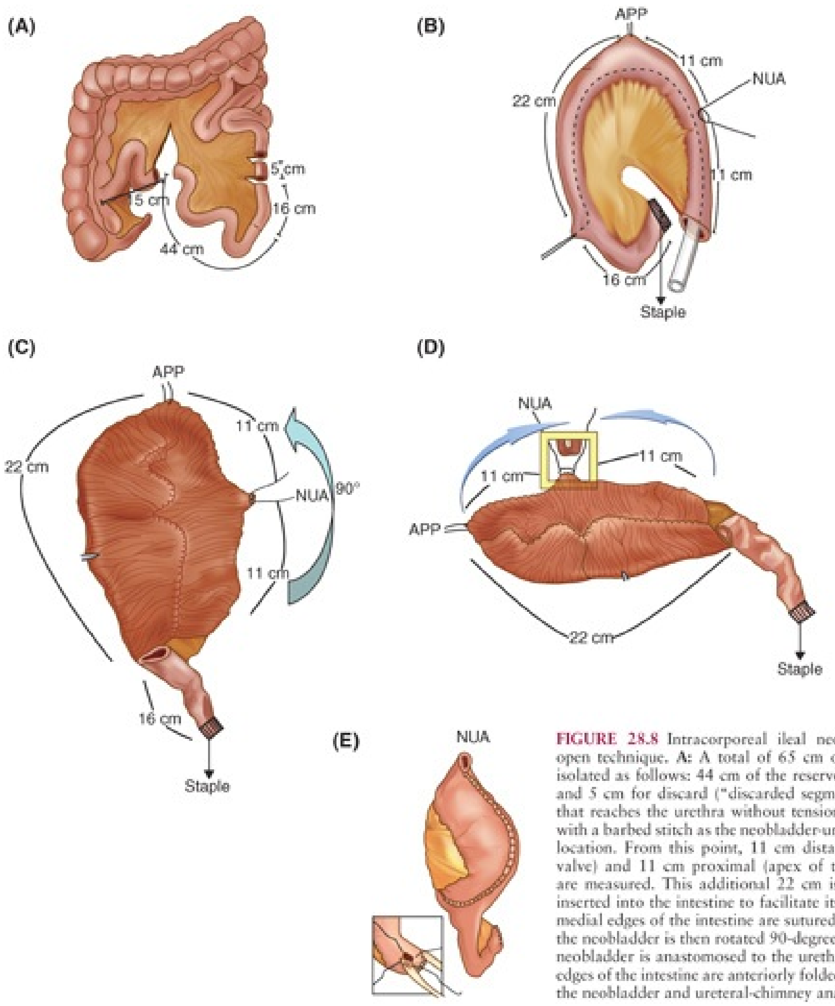

FIGURE 28.8 Intracorporeal ileal neobladder: duplicating the open technique. **A:** A total of 65 cm of small bowel segment is isolated as follows: 44 cm of the reservoir, 16 cm of the chimney, and 5 cm for discard ("discarded segment"). **B:** A loop of ileum that reaches the urethra without tension is identified and marked with a barbed stitch as the neobladder-urethral anastomosis (*NUA*) location. From this point, 11 cm distal (toward to the ileocecal valve) and 11 cm proximal (apex of the posterior plate [*APP*]) are measured. This additional 22 cm is marked. A chest tube is inserted into the intestine to facilitate its detubularization. **C:** The medial edges of the intestine are sutured and the posterior plate of the neobladder is then rotated 90-degree counterclockwise. **D:** The neobladder is anastomosed to the urethra (*square*) and the lateral edges of the intestine are anteriorly folded. **E:** Final configuration of the neobladder and ureteral-chimney anastomosis (*insert*).

Inserting a 60-mm laparoscopic stapler through the 15-mm port in the left iliac fossa allows for a good angle for isolation and reconstruction of the small bowel intestine. Normally, one cartridge of staples is enough to allow adequate bowel mobilization without compromising its vascularization. Indocyanine green ("firefly") can be used to facilitate visualization of mesentery vascularization and ensure no vascular injury occurred while firing the stapler through the bowel and mesentery (Fig. 28.9). The isolated intestinal segments are now properly marked and transected, and the surgery proceeds with the bowel continuity reconstruction. For this, the suture lines of the staples are removed, the bowel edges are aligned, and the side-to-side intestinal anastomosis is performed with the 60-mm laparoscopic stapler firing along the antimesenteric border and then across the open intestinal borders. The mesenteric window is closed with an interrupted suture.

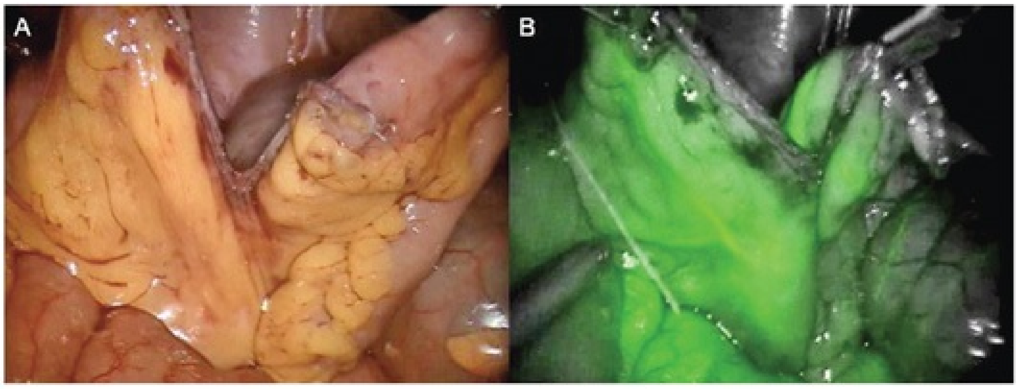

FIGURE 28.9 A: Bowel division using intestinal stapler. B: The use of Indocyanine green ("green dye") under infrared light permits the identification of mesentery vascularization.

Bowel Detubularization and Suture of the Posterior Plate of the Neobladder

With the fourth robotic arm pulling the 22-cm point (apex of the posterior plate) toward the pelvis, a 24Fr chest tube is inserted through the 12-mm port in the upper left quadrant and inserted into the small intestine. This greatly facilitates the longitudinal opening of the intestine (with hot scissors) in the antimesenteric border but near to the medial part of the mesentery. The medial edges of the intestinal segments are aligned and interrupted sutures (2-0 Vicryl) are placed to allow handling and symmetry of the pouch. A running suture using a 2-0 V-Loc stitch on a CT-1 needle is carried out from distal to proximal and the posterior plate of the neobladder is created. A "free-hands" suture is performed during the entire pouch creation and, in order to save time, it can be facilitated by (a) the assistant pulls the stitch with the hook for every needle during the running suture and (b) the use of a barbed V-Loc stitch avoids losing the stitches, therefore keeping the suture line watertight.

Neobladder-Urethral Anastomosis and Folding the Pouch

After suturing the posterior plate of the neobladder, it is rotated 90 degrees counterclockwise to align the previously placed 3-0 V-Loc stitch (neobladder-urethral anastomosis point; 11 cm) with the urethra. At this point, the antimesenteric edge that was previously marked with 3-0 V-Loc is sutured to the distal Denonvilliers fascia, adjacent to the rectourethralis muscle, to decrease tension on the anastomosis. The urethra-neobladder anastomosis is then performed with a double-armed 3-0 Monocryl suture on a RB-1 needle. The anastomosis begins at the posterior edge of the urethra ("6 o'clock") and continues anteriorly in a running fashion over a urethral catheter (22Fr Couvelaire) (Fig. 28.10). The anastomosis is completed when the left and right running sutures reach the midline. This is followed by the anterior folding of the lateral edge of the intestine, performed by a running suture using barbed 2-0 V-Loc on a CT-1 needle to create a spherical configuration for the neobladder. A small opening is left in the anterior suture line to allow passage of bilateral ileoureteral stents.

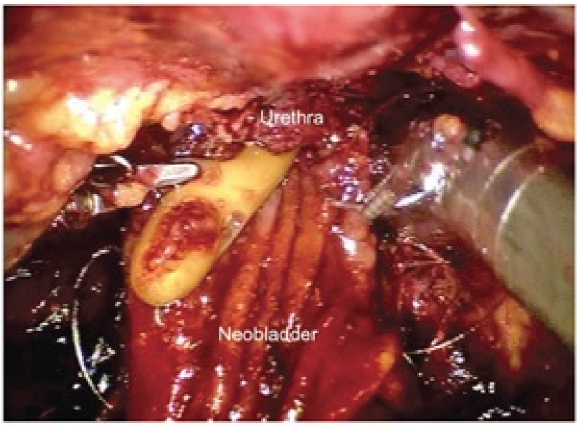

FIGURE 28.10 Neobladder-urethral anastomosis.

Ureteral-Chimney Anastomoses

For ureteral anastomoses using the chimney of the neobladder, the distal parts of the ureters that were clipped with Hem-O-Loks are resected. A guide wire is inserted through a 2-mm MiniPort located in the right inferior quadrant to facilitate insertion of a 7Fr double-J ileoureteral stent (Fig. 28.11). The ureters are spatulated and separately anastomosed over the stents at the antimesenteric border of the chimney using 4-0 Vicryl on a RB-1 needle with interrupted sutures as described by Bricker (21). A running suture using 3-0 Vicryl is performed at the proximal end of the chimney to avoid contact of urine/mucus with the staples, preventing stone formation. The remaining portion of the pouch that was left open is now closed and 180 mL of saline is injected into the neobladder to confirm no leak (Fig. 28.12). A closed suction drain system is inserted through the portal in the right iliac fossa and positioned in the pelvis.

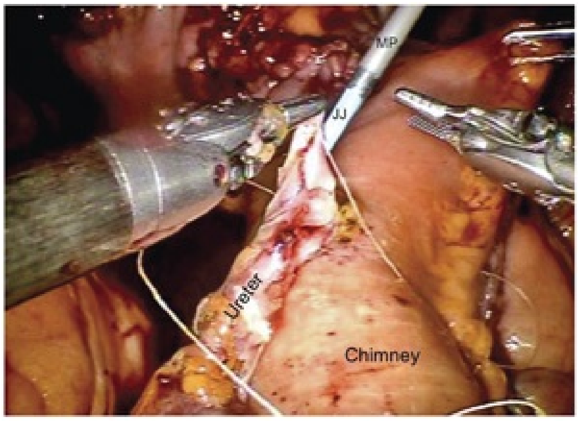

FIGURE 28.11 During the ureteral-chimney anastomosis, a double-J ureteral stent (*JJ*) is inserted into the ureter through a 2-mm MiniPort (*MP*) punctured in the right inferior abdominal quadrant.

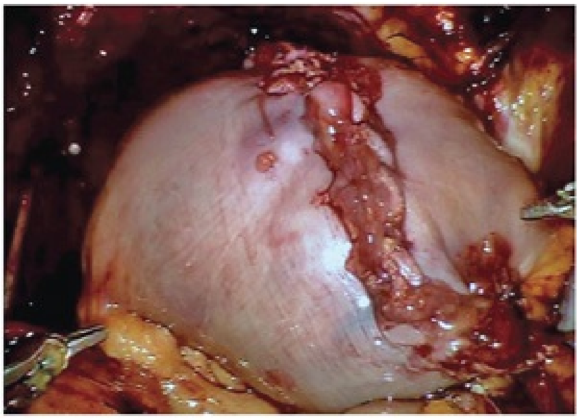

FIGURE 28.12 The spherical final aspect of the OIN performed entirely intracorporeal using robot assistance.

The previously bagged specimen is removed through an enlargement incision in the midline camera port (or through the vagina in women as previously described). The port placement incisions are sutured with the Carter-Thomason CloseSure System, and the patient is sent to the recovery room.

Intracorporeal (Bricker) Ileal Conduit

For the urinary ileal conduit (IC), a stoma site is marked prior to RARC for all patients by an enterostomal therapist in a location separate from the patient's skin folds or bone eminences (21). The technique for the intracorporeal robotic IC replicates the open procedure with a few minor modifications (7). A 15-cm ileal segment 15 cm proximal to the ileocecal valve is isolated using two applications of 60-mm laparoscopic staples; the isolated segment is then dropped posteriorly. Ileoileal continuity is restored with a side-to-side anastomosis using the Endo GIA stapler, as described earlier for the ileal neobladder. The mesenteric window is closed with interrupted suture. The proximal end of the conduit is closed with a 3-0 Vicryl running suture to exclude the staples, avoiding their contact with urine/mucus and preventing stone formation. The distal ends of the ureters are spatulated and two separate anastomoses are performed over 7Fr double-J ileoureteral stents using interrupted sutures as described earlier. The stoma is then fashioned for IC maturation. With Allis forceps, the assistant holds and pulls out the distal part of the IC. The staple line of the distal part of the ileal segment is resected and the IC is matured in the previously marked location on the patient's skin. The ports are then closed and the drain is placed as previously described for the neobladder.

POSTOPERATIVE CARE

Immediately after surgery, the patient is sent to the recovery room and then to the intensive care unit. The nasogastric tube is removed and intravenous fluids are continued until bowel function is regained. Per oral diet is progressive according to the patient's tolerance. The antibiotic is discontinued during postoperative day (POD) 1. Patients are encouraged to ambulate early and the neobladder is gently irrigated with 50 mL of saline every 4 hours to prevent plugging of the catheters by mucus. The drain is removed when its output is less than 150 mL per 24 hours and the liquid analysis is not compatible to urine. A cystography is routinely performed at POD 21 and urethral and ureteral catheters are removed if there is no leakage (Fig. 28.13).

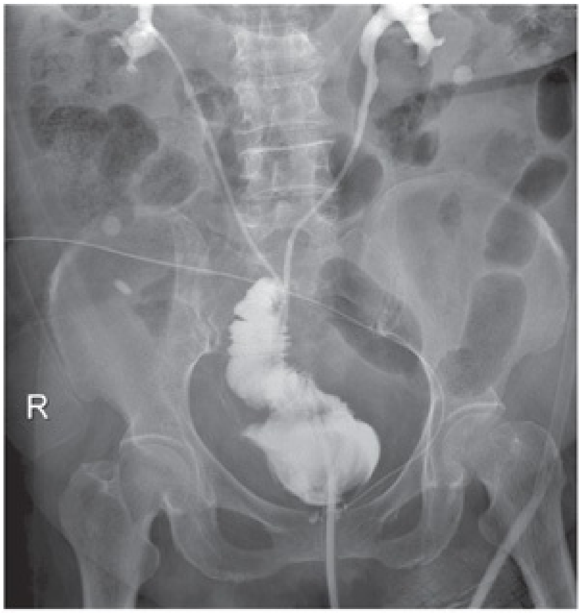

FIGURE 28.13 Cystogram on POD 21.

ONCOLOGIC OUTCOMES

Overall

RARC is a relatively recent procedure; thus, there is a paucity of studies reporting long-term outcomes in a large cohort of RARC patients. Khan et al. (22) reported on oncologic outcomes ranging from 5 to 8 years of follow-up for a cohort of 14 patients undergoing RARC. They report a disease-free survival of 50%, a disease-specific survival of 75%, and an overall survival of 65%, and none of these patients experienced deterioration in renal function. Although the authors report that they found it difficult to properly perform pelvic lymphadenectomy because they used the first-generation da Vinci robot, they concluded that the 5-year oncologic outcomes are equivalent to those reported by a robust series of ORC (18,22). A recent study reported the oncologic outcomes of the longest follow-up to date for patients undergoing RARC ($n = 17$) or LRC ($n = 104$). The majority of the tumors were urothelial carcinomas (81%) and muscle invasive (≥ pT2 in 67%). The positive soft tissue margins rate was 6.6% and 20% of the patients had lymph node metastasis on final pathology. With a median follow-up of 5.5 years, 48% of the patients were disease-free and 23% died from BCa. The actuarial 10-year recurrence-free survival was 54%, cancer-specific survival was 63%, and overall survival was 35% (23). These results are similar to those reported for ORC (24).

The oncologic outcomes of RC depend on many factors such as disease stage, surgical margins, and lymph node metastases (14,25). Compared to ORC, the gold standard, RARC does not appear to be inferior in terms of surrogate oncologic outcomes (positive surgical margins and number of lymph nodes resected) or perioperative complications. Additionally, RARC has the benefit of decreased blood loss and transfusion rates but a longer operative time (10,26–28) than ORC. Although enrolling a small number of patients, Parekh et al. (27) conducted a prospective randomized clinical trial comparing the results of RARC ($n = 20$) versus ORC ($n = 20$) and reported no difference between the groups in terms of operative time, hospital stay, postoperative complications, pathologic staging, positive surgical margins (5% for each group), or number of lymph nodes resected; the RARC group had, however, less blood loss. Similar results were reported by Nix et al. (26); however, a longer operative time was reported for the RARC group. Additionally, they demonstrated other benefits of a minimally invasive approach such as shorter time to bowel movements and flatulence and a decreased need for postoperative analgesia.

SURGICAL MARGINS

Positive surgical margins (PSM) in the soft tissue of RC specimen are an independent risk factor for local recurrence, disease-specific survival, and overall survival (29,30). Due to the lack of tactile feedback in the robotic approach, PSM could be an important issue for RARC. In this regard, a multi-institutional study evaluated 513 surgical RARC specimens and reported a PSM rate of 6.8%. The authors reported that older patients, number of metastatic lymph nodes, and pathologic stage were independent risk factors for PSM. In fact, the rate of PSM was 1.5% for pathologic stage ≤ pT2, 8.8% for pT3, and 39% for pT4. There was no significant association with PSM rate and the number of surgeries performed per institution or per surgeon (25). These findings are comparable to those of the ORC (29,30).

LYMPHADENECTOMY

Pelvic lymphadenectomy should be performed during RC because it promotes better accuracy of pathologic staging and may impact oncologic outcomes (31). Many factors such as lymphadenectomy extension (extended or superextended), lymph nodes yield, or quality of lymphadenectomy could potentially present limitations for proper robotic lymphadenectomy (RAL) for BCa (16,31). However, recent studies have shown and demonstrated that RAL can be of excellent quality and quantity, even in challenging cases such as postradiotherapy or after abdominal vascular graft placement (12,32–36).

In a unique study, Davis et al. (32) performed RAL in 11 patients who were subsequently converted to open lymphadenectomy to assess the amount of additional lymph nodes that could be removed with the open approach. The results showed that the median number of lymph nodes dissected by RAL was 43 (range: 19 to 63) and the subsequent open lymphadenectomy was able to dissect a median of 4 (range: 0 to 8) additional nodes. This gave a yield of 93% for RAL in relation to the open lymphadenectomy. Another study compared the RAL in 35 patients versus open lymphadenectomy in 120 patients; Abaza et al. (33) found no difference in lymph node yield between the two approaches (RAL = 37.5 versus open = 36.9, $p = 0.68$). Furthermore, only 6% of patients undergoing RAL and 10% of open lymphadenectomy patients had less than 20 lymph nodes retrieved. The authors concluded that the quality of RAL is equivalent to the open lymphadenectomy.

FUNCTIONAL OUTCOMES

There is minimal literature reporting the functional outcomes following RARC. Tyritzis et al. (37) reported the functional outcomes of 70 patients (62 males and 8 females) who underwent RARC and intracorporeal OIN. Of the patients who underwent nerve-sparing cystoprostatectomy, 81.2% were potent (erections adequate for penetration) with ($n = 16$, 50%) or without ($n = 10$, 31.2%) the use of PDE5-I at 1-year follow-up, and four out of the six females evaluated on follow-up were sexually active. The 1-year daytime and nighttime continence (use of 0 to 1 pad per day) rate was 88.2% and 73.5%, respectively (37).

URINARY DIVERSION

Currently, there is still no consensus about the best UD following RC; therefore, UD should be individualized according to the patient's characteristics and expectations (38). Although cystectomy and lymphadenectomy are standardized procedures and are more likely to be performed using a minimally invasive approach with an acceptable operative time, intracorporeal urinary diversion (IUD) poses a larger challenge. In fact, laparoscopic IUD is laborious, leading to prolonged operative time, and thus more likely to be performed by selected dedicated and skilled surgeons (5,6,39,40). This has led to the abandonment of laparoscopic IUD by several groups and it is performed extracorporeally by a small laparotomy (40,41).

Although the emergence of the robotic platform, specifically with EndoWirst system, has greatly improved the ergonomics and facilitated intracorporeal reconstructive urologic surgery, the vast majority of UD is still being performed extracorporeally and IC is the diversion of choice in up to 90% to 97% of RARC (9,42–46). In fact, RARC is more likely to be performed in urban locations, teaching hospitals, and by high–annual volume surgical hospitals and surgeons (9,10).

Beecken et al. (47) reported the first case of robotic IUD (RIUD) with an ileal neobladder in 2003; it was a successful procedure with a duration of 8.5 hours. More than 10 years after the first report of RIUD, there have been around 219 RIUD neobladders reported to date and the average operative time still ranges from 7 to 9.9 hours (20,37,44,46–49). Most authors performing robotic intracorporeal neobladder sought to reproduce the principles of the open technique, such as length of bowel and good filling capacity while maintaining a low pressure, as described by Studer et al. (19,20,37,42,48,49). Data of 935 RARC patients from the International Robotic Cystectomy Consortium comparing IUD versus extracorporeal urinary diversion (EUD) demonstrated that IUD was performed in 167 (18%) patients (IC = 106 [11%], neobladder = 61 [7%]) and EUD in 768 (IC = 570 [61%], neobladder = 198 [21%]) patients. Of the 18 institutions' members of the Consortium, 10 performed the UD solely by open approach. Interestingly, the operative time (414 minutes), estimated blood loss, and hospitalization were not significantly different between IUD and EUD. However, the 30-day (5% versus 15%, $P < .001$) and 90-day (12% versus 19%, $P = .016$) readmission rates and the 90-day (1.6% versus 4.9%, $P = 0.043$) mortality rate were lower for the IUD group. On multivariable logistic regression analysis, the type of UD (continent versus conduit) was a predictor for the likelihood of a complication (odds ratio: 1.5 [95% CI], $P = .04$) but the location of UD (intracorporeal versus extracorporeal) was not (odds ratio: 1.04 [95% CI], $P = .859$) (46).

Some authors use titanium staples to create laparoscopic or robotic neobladders (39,41,50,51). The use of staplers may facilitate creating the reservoir and may save operative time. The main concern with this technique is the stone formation and functional outcomes of these reservoirs. In fact, Leslie et al. reported an 8% rate of stone formation in 983 patients with three types of orthotopic neobladders in open surgery (52). The results demonstrated a significant difference between the rate of stone formation between the T-pouch (9.6%) and Kock urethra (9.9%), when staplers were used, and Studer (4.8%), with the findings similar to other series (11,51). However, studies with a larger patient cohort and longer follow-up are needed to better evaluate RIUD using staplers.

COMPLICATIONS

Although RARC can be technically demanding, the rate of conversion to open surgery for RARC approaches zero, but combine it with IUD and this rate can approach 5% (37,53). RC is a major surgery and is associated with high complication rates regardless of its approach (38,42). It is difficult to compare postoperative complications among RC series because the patients are subjected to different types of UD, that is, intra- or extracorporeal and IC or OIN. Although a majority of studies report 30-day and 90-day postoperative complication using Clavien-Dindo system, there is a lack of standardization for reporting RARC complications (42,54,55). Overall, studies comparing RARC with ORC consistently demonstrated that RARC had less blood loss, required fewer blood transfusions, but were performed with a longer operative time. Furthermore, although there are differences among the studies, RARC is associated with superior, or at least not inferior, postoperative outcomes such as time to flatus; time to bowel movement; parenteral nutrition use; length of hospital stay; overall, minor or major complications; readmission rates; and perioperative deaths (9,10,26–28,56–59). These results were confirmed by a systematic review and meta-analysis of 962 patients that underwent RARC or ORC (59). A population-based study using the U.S. Nationwide Inpatient Sample compared the postoperative results of 1,444 ORC versus 224 RARC patients. The results demonstrated that the RARC group had fewer complications and deaths during hospitalization, with no statistically significant difference in length of stay. However, these results should be analyzed with caution because the characteristics of the tumors were not taken into account nor were the outcomes after the patients were discharged (10). Leow et al. (9) analyzed a population-based cohort of 34,672 ORC versus 2,101 RARC cases across 279 hospitals in the United States and reported that major complication rates were similar between the groups, but the RARC group presented with a 46% decreased risk for minor complications. Furthermore, the RARC group had shorter hospitalizations. Unfortunately, the study did not control for oncologic characteristics (9). Matched randomized prospective studies showed no significant difference between RARC and ORC patients regarding the length of hospital stay, postoperative complications, and mortality rate. However, due to the small number of patients analyzed, these studies have limited power for comparison (26–28). Ng et al. (58) compared 104 ORC versus 83 RARC patients and reported a higher complication rate for ORC versus RARC, 59% versus 41% ($p = 0.04$), respectively. The authors also reported a greater blood loss, transfusion rate, and longer hospital stay for ORC. They also found that the robotic approach was an independent predictor for fewer complications (58).

A study analyzing 939 RARC patients comprised from a multi-institutional international database reported that the majority of patients were men (80%) with an American Society of Anesthesiologists (ASA) score ≥3 (53%) and 47% had prior abdominal surgery. IC was the most performed UD (68%), and the UD was more frequently performed via the open approach (77%). The mean estimated blood loss and hospital stay were 400 mL and 8 days, respectively. Blood transfusions were required in 15% of patients. Within 90 days after surgery, 48% of patients experienced complications, 20% were readmitted, and 4.2% died. The most frequent complications were gastrointestinal (27%), followed by infection (23%), genitourinary (17%), and cardiac (10%). Increasing age, neoadjuvant chemotherapy, and blood transfusions were independent predictors for any and high-grade complications (42). It is noteworthy that body mass index, ASA score, comorbidity, and operative time have also been reported as independent predictors for postoperative complications (13,14,46,54,58). Two studies, from the same group, used a similar cohort of 196 and 209 RARC with EUD patients and found on multivariable analysis that orthotopic UD is an independent predictor for major complications (54,55). They found that patients undergoing IC had a decreased likelihood of complications compared to patients whom either had an Indiana pouch or an OIN substitute diversion despite the selection of a more comorbid population for IC (55).

LEARNING CURVE

Some studies have assessed the learning curve for RARC (60–62). Guru et al. (62) evaluated 100 consecutive cases of RARC and reported that the operative time decreased until the 16th case, where a plateau was reached. Pruthi et al. (61) demonstrated that oncologic results are satisfactory beginning with the first case in a series of 50 RARC cases and that the operative time and estimated blood loss both improved up to the 30th case, where significant differences were no longer observed. Hayn et al. (60) analyzed the learning curve for RARC by reviewing the data from 496 patients from 14 institutions consisting of 21 surgeons with prior experience for robotic-assisted radical prostatectomy. The authors divided the cases into three groups according to the experience of surgeons with RARC: those who performed <30, 30 to 50, or >50 RARC cases. They reported that the operative time decreases and the node yield increases with the surgeon's experience. They also estimated that 30 cases was an acceptable number for proficiency in performing RARC (60).

Azzouni et al. (63) reported on an initial experience of 100 consecutive cases of robot-assisted intracorporeal IC. The authors divided the patients into four groups of 25 and reported a statistically significant decrease in the UD time (140 to 103 minutes, *P* = .002) but a statistically significant increase in both the length of hospitalization (7 to 9 days, *P* = .014) and transfusion rate between the groups (from 0% to 24%, *P* = .025). No statistically significant difference was observed in total operative time or complications rate between the groups. This is in contrast to a study that evaluated the learning curve for RARC with RIUD in 45 patients divided into three groups. It found a reduction in complications, operative time, and length of hospital stay throughout the series. There was no significant difference in the number of nodes yielded or PSM rate (64).

QUALITY OF LIFE

RC significantly impacts all aspects of life, from financial impact to overall mental and physical well-being (65). As RARC gains popularity and becomes an accepted alternative for treatment of BCa, there is limited data available regarding the quality of life (QoL) for patients undergoing this burdensome surgery. Because of its recent advent, the reports within the literature discuss only the short-term impact (less than 1 year), and to date, no study demonstrates the long-term effects of RARC on QoL (66,67). Stegemann et al. (66) reported the short-term (90 days) health status for 91 RARC patients measured using the Convalescence and Recovery Evaluation (CARE), which encompasses four domains: pain, gastrointestinal, cognition, and activity. They found that RARC patients approached preoperative baseline levels within 90 days using the CARE in the total CARE, pain, cognition, and activity domains but not for the gastrointestinal domain. Poch et al. (67) used the Bladder Cancer Index and the Body Image Scale to determine the short-term QoL outcomes after RARC for 43 patients. They found that RARC patients were able to recover both the urinary and bowel domains in less than 6 months, but the body image perception and sexual function domains required more than 6 months and more than 16 months, respectively.

COSTS

The costs of a complex operation such as RARC can certainly be a limiting factor for many institutions. Assessing the cost of RARC is challenging because it can be influenced by several factors: logistical costs of operation, use of the robot, surgical equipment, operative time, hospital stay, complications, total recovery time, and long-term functional and oncologic outcomes, to name a few. Studies have shown that when compared to ORC, the direct cost for RARC is higher, and the higher cost of RARC is related to the supplies (9,10,68). However, when considered as a whole, RARC may be more cost-effective than ORC (69–71).

FINAL CONSIDERATIONS

As mentioned earlier, although RARC presents perioperative advantages in comparison to ORC, the length of hospital stay and postoperative complications still need to be improved. We advocate that decreasing operative time and using protocols such as ERAS are important targets to improve perioperative outcomes after RARC. Currently, there are no reports within the literature for the use of ERAS after RARC; however, the reports for ORC are encouraging (72). Another promising approach to decrease operative time and morbidity related to RARC is the use of bioengineered tissue for the UD. Preclinical results are encouraging and phase 1 clinical trials are ongoing (73–75).

PARTIAL CYSTECTOMY, URACHAL EXCISION

The urachus is a vestigial fibrous cord derived from involution of the allantois that extends from the bladder apex to the umbilicus and forms the median umbilical ligament. Urachal remnant is a rare congenital anomaly, with an incidence of 2:300,000 in infants and 1:5,000 in adults. Traditional surgical management of benign urachal disease involves the radical excision of all anomalous tissue with or without a cuff of bladder tissue via the open approach (76). Urachal carcinoma accounts for <0.5% to 2% of all bladder tumors and approximately 40% of vesical adenocarcinomas.

Patients with resectable tumors traditionally underwent en bloc cystoprostatectomy and wide excision of the urachus and umbilicus. Extended partial cystectomy and umbilectomy provide survival rates comparable to those of radical cystectomy (77). The surgical approach has leaned more toward bladder sparing because published reports have not shown an advantage compared to radical surgery (78).

Surgical Techniques

Urachal Adenocarcinoma

Patient preparation, positioning, and port placement are similar to those previously described for RARC (79,80). The peritoneal and preperitoneal tissue between the medial umbilical ligaments is dissected free of the transversalis fascia. The dissection must include an extensive resection of the peritoneum lateral to the two medial umbilical ligaments, which defined the lateral limits, the posterior sheath of the rectus muscle of the abdomen to the arcuate line and the muscle fibers of the rectus muscle below it, the extraperitoneal fat in the space of Retzius as the anterior limit, the urachus up to the umbilicus superiorly, and sparing the umbilical skin.

The bladder is distended with 200 mL normal saline to facilitate the mobilization and dissection. The junction of the solid tumor with the bladder is determined on the anterior aspect by inflating and deflating the bladder, and a cystotomy is made. The excision of the bladder dome is performed with a 2-cm margin of normal mucosa. The specimen is enclosed within the Endo Catch bag and placed in the right iliac fossa. The bladder is closed in two layers using absorbable sutures.

Bilateral extended pelvic lymphadenectomy is performed as described in the RARC section. The three specimens (the resected tumor and two lymphadenectomy specimens) are removed in separate bags through the supraumbilical port.

Urachal Remnants

The patient is placed in a supine position and a Foley catheter is inserted in the bladder. Three trocars are generally used: the 12-mm camera port is placed in the midline above the umbilicus and two 8-mm robotic trocars are placed on either side, lateral to the rectus muscle. There are several other possible trocar placements as well (81,82).

The medial umbilical ligaments are clipped and divided. The peritoneal and preperitoneal tissue between the medial umbilical ligaments is dissected free of the transversalis fascia. Dissection is carried along the preperitoneal plane toward the umbilicus, surrounding the cyst. The cephalic side of the lesion is ligated at the umbilicus and divided. The umbilicus is usually not excised. The bladder is filled via the urethral catheter and the cuff is removed. The specimen is placed in a laparoscopic bag and removed by the 12-mm port site. The bladder defect is closed using 4-0 and 3-0 running suture.

ROBOTIC BLADDER DIVERTICULECTOMY

A bladder diverticulum is a herniation of the bladder mucosa as a result of bladder outlet obstruction. Bladder diverticulectomy (BD) has been performed using several approaches, such as open, laparoscopic, or robotic (83–85). An endolaparoscopic approach combining laparoscopic diverticulectomy with transurethral resection of the prostate (TURP) provided decreased blood loss, postoperative analgesic requirement, and shorter hospitalization compared to open surgery (83–87). Limited reports exist as regard to robotic bladder diverticulectomy (RBD) with approximately 44 cases reported to date (86). We describe the surgical technique of transperitoneal extra- and transvesical RBD.

Surgical Technique

Patient’s position and ports placement are similar to RARC described earlier.

Extravesical Approach

Once the bladder is filled with saline, the peritoneum over the diverticulum is incised under direct visualization (0-degree lens). The diverticulum is dissected circumferentially to its neck using blunt and sharp dissection. A cystotomy is made at the neck of the diverticulum and the diverticulum is excised and is placed in an Endo Catch bag for later retrieval. The scope is then advanced toward the cystotomy and the bladder is surveyed to ensure no injuries to the ureteral orifices (UOs). The ureteral catheter is removed and the cystotomy is closed in two layers. A Jackson-Pratt drain is placed, the ports are removed, and the specimen is retrieved.

Transvesical Approach

This is the preferred approach for many BDs that are large or close to the UOs. Once the bladder is filled with saline, a midline cystotomy is performed. The cystotomy edges are laterally retracted using stay sutures. The UOs are identified and the neck of the diverticulum is scored. The Foley catheter tip is advanced into the diverticulum, the balloon is inflated, and the diverticulum is filled with saline. The diverticulum is dissected to its neck from outside the bladder. The bladder mucosa at the diverticulum neck is incised, and the diverticulectomy and bladder closure are carried out as described previously.

Concomitant Procedure

If a concomitant procedure is planned, a sequential approach is employed. For simultaneous robotic prostatectomy, an extravesical approach is used, and this is carried out first. For concomitant robotic simple prostatectomy (RSP), RBD is carried out first using a transvesical approach. This is followed by transvesical adenomectomy. The bladder is sutured at the end of the enucleation. For a concomitant TURP, the TURP is performed first, followed by RBD.

Postoperative and Follow-up

The patient is discharged with an indwelling 18Fr Foley catheter that is removed after cystogram on POD 7 to 8.

SECTION III ■ PROSTATE

Section Editor: SANDIP M. PRASAD

CHAPTER 29 ■ ANATOMY OF THE PROSTATE

JONATHAN PAUL MANLEY, EDWARD W. ROWE, AND CHRISTIAN ANDREAS BACH

Precise knowledge of prostatic anatomy is a prerequisite for successful surgical intervention involving the prostate, be it radical prostatectomy, transurethral resection of prostate, brachytherapy, or prostatic biopsy. Our understanding of prostatic surgical anatomy has evolved over time by looking at pathologic specimens, transrectal ultrasound, multiparametric MRI images, and last but by no means least the advent of laparoscopy and robotic-assisted surgery, which benefits from increased magnification and illumination.

EMBRYOLOGY

The prostate develops from the distal urogenital sinus (the ventral portion of the cloaca) under the influence of testosterone from the fetal gonads. Epithelial outgrowths from the prostatic urethra bud into the surrounding mesenchyme from week 10 of embryologic growth. These buds subsequently signal back to overlying epithelial cells, inducing prostatic ductal formation. By week 12, there are five groups of tubules that progress to form the lobar anatomy of the prostate (1–3).

GROSS ANATOMY

The normal prostate is a fibromuscular and glandular organ located within the male pelvis. It resembles an inverted pyramid, is approximately 20 to 30 mL in volume, and is 4 cm in length by 4 cm at it widest point. Commonly, the prostate is described as having an apex, the inferior limit, and a base on which the bladder rests. Throughout its length run the urethra and ejaculatory ducts. Related structures include the rectum and Denonvilliers fascia that lie posterior to the prostate and the paired seminal vesicles and ampullae of the vasa deferentia that lie posterolateral to the prostate and posterior to the bladder (Fig. 29.1).

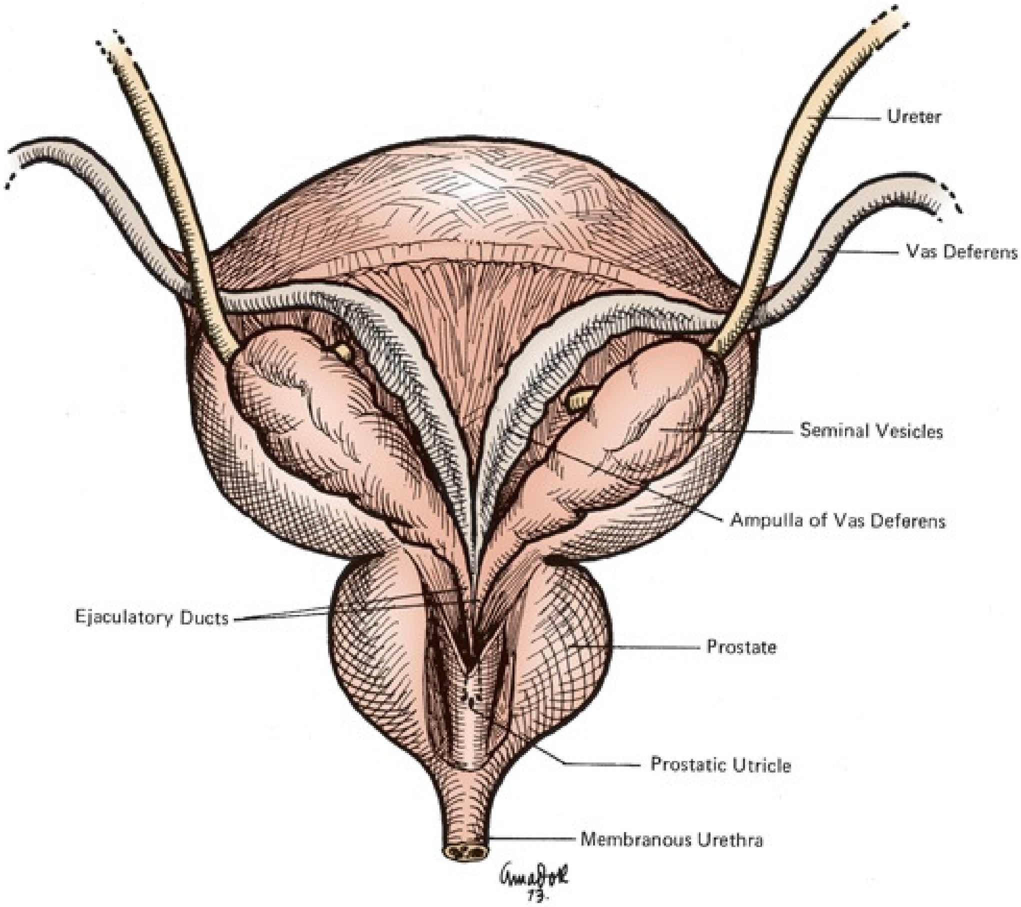

FIGURE 29.1 Relationship of the prostate and the seminal vesicles.

ZONAL ANATOMY

Historically, intraprostatic anatomy has been difficult to define. Previously, the prostate has been described as a lobar structure, most commonly with five lobes: two lateral, a median, a posterior, and an anterior lobe. The zonal intraprostatic anatomical structure proposed by McNeal (4), following microscopic examination of the prostate, is now widely accepted. The zones include the peripheral zone, transition zone, central zone, and periurethral zone and the anterior fibromuscular stroma (5). The peripheral zone is most posterior and is composed of long, branched glands from which the majority of carcinomas are thought to derive. The central zone consists of short glands from which prostatic hypertrophy is thought to arise (Fig. 29.2).

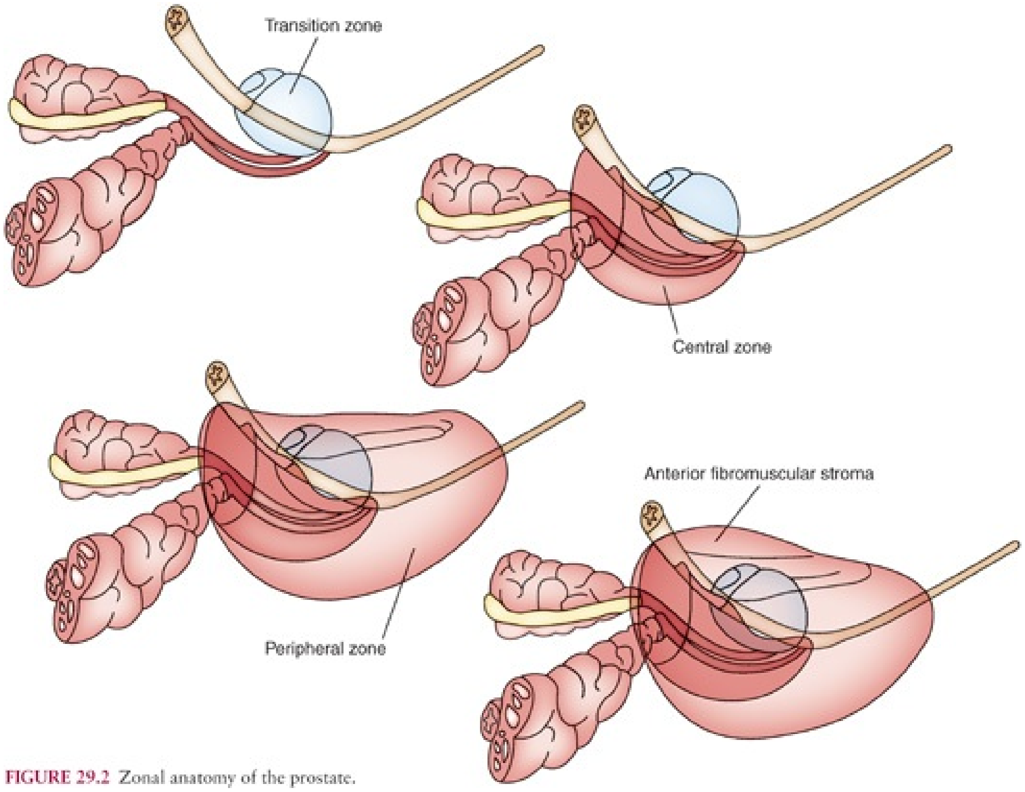

FIGURE 29.2 Zonal anatomy of the prostate.

The prostate is often described as having a “capsule”; however, it is not an anatomically discrete structure rather an aglandular fibromuscular layer contiguous and inseparable with the acini and parenchyma of the prostate. Surrounding this are the periprostatic fasciae, as described in the following section.

URETHRAL ANATOMY

The urethra traverses the prostate from bladder to prostatic apex (approximately 1 cm from the pelvic floor). The external sphincter may be visualized, on cystoscopy, as a ridge of urethral mucosa distal to the verumontanum. The verumontanum represents the terminal end of the ejaculatory ducts as they course through the prostate from seminal vesicles/vas deferens, and at this point, the urethra angles upward by approximately 45 degrees. The opening in the apex of the verumontanum is known as the prostatic utricle (a remnant of the müllerian duct) (6).

PELVIC FASCIAL ANATOMY

With recent advances in robotic pelvic surgery, we have gained a more comprehensive understanding of the pelvic fascia. Unfortunately, the nomenclature of pelvic fascia is not well standardized; to simplify things, the pelvic fascia may be divided into the parietal endopelvic fascia that primarily covers pelvic musculature and the visceral endopelvic fascia covering the pelvic organs.

The parietal endopelvic fascia covers the muscles of the pelvic wall and floor (piriformis, obturator internus, levator ani, and coccygeus) and joins the transversalis fascia and the periosteum of the hipbones. By fusing with the underlying visceral fascia, it forms a thickened structure; the arcus tendineus fascia pelvis (tendinous arch) stretching from the puboprostatic ligaments (PPLs) to the ischial spine (7,8). Ventrally, the proximal prostate is covered by muscle fibers originating from the bladder, forming a structure known as the “detrusor apron.” The prostate is stabilized and supported by the PPLs that form fibrous bands from the visceral endopelvic fascia to the posterior aspect of the pubic bone and anterior to the urethral sphincter. It is suggested that the PPLs play an important role in the suspensory system of the continence mechanism (9).

The visceral pelvic fascia invests the pelvic organs and neurovascular structures. It is attached anteriorly to the posterior surface of the pubis (forming the potential space—“the cave of Retzius”) and posteriorly to the ischial spine (7).

It may be subdivided into an anterior, lateral, and posterior (Denonvilliers) periprostatic fascia (8,10). The anterior periprostatic fascia covers the prostate, detrusor apron, and dorsal venous complex (DVC) fusing to the fibromuscular prostatic capsule at the anterior commissure (10). The lateral periprostatic fascia covers the lateral glandular prostate sweeping around to meet the posterior periprostatic fascia. The posterior periprostatic fascia separates the prostate from the rectum and forms an important barrier to the spread of malignancy. Medially, it fuses with the prostatic capsule; laterally, it is separated from the prostatic stroma by a thin adipose layer and the neurovascular bundles (NVBs) of Walsh.

A comprehensive understanding of periprostatic fascia in radical prostatectomy allows for decisions regarding the method of NVB resection (intra-, inter-, or extrafascial). It is suggested that the further from the prostate the resection (i.e., extrafascial dissection), the greater likelihood of a safe oncologic margin, however, the greater chance of erectile dysfunction (4,11) (Figs. 29.3 and 29.4).

VASCULAR AND NEUROLOGIC ANATOMY

The primary arterial supply of the prostate derives from the internal iliac arteries via the inferior vesical branch; however, other anatomic variants and accessory vessels include the internal pudendal, superior vesical, obturator, and middle rectal artery (12). It is suggested that accessory pudendal arteries may be present unilaterally or bilaterally in 4% to 75% of the population. If these aberrant vessels are the sole supply to the corpora cavernosum, then preservation during prostatectomy is required to preserve erectile function (13). The prostatic artery then divides into branches supplying the urethra, transition zone and periurethral glands (the arteries of Flocks), and those supplying the fibromuscular capsule (6).The capsular branches run alongside cavernous nerves to form the NVBs. Clear understanding of the NVB structure allows for “nerve-sparing” techniques improving functional outcomes postradical prostatectomy.

The pelvic plexus, located on the lateral wall of the rectum, contains sympathetic nerve fibers from the ganglia of T12–L2 responsible for emission as well as parasympathetic fibers originating from S2 to S4 that stimulate erection in the corpus cavernosum by causing vasodilatation. The majority of these nerve fibers travel laterally to the bladder neck and proximal prostate to coalesce as the NVB. The NVB runs distally within the periprostatic fascia toward the apex, where the NVB lie in the 2 and 10 o’clock positions, before piercing the pelvic floor to innervate the corpora cavernosa (8). Recent studies have shown that up to one-third of periprostatic nerve fibers run on the anterolateral aspect of the prostate, and as such, the “high release” and “veil of Aphrodite” robotic prostatectomy techniques are now used to preserve as many parasympathetic fibers and much erectile function as possible (14) (Figs. 29.5 and 29.6).

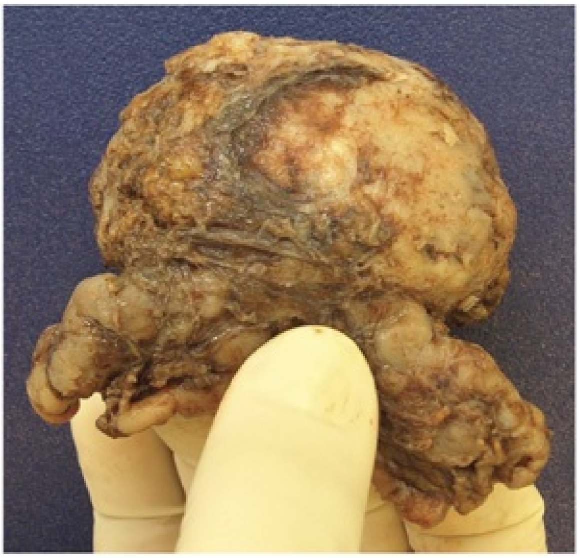

FIGURE 29.5 Prostatic specimen showing unilateral nerve spare. (Courtesy of Dr. John Oxley and Mr. Edward Rowe)

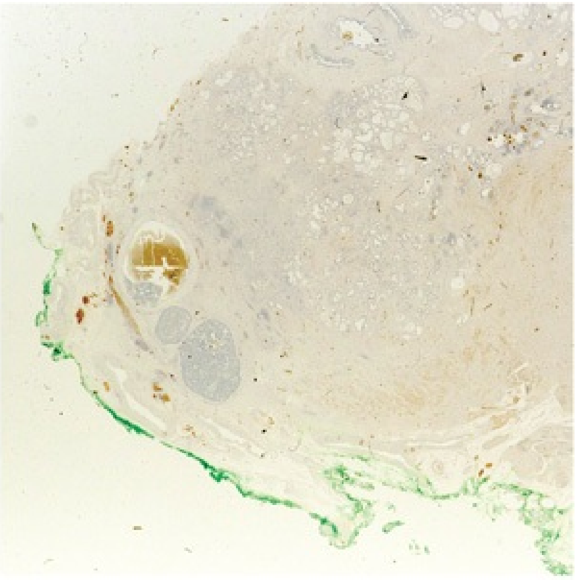

FIGURE 29.6 Prostatic histologic specimen stained for the neurovascular bundles. (Courtesy of Dr. John Oxley).

The prostatic venous drainage is by way of the DVC (Santorini plexus) to the internal iliac vein. The deep dorsal vein leaves the corpus cavernosus, travels under the pubic arch, and splits to form the superficial branch and two lateral branches. The superficial branch lies between the PPLs on the anterior surface of the prostate before piercing the fascia and joining the DVC. The lateral branches form plexuses that merge with the DVC around the bladder and rectum before draining via vesical and pudendal branches to the external iliac vein. An avascular plane is present at the prostatourethral junction between the prostate and DVC; this forms the landmark for DVC control during radical prostatectomy (15) (Figs. 29.7 to 29.9).

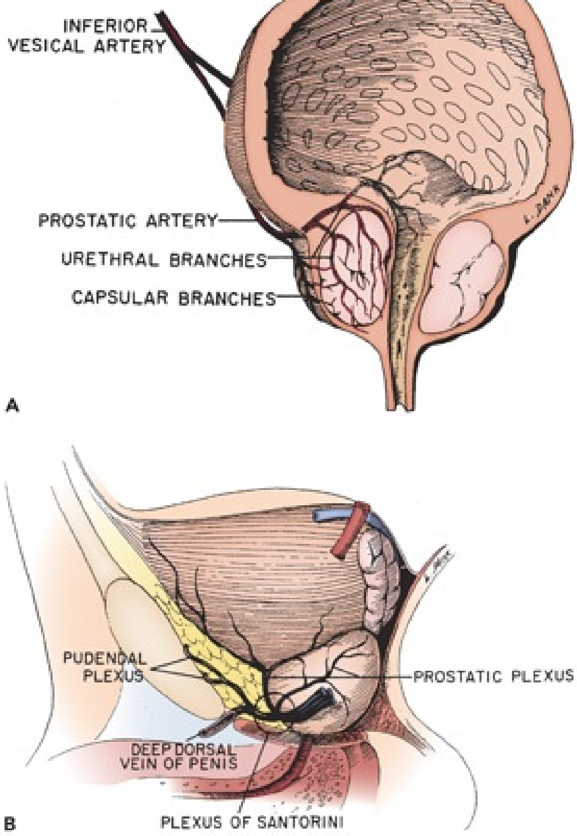

FIGURE 29.7 Vascular anatomy of the prostate. **A:** Arterial anatomy. **B:** Venous anatomy.

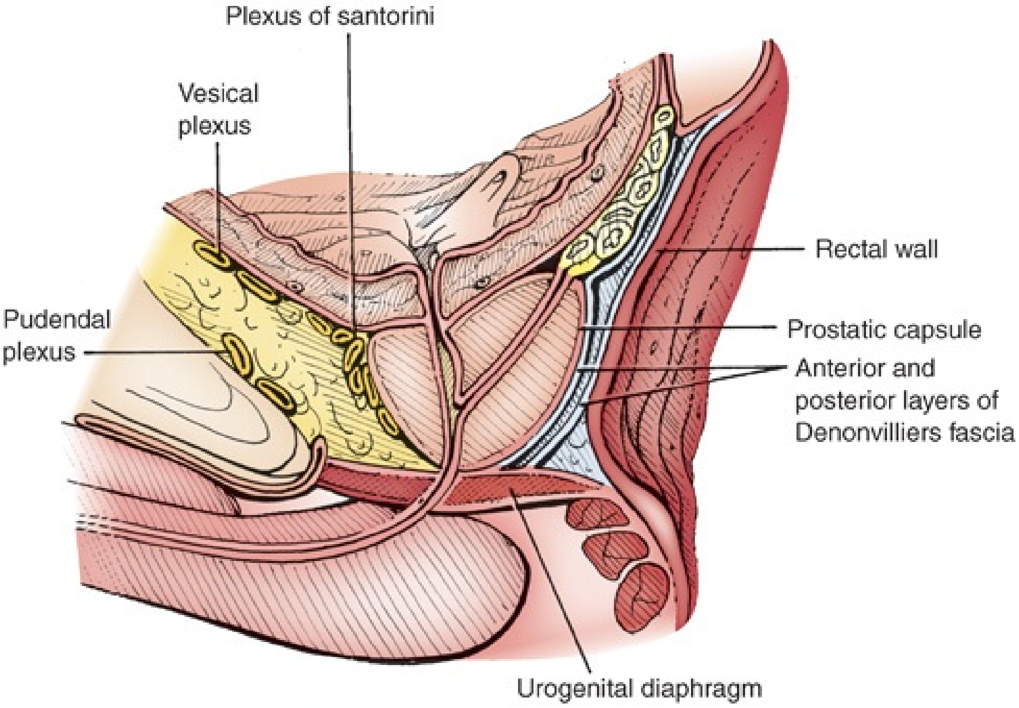

FIGURE 29.8 Relation of prostate to surrounding structures.

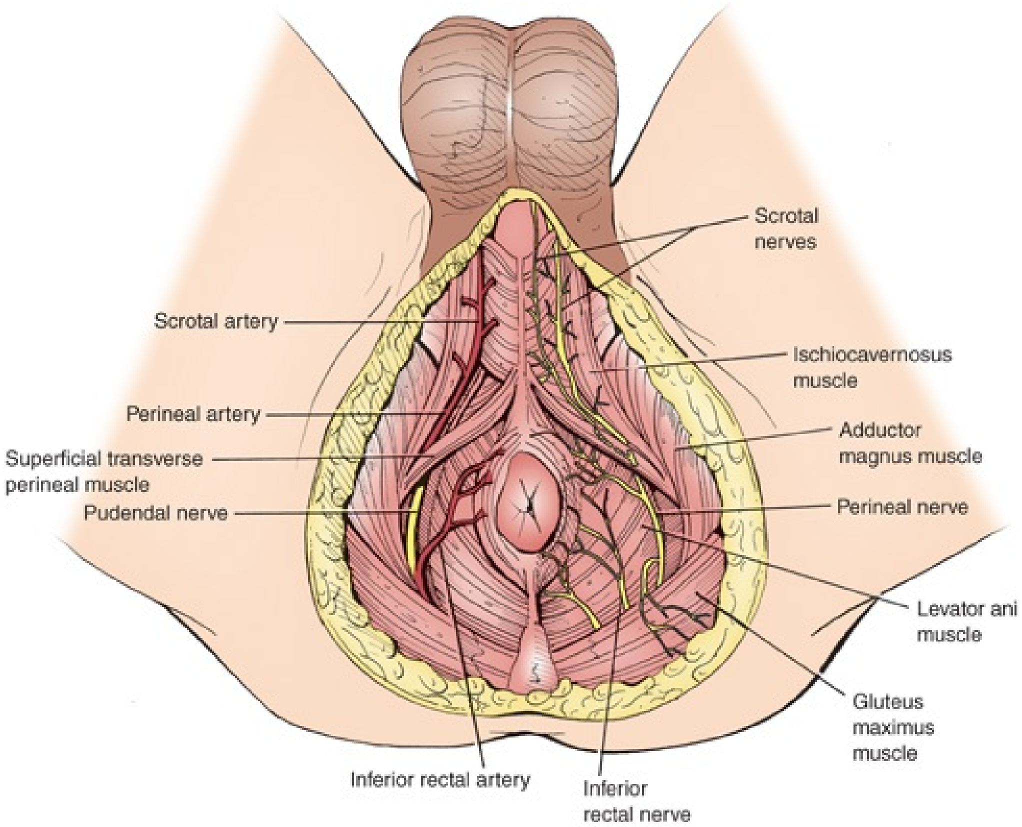

FIGURE 29.9 Pelvic nerves and musculature.

LYMPHATIC ANATOMY

The predominant lymphatic drainage is along the path of the prostatic artery to the obturator nodes. These nodes are located in a triangle bounded by the obturator nerve, the external iliac vein, and the femoral canal. Further drainage then occurs to the external iliac and common iliac nodes, with other potential metastatic sits including the external iliac and presacral nodes.

CHAPTER 30 SURGERY FOR BENIGN PROSTATIC OBSTRUCTION

MUSAAB YASSIN, SANDIP M. PRASAD, AND HASHIM HASHIM

Benign prostatic hyperplasia (BPH) is a histologic diagnosis that refers to the proliferation of smooth muscle and epithelial cells within the prostatic transition zone. The precise etiology is unknown (1–3). Lower urinary tract symptoms (LUTS) secondary to benign prostatic enlargement are thought to result from bladder outlet obstruction (BOO) from the enlarged tissue (static component) and from increased smooth muscle tone and resistance within the enlarged gland (dynamic component). Both of these would results in LUTS secondary to benign prostatic obstruction (BPO). Obstructive voiding symptoms (e.g., hesitancy, slow stream, intermittent stream) have often been attributed to BPO. Overactive bladder symptoms (e.g., frequency, urgency, nocturia) secondary to detrusor overactivity (a urodynamic diagnosis) is thought to be a contributor to the storage symptoms seen in LUTS secondary to BPO (LUTS/BPO) (3).

It has been reported that among 50-year-old men the lifetime incidence of surgical or medical intervention for BPO may be as high as 35% (4). Wasson et al. (5) found that in a 3-year, multicenter, randomized controlled trial (RCT) comparing men with moderate LUTS/BPO treated by either watchful waiting or transurethral resection of the prostate (TURP), 24% of men in the watchful waiting arm eventually underwent surgical intervention.

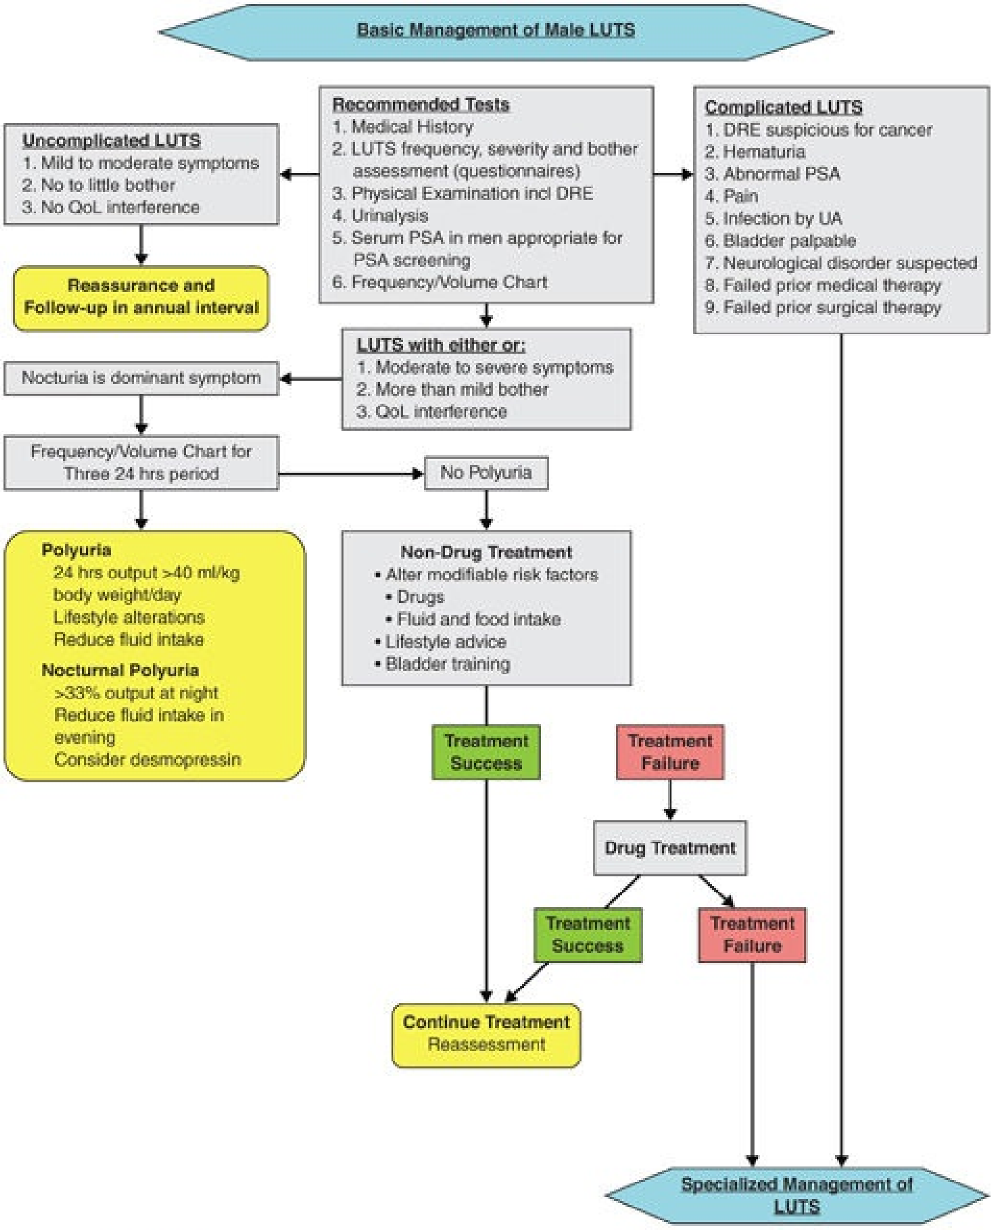
Although LUTS/BPO is not often a life-threatening condition, its impact on quality of life (QoL) can be significant and should not be underestimated (6). The most important motivations for seeking treatment were the severity and the degree of bother associated with the symptoms. These were also important considerations when assessing BPO and deciding when treatment is indicated (3).

It is necessary as health care professionals to be aware of the complex dynamics and interactions of the bladder, bladder neck, prostate, and urethra and their effect on patients’ symptoms (3). Recently, the treatment was more focused on the alteration of disease progression and prevention of complications that can be associated with LUTS/BPO in addition to the traditional approach of improving bothersome LUTS (7). A variety of conservative and pharmacologic treatments are employed including alpha-adrenergic antagonists (alpha-blockers), 5-alpha-reductase inhibitors (5-ARIs), anticholinergics, and phytotherapeutics (3) before surgical therapy is considered.

Surgical management of BPO has evolved significantly along with changes in medical management. A century ago, open prostatectomy was considered the standard surgical treatment of men with LUTS/BPO requiring removal of the adenoma. Subsequently, TURP was developed and became the first significant “minimally invasive surgical procedure.” More recently, a number of alternative surgical therapies have been introduced to treat men with BPO, most prominently laser-based therapies.

DIAGNOSIS

The American Urological Association (AUA) published their 2010 guidelines on the management of LUTS/BPO. A basic evaluation should be performed on every patient presenting to a health care provider with LUTS (Fig. 30.1 and Table 30.1). A validated questionnaire, such as the AUA Symptom Index or the International Prostate Symptom Score (IPSS), will better quantify the effect of patients' LUTS on their QoL.



Basic Management of Male LUTS
Recommended Tests
1. Medical History
2. LUTS frequency, severity and bother assessment (questionnaires)
3. Physical Examination incl DRE
4. Urinalysis
5. Serum PSA in men appropriate for PSA screening
6. Frequency/Volume Chart
Uncomplicated LUTS
1. Mild to moderate symptoms
2. No to little bother
3. No QoL interference
Reassurance and Follow-up in annual interval
Complicated LUTS
1. DRE suspicious for cancer
2. Hematuria
3. Abnormal PSA
4. Pain
5. Infection by UA
6. Bladder palpable
7. Neurological disorder suspected
8. Failed prior medical therapy
9. Failed prior surgical therapy
LUTS with either or:
1. Moderate to severe symptoms
2. More than mild bother
3. QoL interference
Nocturia is dominant symptom
Frequency/Volume Chart for Three 24 hrs period
No Polyuria
Polyuria
24 hrs output >40 ml/kg body weight/day
Lifestyle alterations
Reduce fluid intake
Nocturnal Polyuria
>33% output at night
Reduce fluid intake in evening
Consider desmopressin
Non-Drug Treatment
• Alter modifiable risk factors
• Drugs
• Fluid and food intake
• Lifestyle advice
• Bladder training
Treatment Success
Treatment Failure
Drug Treatment
Treatment Success
Treatment Failure
Continue Treatment
Reassessment
Specialized Management of LUTS

FIGURE 30.1 Basic management of lower urinary tract symptoms (*LUTS*) in men. The AUA guidelines on the management of LUTS/BPO in 2012 adopted the recommendations for diagnosis based on the 2005 International Consultation of Urologic Diseases and an article by Abrams et al. in 2009. *DRE*, digital rectal exam; *PSA*, prostate-specific antigen; *QoL*, quality of life; *UA*, urinalysis. (Adapted with permission from Chapple C, Abrams P. *Male Lower Urinary Tract Symptoms [LUTS]: An International Consultation on Male. Fukuoka, Japan, September 30 – October 4, 2013*. Montréal, Canada: Société Internationale d'Urologie and International Consultation on Urological Diseases, 2013.)

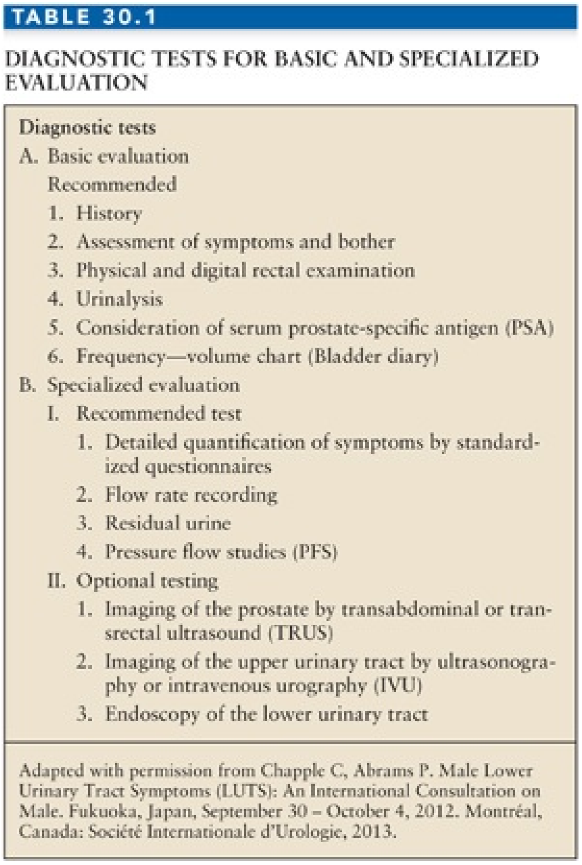


TABLE 30.1

DIAGNOSTIC TESTS FOR BASIC AND SPECIALIZED EVALUATION

Diagnostic tests

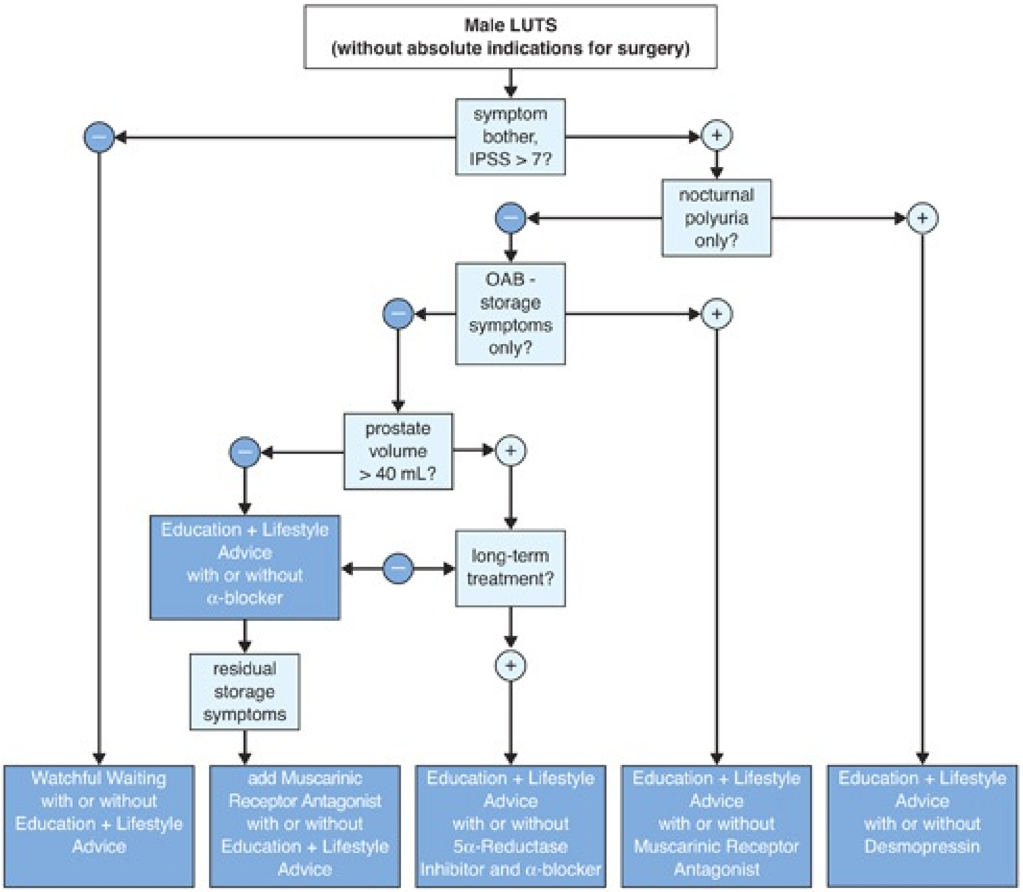
A. Basic evaluation
  Recommended
  1. History
  2. Assessment of symptoms and bother
  3. Physical and digital rectal examination
  4. Urinalysis
  5. Consideration of serum prostate-specific antigen (PSA)
  6. Frequency—volume chart (Bladder diary)

B. Specialized evaluation
  I. Recommended test
    1. Detailed quantification of symptoms by standardized questionnaires
    2. Flow rate recording
    3. Residual urine
    4. Pressure flow studies (PFS)
  II. Optional testing
    1. Imaging of the prostate by transabdominal or transrectal ultrasound (TRUS)
    2. Imaging of the upper urinary tract by ultrasonography or intravenous urography (IVU)
    3. Endoscopy of the lower urinary tract

Adapted with permission from Chapple C, Abrams P. Male Lower Urinary Tract Symptoms (LUTS): An International Consultation on Male. Fukuoka, Japan, September 30 – October 4, 2012. Montréal, Canada: Société Internationale d'Urologie, 2013.

CONSERVATIVE AND MEDICAL THERAPY

Following a thorough history, directed physical examination and assessment, conservative and medical therapy should be the initial treatments of choice. The medical treatment algorithms are described in Figures 30.2 and 30.3 (adopted from the European Association of Urology guidelines) but will not be discussed in this chapter.



Male LUTS
(without absolute indications for surgery)
symptom bother, IPSS > 7?
−
+
nocturnal polyuria only?
OAB - storage symptoms only?
prostate volume > 40 mL?
Education + Lifestyle Advice with or without α-blocker
long-term treatment?
residual storage symptoms
Watchful Waiting with or without Education + Lifestyle Advice
add Muscarinic Receptor Antagonist with or without Education + Lifestyle Advice
Education + Lifestyle Advice with or without 5α-Reductase Inhibitor and α-blocker
Education + Lifestyle Advice with or without Muscarinic Receptor Antagonist
Education + Lifestyle Advice with or without Desmopressin

FIGURE 30.2 Treatment algorithm of male lower urinary tract symptoms (*LUTS*) using medical and/or conservative treatment options. Treatment decisions depend on results assessed during initial evaluation. INDICATIONS FOR SURGERY

There are certain absolute indications for surgical treatment of LUTS/BPO (Table 30.2). Typically, however, the management of patients depends on the degree of inconvenience they experience from their LUTS. The AUA clinical guidelines on LUTS/BPO recommend that men who experience nonbothersome symptoms of BPO should not be managed surgically. Patients with bothersome symptoms should undergo treatment, and the physician should review the benefits and risks of all approaches and interventions with the patient.

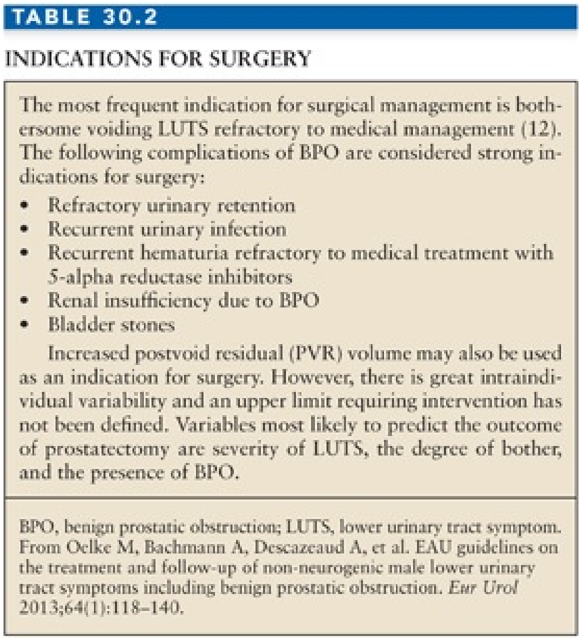

TABLE 30.2

INDICATIONS FOR SURGERY

The most frequent indication for surgical management is bothersome voiding LUTS refractory to medical management (12). The following complications of BPO are considered strong indications for surgery:

- Refractory urinary retention
- Recurrent urinary infection
- Recurrent hematuria refractory to medical treatment with 5-alpha reductase inhibitors
- Renal insufficiency due to BPO
- Bladder stones

Increased postvoid residual (PVR) volume may also be used as an indication for surgery. However, there is great intraindividual variability and an upper limit requiring intervention has not been defined. Variables most likely to predict the outcome of prostatectomy are severity of LUTS, the degree of bother, and the presence of BPO.

BPO, benign prostatic obstruction; LUTS, lower urinary tract symptom. From Oelke M, Bachmann A, Descazeaud A, et al. EAU guidelines on the treatment and follow-up of non-neurogenic male lower urinary tract symptoms including benign prostatic obstruction. *Eur Urol* 2013;64(1):118–140.

SURGICAL TECHNIQUES

There are several surgical techniques that can be considered for treating voiding LUTS/BPO. They can be divided into the following:

1. Minimally invasive therapy (MIT)
2. Endoscopic transurethral surgical treatments
3. Open surgical procedures
4. Laparoscopic or robot-assisted procedures
5. Investigational procedures

Minimally Invasive Therapy

MIT includes procedures that destroy or denature prostate tissue using a variety of energy sources, injected agents, or physical methods to draw open the prostatic urethra, that is, the procedures that do not lead to the physical removal of prostatic tissue. Laser prostate treatments are not included as they are generally used to remove tissue by ablation, resection, or enucleation (7).

The growing concern over the morbidity associated with treatment for BPO with TURP or open simple prostatectomy was a primary driving force behind the development of MIT approaches. These therapies typically are available for the treatment of patients with bothersome LUTS/BPO. Many of these minimally invasive treatments rely on the administration of high temperatures to produce coagulative necrosis of the prostate tissue. Ultimately, the goal of such hyperthermic treatment is to enlarge the prostatic fossa, similar to a surgical debulking but without the morbidity of surgery. However, these procedures are rarely done even in major North American and European centers.

Transurethral Microwave Thermotherapy

Transurethral microwave thermotherapy (TUMT) heats the prostate using a microwave antennae mounted on a urethral catheter and does not require cystoscopy except for initial measurement of prostatic length. This interventional therapy is effective in partially relieving the symptoms and bother believed secondary to BPO (3). The durability of TUMT treatment appears to have improved with the development of higher energy devices.

Practical Considerations. TUMT is likely more effective than medical therapy in reducing patients' LUTS, but it is likely less effective than surgical therapy. It is the least operator-dependent of the BPO interventions and predicting responders is difficult and inconsistent (3).

The view that these approaches lack sufficient durability of effect has resulted in a limited role of TUMT in the management of LUTS, despite potential advantages including outpatient capability, lack of sexual side effects, and avoidance of general anesthesia (3).

Transurethral Needle Ablation

Transurethral needle ablation (TUNA) affects prostate tissue by a thermal mechanism, with heat delivered via radiofrequency energy. Radiofrequency ablation (RFA) relies on the effects of passing electric current through tissue. This results in creation of lesions leading to coagulative necrosis. Initially, RFA was delivered as a monopolar technology in the form of TUNA of the prostate, but bipolar technology was subsequently developed (7).

A TUNA procedure involves cystoscopically placing two needles directly into the prostate by piercing the urethra and then administering radiofrequency energy that heats the prostate tissue to 100°C. As with microwave therapy devices, TUNA induces a coagulative necrosis effect. The efficacy of TUNA is comparable to that of microwave thermotherapy (8).

Practical Considerations. TUNA of the prostate is an appropriate and effective treatment alternative for bothersome moderate or severe LUTS/BPO (3). It is safe with low perioperative complications including bleeding. It has a low to nonexistent rate of sexual dysfunction and is attractive for that alone. Further surgical intervention is more likely to occur with TUNA compared with TURP, although the overall risk for morbidity clearly favors TUNA (3,7,9).

Endoscopic Transurethral Surgical Treatments

Electrosurgery

Transurethral Incision of the Prostate (TUIP) and Monopolar Transurethral Resection of the Prostate (M-TURP). The patient is placed in a dorsal lithotomy position, with the thighs abducted to allow manipulation of the resectoscope. After sterile preparation and draping is completed, the patient's anterior urethra is calibrated/dilated using Van Buren/Clutton sounds up to 30Fr. It is only necessary to calibrate the anterior urethra; excessive manipulation of the prostatic urethra may result in bleeding, which can make visualization difficult. Proper calibration is essential to reduce the theoretical risk of subsequent fossa navicularis or urethral stricture caused by the resectoscope manipulation, although some data suggest that the use of a urethral catheter postoperatively is the nidus for stricture (10). A 26Fr or 28Fr resectoscope is then inserted into the urethra. A 3% glycine or sorbitol solution is used for irrigation at gravity pressure. Cutting and coagulation currents should be adjusted to the appropriate levels for the electrical generator used for the case.

If the prostate volume is small (30 mL or less), the lateral lobes of the prostate are not coapting, there is no median lobe, and there is a high bladder neck, it may be appropriate to proceed with a transurethral incision of the prostate (TUIP), also known as bladder neck incision (BNI), especially in young, sexually active men (7). The bladder should be filled via the continuous-flow resectoscope, and with a TUIP-type electrocautery knife, incisions should be created and deepened until the capsule of the prostate is reached and extended just proximal to the verumontanum. The most popular unilateral incision is located at the 6 o'clock position, although the most commonly performed bilateral incisions are at the 5 and 7 o'clock positions (11).

If the prostate is more than 30 mL, or if there is a median lobe or the lateral lobes are coapting, a TURP is the more appropriate procedure to perform (Table 30.3). Monopolar transurethral resection of the prostate (M-TURP) is performed with an electrocautery loop and glycine or sorbitol irrigation. However, bipolar TURP devices have been developed that permit the resection of prostate tissue in a saline irrigant. If there is a median lobe present, resection should initially begin with this structure to allow the tissue resected later on from the later lobes to flow easily into the bladder. In a stepwise fashion, the median lobe is resected with the electrocautery loop. Resection of the median lobe is complete when bladder neck fibers are visualized. Particularly during the resection of the median lobe, care should be taken to not damage/involve the ureteral orifices in the resection.

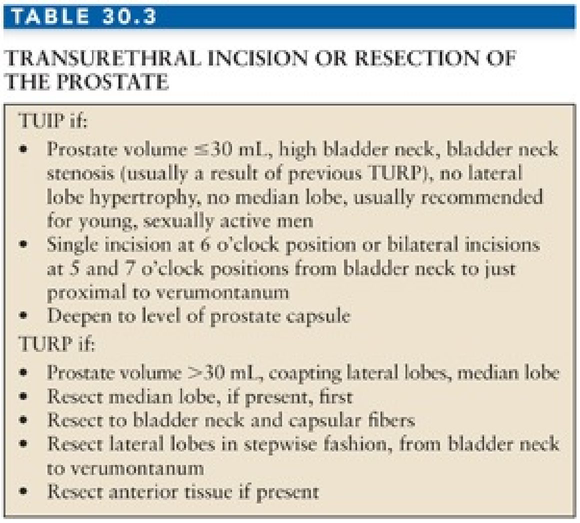

TABLE 30.3

TRANSURETHRAL INCISION OR RESECTION OF THE PROSTATE

TUIP if:

- Prostate volume ≤30 mL, high bladder neck, bladder neck stenosis (usually a result of previous TURP), no lateral lobe hypertrophy, no median lobe, usually recommended for young, sexually active men
- Single incision at 6 o'clock position or bilateral incisions at 5 and 7 o'clock positions from bladder neck to just proximal to verumontanum
- Deepen to level of prostate capsule

TURP if:

- Prostate volume >30 mL, coapting lateral lobes, median lobe
- Resect median lobe, if present, first
- Resect to bladder neck and capsular fibers
- Resect lateral lobes in stepwise fashion, from bladder neck to verumontanum
- Resect anterior tissue if present

Following complete resection of the median lobe of the prostate, attention can be turned to resection of the lateral lobes. There are several methods of doing this, and the surgeon should be comfortable in adapting his or her technique based on the anatomy of the prostate. The authors start resecting the left lobe starting at the 1 o'clock position, creating a trench, and proceeding from the bladder neck to a point just proximal to the verumontanum. This allows the adenoma to fall medially and downward and separates from the capsule. Resection should be carried down to the fibers of the bladder neck and prostatic capsule. The right lobe of the prostate can be resected in a similar fashion. The surgeon should take care not to resect too deeply and perforate the capsule as well as not to resect beyond (distal to) the verumontanum because that can damage the external urethral sphincter and cause stress urinary incontinence.

Following complete resection of the lateral lobes, the anterior tissue of the prostate should be inspected. If obstructing tissue is present at this location, it may be resected. The Ellik evacuator can then be used to remove the resected tissue fragments, which should be sent for pathologic analysis. The prostatic fossa should be reinspected because oftentimes open blood vessels are more apparent following Ellik evacuation and additional obstructive adenoma may appear that needs further resecting. Hemostasis should be ensured at the end of the procedure and all prostatic "chips" must be removed from the bladder. If it is difficult to establish hemostasis with the loop electrode, a rolling-ball electrode can be used. A three-way Foley catheter should be placed at the end of the procedure, and the authors use a 22Fr, three-way catheter with a 30-mL balloon. Continuous bladder irrigation with saline is generally necessary overnight; if bleeding persists, the Foley catheter may be placed on gentle and temporary traction.

Practical considerations. The choice between TURP and TUIP should be primarily based on prostate volume, with prostates 30 mL being mainly considered for TUIP and prostates of 30 to 80 mL for TURP. The advantages of TUIP are reduced bleeding incidents, shorter operation time, avoidance of transurethral resection (TUR) syndrome if using M-TURP, minimal and shorter postoperative bladder irrigation, lower risk of retrograde ejaculation, and shorter times for catheterization and hospitalization. The disadvantages are a higher rate of symptom recurrence and the need for additional surgery (3,11).

Urinary tract infections should be treated prior to TURP or TUIP. Three systematic reviews favored the use of antibiotic prophylaxis which would significantly reduce sepsis and the need for additional antibiotics after TURP. There was also a tendency toward higher efficacy in favor of short antibiotic courses compared to a single dose (11,13,14).

The ideal irrigant fluid for transurethral resection would be minimally conductive to avoid current dissipation from the electrode and to maximize the current at its point of contact with the tissues. Furthermore, the fluid has to be harmless when absorbed in the intravascular space. Such a fluid does not exist.

The types of irrigant fluids commonly used are the following (15):

- Normal saline (conducts electricity and therefore is not suitable for use with monopolar current): It is the irrigant of choice for diagnostic procedures (including cystoscopy) and for bladder irrigation postoperatively. It is suitable for use with laser resection/vaporization as well as bipolar TURP.
- Glycine (1.5%) (poor electrical conductor and hence is used for conventional M-TURP electrosurgery): It is relatively hypotonic but not cytolytic and carries a risk of dilutional hyponatremia. Glycine is an amino acid that inhibits neurotransmission in the retina, spinal cord, and midbrain.
- Water (poor conductor and can be used for M-TURP): It is hypotonic compared with plasma, and there is a risk of dilutional hyponatremia if it is used for prolonged periods of time. In addition, it is cytolytic that has the disadvantage of causing hemolysis if absorbed during TURP.
- Ethanol monitoring is a fairly new method of assessing fluid absorption during TURP. By using an irrigating fluid containing a trace amount of ethanol, a pocket-sized breathalyzer can measure the patient's end-expiratory ethanol concentration. Ethanol 1% is the standard strength, although ethanol 2% offers higher sensitivity and is suitable for research purposes (16,17).

Bipolar Transurethral Resection of the Prostate. Bipolar transurethral resection of the prostate (B-TURP) exploits a specialized resectoscope loop that incorporates both the active and return electrodes. This results in a dispersal of the current flow in the body, which theoretically reduces the deleterious effects of any stray current flow. The loop can be used to resect tissue as well as coagulate, vaporize, and transect tissue. Because 0.9% sodium chloride solution is used as an irrigation fluid, the risk of TUR syndrome is virtually eliminated (3).

Both postoperative catheterization and hospitalization times were shorter with B-TURP compared to M-TURP; this was thought to be due to reduced bleeding associated with improved coagulation abilities. Postoperative storage symptoms, particularly dysuria, were less common with B-TURP. However, most of these results were trends favoring B-TURP rather than statistically significant differences (18,19). TUR syndrome has not been reported with B-TURP due to the use of physiologic saline irrigation fluid and reduced fluid absorption during the procedure (11,18,20).

Practical considerations. Although the long-term treatment efficacy of M-TURP is widely accepted, the associated morbidity of M-TURP has led to the development of alternative therapy modalities. The choice of a monopolar or bipolar approach should be based on the patient's presentation, anatomy, the surgeon's experience, and discussion of the potential risks and benefits (3,7,11).

To date, five types of bipolar resection devices have been developed, which differ in the way in which bipolar current flow is delivered to achieve the plasmakinetic effect. These include the plasmakinetic system (Gyrus), transurethral resection in saline system (Olympus), Karl Storz, and Wolf. The devices plasmakinetic enucleation of the prostate or the "mushroom" technique has been described with the plasmakinetic bipolar system (Gyrus ACMI, Olympus Corporation, Tokyo, Japan) using 0.9% saline solution as an irrigation fluid. Essentially, mucosa at the apical adenoma is incised close to the verumontanum from the 5 o'clock to the 7 o'clock position. These grooves are deepened to the level of the surgical capsule. The distal middle lobe is dissected from the surgical capsule by the resectoscope sheath tip, and the surgical capsule is identified. Denuded supply vessels and hemorrhage spots on the capsule surface are identified and coagulated using the bipolar plasmakinetic loop to block the blood supply to the lobe. The right and left lobes are enucleated with the loop with arrest of bleeding. Finally, the bladder neck and enucleated lobes hanging at the bladder neck are resected (21,22).

Laser Surgery

An understanding of the wavelength or crystal used to produce laser energy during surgery of the prostate is critical when determining the type of laser vaporization to use. This is because tissue interaction caused by laser energy varies according to the wavelength, applied energy, fiber architecture, and tissue properties. This also means that the clinical results of different wavelengths are not comparable. Non-thermal effects, known as "ablation," also result in tissue destruction. Functional results will therefore differ in terms of perioperative handling of different laser devices, including learning curve, debulking tissue, durability of results, and type of complications (11).

Several types of new generation lasers for prostate surgery have emerged during the last decade, including the holmium:YAG, potassium titanyl phosphate:yttrium aluminum garnet (KTP:YAG), thulium:yttrium aluminium garnet (thulium:YAG), light blue optics:yttrium aluminium garnet (LBO:YAG), and the diode lasers. Energy can be transmitted through a bare, right-angle or interstitial fiber. Each laser has wavelength-specified energy–tissue interaction. Prostatic tissue destruction results from both thermal and nonthermal effects (11).

Holmium Laser Enucleation of the Prostate and Holmium Laser Resection of the Prostate. Extensive short- and long-term data suggest that holmium laser enucleation of the prostate (HoLEP) remains the modern gold standard alternative to TURP and open prostatectomy. The salutary benefits of the complete removal of the transition zone result in consistent outcomes (7).

As the wavelength of the Ho:YAG laser is strongly absorbed by water, the area of tissue coagulation and the resulting tissue necrosis is limited to 3 to 4 mm beyond contact, which is enough to obtain adequate hemostasis (2). Peak power produces non-thermal, localized tissue destruction, resulting in precise cutting of prostatic tissue (11).

The patient is positioned in dorsal lithotomy as for a TURP. Following dilation of the anterior urethra with sounds, a 26Fr or 28Fr resectoscope is inserted into the urethra. The 550-μm end-fire laser fiber is placed through the laser bridge or laser-stabilizing catheter. Normal saline irrigant is used during the procedure, and the resectoscope should be configured to continuous gravity flow.

The technique of HoLEP duplicates the complete adenectomy provided by open or minimally invasive simple prostatectomy. This technique involves identification and dissection in the surgical plane between the adenoma and surgical capsule, and this can be accomplished in a variety of ways. The prostate can be enucleated in a two-lobe or three-lobe technique depending on surgical anatomy and surgeon preference. Once the adenoma has been enucleated, the lobes are displaced into the bladder where a tissue morcellator is then used to retrieve the specimen (7).

If there is a significantly enlarged median lobe, it is often most expeditious to enucleate this structure first, as this maneuver will provide more room to accomplish the lateral lobe dissection (Table 30.4). To enucleate the median lobe, the holmium laser should be set at an energy of 2 J and a frequency of 50 Hz. Two sulci need to be generated at the 5 o’clock position and at the 7 o’clock position (Fig. 30.4). Beginning at the level of the bladder neck in the 5 o’clock position, a groove is cut with the laser along the sulcus from the bladder neck to a point proximal to the verumontanum (Fig. 30.5). This groove is deepened to the level of the surgical capsule. Once accomplished, the process should be repeated at the 7 o’clock position (Fig. 30.6). The final step in the enucleation of the median lobe can then be initiated at a point just proximal to the verumontanum. The laser fiber is moved in a transverse fashion between the apical extent of the 5 and 7 o’clock grooves. As the distal portion of the median lobe begins to separate away from the capsule, the beak of the resectoscope should be used as a leverage point to assist in lifting the median lobe upward. Once the dissection has reached the level of the bladder neck, the most proximal attachments of the median lobe can be divided and the entire median lobe pushed into the bladder.

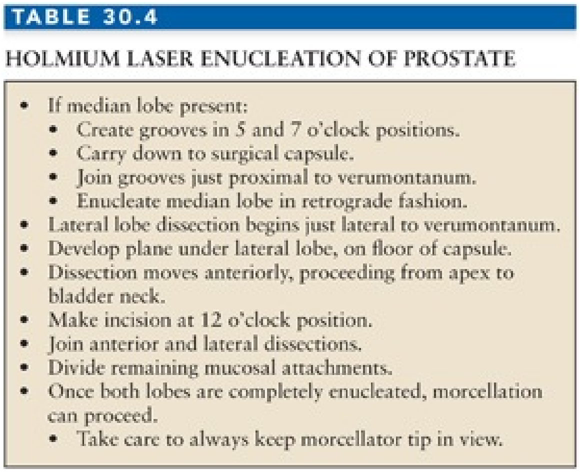

TABLE 30.4

HOLMIUM LASER ENUCLEATION OF PROSTATE

- If median lobe present:
  - Create grooves in 5 and 7 o’clock positions.
  - Carry down to surgical capsule.
  - Join grooves just proximal to verumontanum.
  - Enucleate median lobe in retrograde fashion.
- Lateral lobe dissection begins just lateral to verumontanum.
- Develop plane under lateral lobe, on floor of capsule.
- Dissection moves anteriorly, proceeding from apex to bladder neck.
- Make incision at 12 o’clock position.
- Join anterior and lateral dissections.
- Divide remaining mucosal attachments.
- Once both lobes are completely enucleated, morcellation can proceed.
  - Take care to always keep morcellator tip in view.

FIGURE 30.7 When no median lobe is present, a groove (broken line) is created in the 6 o'clock position.

Dissection of the right lobe is initiated by incising the mucosa lateral to the verumontanum in a transverse fashion, thereby exposing the adenoma near the apex. Once the initial plane is developed under the right lobe, dissection should proceed proximally toward the bladder neck, freeing the lateral lobe from the capsular floor. At some point, it will become apparent that the lateral attachments of the lobe impede dissection. At this point, the surgeon should detach the lateral most aspect of the right lobe, near the apex. During the apical dissection, the laser frequency should be changed to 40 Hz to prevent thermal injury of the urinary sphincter. The dissection should be continued until difficulty is encountered with exposure of the plane proximally. Attention should then be turned to the 12 o'clock region of the prostatic fossa, where the midline groove between the lateral lobes is located. The laser frequency should be readjusted to 50 Hz. Beginning at the bladder neck and proceeding distally, a groove is cut along this anterior position and should span from the bladder neck to the level of the verumontanum. Once the groove is created, it is again widened and deepened to the level of the surgical capsule along its entire extent. The right lobe should then be enucleated from the anterior aspect of the capsule by angling the tip of the laser fiber between the adenoma and the capsule. Capsular definition is often much easier at the bladder neck, so dissection should begin at that point. It is crucial to identify the extent of the remaining lateral attachments near the apex of the lobe. Once the junction between the planes is defined, usually by a mucosal strip or bridge, it is cut by the laser to join the planes. Laser settings should be adjusted to 2 J and 20 Hz during division of this mucosal strip. At this point, the right lobe will be held only by attachments at the bladder neck level. By following this plane further laterally, any remaining attachments in this area can be freed. Finally, one should proceed under the lobe and finish dividing attachments at the floor of the capsule and the posterior bladder neck. The lobe can then be pushed into the bladder by leveraging upward with the beak of the resectoscope. With complete enucleation of the right lobe, attention should be turned to the left lobe, which is enucleated as previously described for the right lobe. Once all lobes have been dissected free and pushed into the bladder, the capsular surface is then inspected carefully, and any bleeding sites should be addressed by defocusing the laser (positioning the tip of the fiber 2 to 3 mm away from the surface). A dry fossa is essential before beginning morcellation to optimize visualization and minimize the risk of bladder injury. The final aspect is to remove the enucleated adenoma by morcellation. The inner sheath of the resectoscope, along with the laser fiber and stabilizing catheter, is removed, and the rigid offset nephroscope is then inserted into the outer resectoscope sheath. Under direct visualization, the tip of the morcellator is inserted into the bladder and guided beneath a portion of adenoma. Once a portion of adenoma is engaged by the morcellator, it is important to keep the tip of the morcellator anteriorly within the bladder and within the visual field at all times to avoid bladder injury (23). The bladder should be kept full with continuous irrigating fluid when morcellation is being performed to reduce the risk of the morcellator catching the bladder wall and damaging that.

Practical considerations. Resection is usually performed when the prostate is smaller than 80 mL, whereas enucleation is used for larger glands. The basic principle of the holmium laser resection of the prostate technique is retrograde resection of the prostate and fragmentation of resected tissue inside the bladder to allow its evacuation through the operating channel of the resectoscope (11). With experience, HoLEP now allows patients with a very large prostate who would traditionally be treated with open prostatectomy to be treated endoscopically (7,24).

In prostates >100 mL, HoLEP proved to be as effective as open prostatectomy for improving micturition, with equally low reoperation rates at 5-year follow-up (11,25). One advantage of HoLEP is that with experience, there is no practical size limitation for its application. Significant improvements in symptoms and flow rate regardless of the size of the prostate have been reported (26). Furthermore, the rate of blood transfusion, catheterization time, and hospital stay did not depend on prostate size (25). Dysuria was the most common perioperative complication with an incidence of approximately 10% (7,11,27).

HoLEP is a cost-effective approach due to the reduction in nursing costs to manage bladder irrigation and clot retention due to the reduced risk for bleeding following surgery (28). Furthermore, the laser fibers and morcellator blades used during HoLEP are reusable, eliminating the costly disposals associated with most other surgical techniques for the treatment of BPO (7). Finally, there is virtually no thermal effect on the tissue, making it ideally suited for histologic examination (7,19)

HoLEP has been demonstrated to safely treat patients taking anticoagulant medication and men with urinary retention (11,29). It is important to realize that the technique is not easy to learn as traditional TURP, and the National Institute for Health and Care Excellence in the United Kingdom have recommended that HoLEP be performed only in specialized centers or with mentorship arrangements in place (30).

Laser Ablation of the Prostate: Holmium and Potassium Titanyl Phosphate. Laser ablation of the prostate employs laser energy to vaporize prostate tissue through the generation of temperatures >100°C. There are two lasers that are commonly used to ablate the prostate: the KTP land the Ho:YAG laser.

The KTP laser, also called GreenLight laser, consists of a 532-nm laser system that employs a high-powered green light visible wavelength. The laser energy can be fully transmitted through aqueous irrigants into the cell, where it is absorbed by hemoglobin, which is then rapidly heated, leading to vaporization of prostate tissue. The short optical penetration that is associated with this wavelength confines its high-power laser energy to a superficial layer of prostatic tissue that is vaporized rapidly and hemostatically with only a 1- to 2-mm rim of coagulation. The thin coagulation zone arises as a result of the quasi-continuous emission characteristics of the 532-nm laser. Typically, continual irradiation of a single point causes heat to diffuse into deeper tissue layers, creating coagulation wherever there is enough convection thermal energy for protein denaturation but insufficient energy for vaporization. These selective characteristics led to the use of the 532-nm laser in prostatectomy being coined “photoselective vaporization of the prostate” (PVP) (7). The Ho:YAG laser is a 100-W system that generates laser energy at a wavelength of 2,120 nm (infrared range), which is absorbed primarily by water and results in an optical penetration depth of 0.4 mm (7).

The current clinical PVP system is a 180 W–capable, 532-nm LBO (lithium triborate)–based laser system with a feedback mechanism to control energy with a water cooled redesigned high-power fiber. These modifications increase the potential vaporization efficiency of this laser. Subsequent modifications include an added coagulation power mode due to the intermittent pulsing and continuous flow of a room temperature irrigant over the tip of the laser fiber (31). However, at 120 W or greater, the higher efficiency seems to be obtained at the expense of hemostasis. This increased power and efficiency highlights a concern that if there was a misfire within the bladder at settings such as 180 W, there could be damage done to the bladder and ureteral orifices with the risk of rapid and potentially unrecognized bladder perforation (7).

Despite the different inherent attributes of the two laser energy sources, the fundamental technique of laser ablation is the same for both laser types. One of the inherent limitations of all laser approaches is that laser energy will desiccate the prostate tissue, ultimately impairing the tissue ablation as the procedure proceeds. With smaller glands, this may not be a meaningful issue; however, with larger glands, tissue desiccation will impede the effectiveness of ablation.

A side-firing laser fiber is used, with a 26Fr or 28Fr continuous-flow resectoscope configured with a laser bridge. Saline is the irrigant of choice. The resectoscope is passed into the bladder, and the locations of the ureteral orifices and verumontanum are confirmed. Laser ablation is a near contact procedure, meaning that the laser fiber should be maintained 1 to 2 mm away from the prostate tissue. The aiming beam and the side markings of the fiber should be identified. If a median lobe is present, this structure should be addressed first. The laser fiber is placed in close approximation to the median lobe tissue, and a slow, sweeping, rotating lateral motion of the laser fiber is performed while activating the laser energy. The tissue should be vaporized in layers, with a sagittal motion of the fiber, taking care to not vaporize the trigone or ureteral orifices. If a median lobe is not present, the laser should be positioned at the bladder neck in the 7 o'clock position, and the tissue should be ablated with a lateral sweeping motion until the fibers of the bladder neck are visualized. A groove should then be extended from the bladder neck to a point just proximal to the verumontanum. The groove should be deepened until capsular fibers are seen. A similar groove should be created in the 5 o'clock position, and then the tissue between the grooves should be ablated.

Returning to the 5 o'clock position, the tissue from this location up to the 1 o'clock position should then be ablated with a slow, continuous sweeping motion. Again, the laser should be maintained near the tissue but not buried into the tissue. Once the lobe is ablated, the contralateral lobe from the 7 o'clock position to the 11 o'clock position should be ablated in the same fashion. Bleeding vessels, most commonly encountered at the 5 o'clock and 7 o'clock positions, can be coagulated by defocusing the laser 2 to 3 mm away from the tissue or by using a lower energy setting. Following ablation of the prostate tissue and assurance of hemostasis, a Foley catheter should be placed. In general, bleeding is not significant, and continuous bladder irrigation is not typically required.

Practical considerations. Holmium laser ablation of the prostate (HoLAP) is suitable for small-to-moderate–sized prostates, but it is not efficient for larger prostate glands; it also generates no tissue specimen for histopathologic analysis (7,32).

HoLAP is an easier technique to learn then HoLEP with a shorter learning curve, but the procedure is rather slow (7,32).

In an RCT, PVP was as effective and safe as TURP for BPO, in particular for prostate sizes <70 mL (33). PVP was associated with less blood loss, lower rates of transfusion, decreased rates of capsular perforation, a lower likelihood of TUR syndrome, and shorter catheterization time and hospital stay, but longer operative length and higher rates of reintervention (34). Adverse sexual outcomes were significantly higher following PVP in larger glands above 70 mL in volume (35).

Thulium Laser Transurethral Vaporesection of the Prostate. Thulium laser transurethral vaporesection of the prostate (ThuVARP) uses a thulium YAG fiber to deliver light of 2,000 nm wavelength in a continuous-wave fashion to vaporize and resect prostatic tissue. Although a thulium laser has the same absorption characteristics as a holmium laser in water and tissue, it has superior properties in soft tissue surgery because of its continuous-wave output. Due to the slightly shorter wavelength, the depth of penetration is decreased to 250 µm (36). Instead of the tearing action on tissue caused by the pulsed emission of Ho:YAG, the continuous-wave output of Tm:YAG allows smooth incision and vaporization of tissue with excellent hemostasis (36). ThuVARP is a technique that resects the prostate in TUR-like tissue "chips." Although Thu:YAG is similar to the Ho:YAG with regard to hemostasis, vaporization capacity is significantly increased by the continuous-wave emitting mode. Therefore, tissue ablation is not only achieved by resection but also by simultaneous vaporization (36).

The ThuVARP "tangerine" technique (37) is so named due to its similarity to peeling a tangerine.

1. Make an incision bilaterally from the bladder neck at 5 and 7 o'clock to the verumontanum.
2. Deepen the incisions to the capsule.
3. Join the incisions at 5 and 7 o'clock, cutting transversely at the level just proximal to the verumontanum to the surgical capsule at 80W power.
4. After step 3 is completed, remove the median lobe.
5. Make a transverse incision at 1 o'clock in a direction from the bladder neck to just proximal to the sphincter.
6. Resect the left lateral lobes in small 'chips' by cutting in a semi-circular crescent curved motion

until the left lobe is resected to capsule. Use 120W power.

7. Repeat the same procedure on the right side.
8. Take small “chips” in a curvilinear manner.

ThuVARP is a safe and acceptable alternative to TURP for the treatment of symptomatic BPO (36). The technique has been shown to have good intermediate-term results when compared to TURP (37–42), although long-term symptom improvement and QoL gains are less quantified. The National Institute for Health and Research Health Technology Assessment in the United Kingdom has funded a trial to compare ThuVARP to TURP. Currently available data suggests that the advantages of ThuVARP are reduced blood loss, shorter hospital stay, earlier return to normal activities, shorter duration of catheterization, improved visualization during resection, and reduced incidence of TUR syndrome (43).

Practical considerations. ThuVARP uses the same resectoscope as TURP except for the need of an end-firing laser and bridge. ThuVARP showed equivalent efficacy when compared to TURP in one RCT and one nonrandomized prospective controlled trial with small- and medium-volume glands. Thu:YAG-treated patients had shorter duration of catheterization and shorter hospitalization times. Severe adverse events were significantly lower for ThuVARP compared with TURP (primarily, intraoperative and postoperative bleeding) (36). Because ThuVARP can be performed as an outpatient procedure, it carries the benefits of decreased cost due to avoidance of inpatient admission and associated issues (e.g., nosocomial infections).

Although ThuVARP is the most promising of all available laser prostatectomy techniques due to its sharing the same surgical skill set as TURP, unlike holmium (HoLEP), which has a steep learning curve.

The available clinical and preclinical experimental data suggests that Thu:YAG can be used in patients on anticoagulative drugs, similar to Ho:YAG, which has lower coagulative properties due to the pulsed energy application mode (36). Unlike KTP, ThuVARP can also retrieve prostatic tissue for histology.

Open Surgery (Prostatectomy)

Open prostatectomy is the oldest surgical treatment modality for LUTS secondary to BPO. Obstructive prostatic adenomas are enucleated using the index finger, either from the inside of the bladder (suprapubic procedure) or through the anterior prostatic capsule (retropubic procedure).

Suprapubic Prostatectomy

The patient is placed in a supine position, and the lower abdomen and genitalia are prepared and draped into the surgical field. A Foley catheter is placed into the bladder urethrally and secured into position. The initial approach is through a low midline incision or Pfannenstiel incision, and the fascia should be opened from the umbilicus to the symphysis pubis. The space of Retzius is entered, perivesical fat identified, and a self-retaining retractor positioned. The bladder should be identified and cleaned of anterior perivesical fatty tissue. The bladder should be filled to capacity by gravity. Stay sutures should be positioned in the detrusor just to the left and right of the midline, and a vertical incision in the bladder should then be created with electrocautery.

After opening the bladder, the intravesical component of the prostate should be identified. The ureteral orifices should be located, and to facilitate identification as the procedure progresses, they may be cannulated with 5Fr feeding tubes. To begin the enucleation process, an incision in the posterior aspect of the intravesical component of the prostate is made with electrocautery (Fig. 30.8). Care should be taken to ensure that the incision is safely away from the ureteral orifices and trigonal region. The capsule should be sharply freed from the adenoma, and the surgeon's finger can then be used to develop the space between the adenoma and the capsule (Fig. 30.9). By moving the finger in a lateral arc, this plane is extended down to the apical aspect of the prostate. Once the adenoma is completely freed from its attachments by this blunt dissection technique, it may be removed from the surgical field (Fig. 30.10). The prostatic fascia should be packed with sponges and pressure held for 5 minutes to aid in hemostasis. Absorbable 2-0 sutures should be placed in a figure-of-eight fashion at the 5 and 7 o'clock positions to control any blood vessels, which are typically encountered at these locations (Fig. 30.11). A 22Fr Foley catheter with a 30-mL balloon should be placed transurethrally (Fig. 30.12).

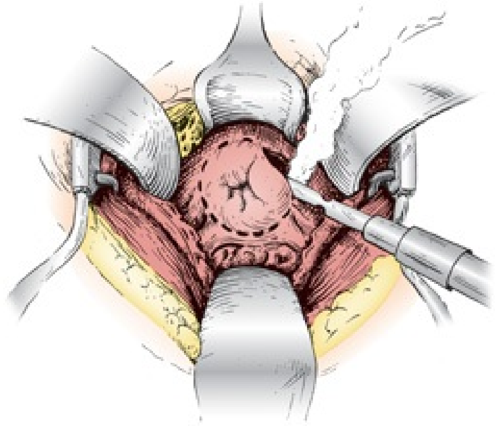

FIGURE 30.8 Incision of mucosa (dotted line) over the adenoma.

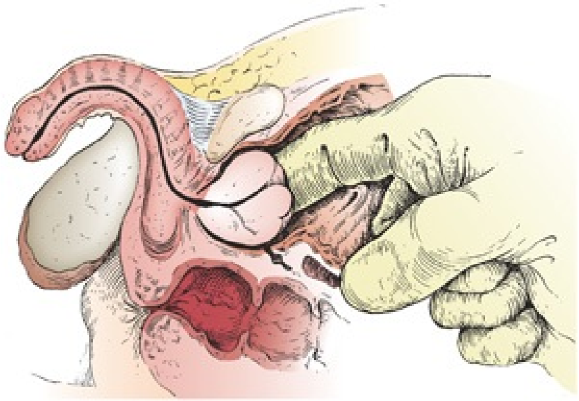

FIGURE 30.9 Digital enucleation of the adenoma.

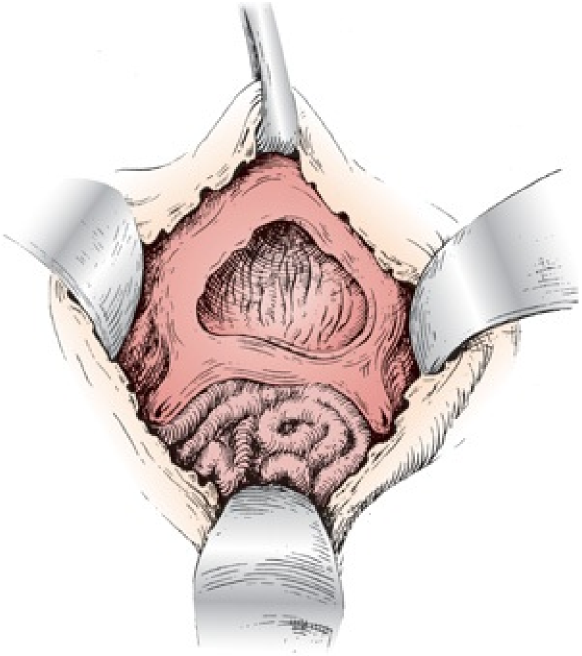

FIGURE 30.10 View of the empty prostatic fossa.

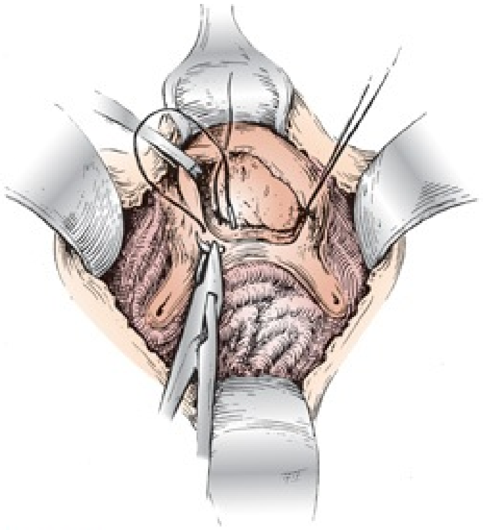

FIGURE 30.11 Hemostatic suture ligatures at the 5 o'clock and 7 o'clock positions.

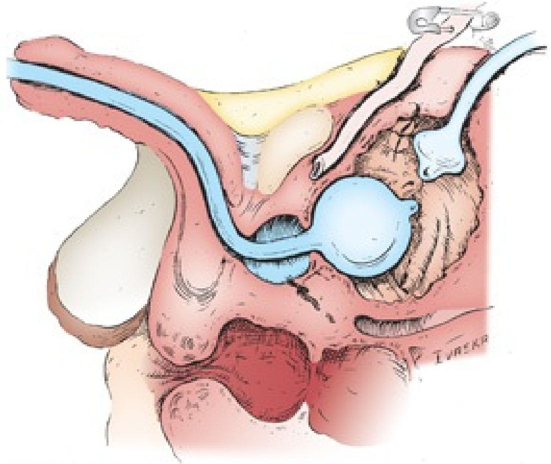

FIGURE 30.12 Foley catheter snug at the bladder neck: prevesical drain and suprapubic tube.

The bladder should be closed in two layers with running 3-0 and 2-0 absorbable suture. A suprapubic tube should be placed through the dome of the bladder, and the bladder subsequently closed around this tube in a purse-string fashion. A Penrose or Blake closed suction drain is then placed in the space of Retzius. The fascia is then reapproximated with the preferred fascial suture, and the skin is reapproximated with absorbable continuous suture or staples. The drains are sutured into place with 2-0 nylon suture. A continuous bladder setup using the suprapubic tube and the Foley catheter aids in maintaining patent drainage and minimizing blood clot formation.

Retropubic (Millin) Prostatectomy

The patient is placed in a supine position, and the lower abdomen and genitalia are prepared and draped into the surgical field. A Foley catheter is placed into the bladder trans-urethrally and secured into position. The initial approach is through a low midline incision, and the fascia should be opened from the umbilicus to the symphysis pubis. A Pfannenstiel incision can also be used. The retropubic space of Retzius is entered, perivesical fat identified, and a self-retaining retractor positioned. The fatty tissue overlying the bladder and prostatic capsule should be cleared.

At the midportion, on the outside of the prostatic capsule, 2-0 Vicryl sutures should be placed proximally and distally, to ligate the superficial blood vessels (Fig. 30.13). With electrocautery, an incision is created transversely between these two sutures (Fig. 30.14). A plane of dissection between the adenoma and the capsule should be bluntly created on either side of this incision (Fig. 30.15). The adenoma is progressively freed of its anterior, lateral, and posterior attachments with digital dissection. Following complete mobilization of the adenoma, its attachment to the membranous urethra can be sharply divided and the adenoma retrieved through the capsular incision; 2-0 Vicryl sutures should be placed in the 5 and 7 o’clock positions for hemostasis (Fig. 30.16). A 22Fr Foley catheter with a 30-mL balloon is placed, and the prostatic capsule is closed with 2-0 Vicryl sutures. A closed suction drain is placed in the space of Retzius; the fascia should be reapproximated with the surgeon’s preferred fascial closure suture, and the skin should be reapproximated with a continuous dissolvable subcutaneous suture or staples.

Practical Considerations. Open prostatectomy is an effective treatment alternative for men with moderate to severe LUTS who are significantly bothered by these symptoms secondary to BPO. The choice of approach should be based on the patient's individual presentation including anatomy, the surgeon's experience, and discussion of the potential benefit and risks for complications (3).

Current indications for open prostatectomy include large prostates for which the surgeon does not feel comfortable performing TURP and for which other techniques such as HoLEP are not available. The presence of coexisting conditions such as large bladder stones, inguinal hernias, and large bladder diverticula may dictate an open surgical approach (7).

Open prostatectomy is the treatment of choice for large glands (>100 mL). There is usually a longer hospital stay and a larger loss of blood associated with open procedures compared with minimally invasive or cystoscopic approaches (3). It is the most invasive, but also the most effective and durable, procedure for the treatment of LUTS/BPO. Only HoLEP delivers similar results and with less morbidity (44–46). In the absence of an endourologic armamentarium and a Holmium laser, open prostatectomy appears to be the treatment of choice for men with prostates greater than 100 mL and drug treatment–resistant LUTS/BPO (11). An alternative in big glands is to use a larger resectope and only resect one side of the gland with bipolar TURP, then assess the patient's symptoms. If still bothered then the other lobe can be resected at a later stage. In other words, offer a staged TURP procedure.

Total prostate-specific antigen (PSA) levels <1 ng/mL have been described following open prostatectomy, suggesting that the largest part of the preoperative PSA level is associated with the adenomatous tissue, with very little contribution of the peripheral zone of the prostate (7,47).

Laparoscopic or Robot-Assisted Procedures

With the adoption of robotic assistance in the management of prostate cancer through robot-assisted laparoscopic radical prostatectomy (RALP) in the past decade worldwide, the use of minimally invasive technologies in the management of large glands as an alternative to open prostatectomy or complex/multiple transurethral procedures. The first laparoscopic simple prostatectomy was performed in 2002 (48), and initial series demonstrated increased operative times but shorter hospital stay and time of catheterization (49) compared with open simple prostatectomy. A large multi-institutional series of minimally invasive simple prostatectomy in over 1,300 patients from 23 institutions demonstrated low transfusion rates (3.5%), intraoperative complications rates (2%), and conversion rates (3%) with significant 12-month improvements in IPSS (50).

Robot-Assisted Laparoscopic Simple Prostatectomy

In 2008, Sotelo and colleagues (51) demonstrated the feasibility of RALSP, and subsequent studies have demonstrated similar improvements in voiding compared with open simple prostatectomy but with longer operative time and shorter length of stay and decreased blood loss (50). The technique is still in evolution, and can be performed through a transperitoneal or extraperitoneal approach. One of the main limiting factors is cost-effectiveness. Below are the steps of performing the procedure.

1. The patient is placed in dorsal lithotomy position with all pressure points padded and supported. The patient is secured to the table and then prepped and draped. A 20Fr Foley catheter is placed sterilely on the field.
2. Access to the abdomen is obtained through Veress needle or Hassan technique (surgeon preference), and the abdomen is insufflated to a pressure of 15 mm Hg.
3. Port placement is similar to RALP, with a 12-mm camera port placed just above the umbilicus, three 8-mm robotic ports, and a 12-mm and 5-mm assistant ports (see Chapter 33).
4. Similar to RALP, the bladder is released by anterior incision of the peritoneum to expose the space of Retzius. A combination of sharp and blunt dissection is performed to expose the prostate.
5. Defatting of the prostate and prostatovesical junction is performed to visualize the bladder neck. Typically, the endopelvic fascia does not need to be opened, and the dorsal vein complex may be left intact, but some authors do advocate for these steps.

6. Once the bladder neck is identified, the anterior bladder neck is divided and the Foley catheter is removed.
7. Stay sutures may be placed into the median lobe for anterior retraction or the fourth arm may be used to retract the adenoma superiorly. In patients with bladder stones, the bladder neck incision is often widened to extract these successfully.
8. The initial incision is made at the junction between the adenoma and the bladder neck posteriorly, taking care to identify the adenoma enucleation plane within the prostatic capsule. This plane is taken laterally and apically with a combination of sharp and blunt dissection; if this dissection is performed in the correct plane close to adenoma, this step typically has little bleeding. Dissection is carried out in anterior, posterior, and lateral planes until the distal urethra is encountered.
9. The Foley catheter is replaced and the distal urethra is divided circumferentially sharply at the apex. The specimen is removed and placed into a laparoscopic specimen extraction bag.
10. Hemostasis can be achieved using monopolar and bipolar energy along with selective suture ligation of the prostatic pedicles if needed.
11. The mucosa of the bladder is advanced to the posterior urethra using a 3-0 Monocryl suture; this step may be useful in hemostasis and is similar to the Rocco stitch used in RALP in regard to technique.
12. The cystotomy is closed in two layer using 2-0 Vicryl suture, and a 20Fr two-way catheter is placed with 30 mL in the balloon. A Jackson-Pratt drain is placed in the retropubic space.
13. Specimen retrieval and port closure are performed in the standard fashion as following RALP (see Chapter 33).

RALSP can also be performed using a transvesical technique wherein the bladder is left suspended in its native anatomic orientation and a large transverse cystotomy is made directly into the dome of the bladder. This is an excellent approach when bladder stones are present and the remainder of the enucleation follows the approach discussed earlier with the camera and surgical instruments operating through the cystotomy, which is closed at the end of the procedure.

Investigational Surgical Procedures

Prostatic Urethral Lift

This new treatment involves drawing the prostatic urethra open using endoscopically implanted prostheses using a specially designed delivery system (52–55). The prosthesis is made of two metallic tabs connected by nonabsorbable suture material. One tab is positioned on the capsular side of the prostate and the other on the urethral surface, and the suture is placed under tension, thereby creating a compressing effect between the two tabs (Figs. 30.17 to 30.19). Usually, between two and four of these prostheses are placed on each prostatic lobe, and the procedure can be performed under local anesthesia with or without sedation in an ambulatory setting.

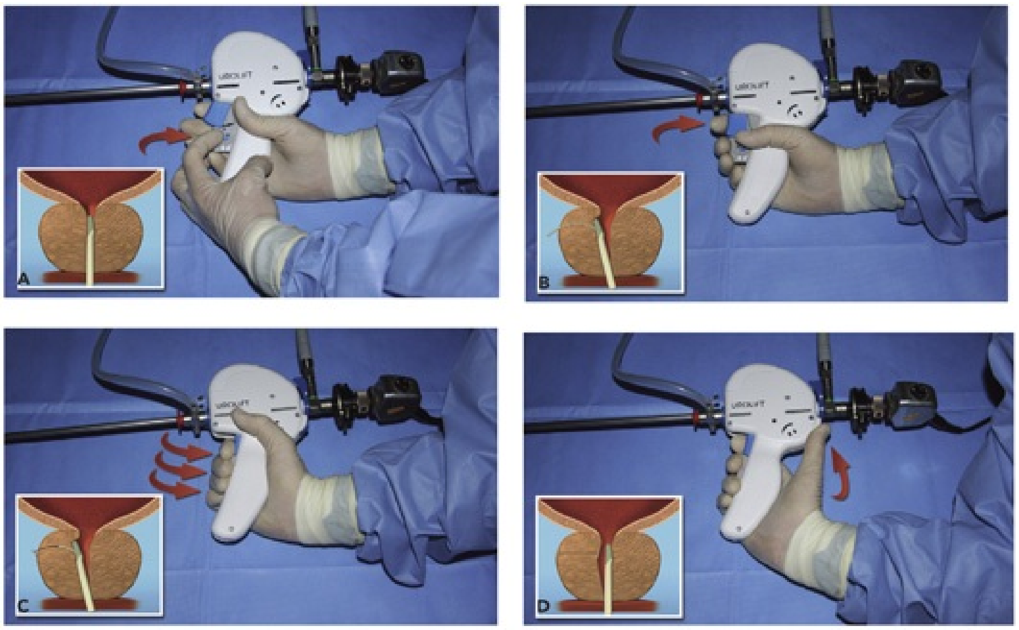

FIGURE 30.17 UroLift system delivery steps: (**A**) Release safety lock (red arrow); (**B**) deploy needle (red arrow); (**C**) retract needle, delivering capsular tab and tensioning monofilament (red arrow); and (**D**) attach urethral end piece and trim monofilament (red arrow). Contraindications (56)

1. The presence of a median lobe, as the prostatic urethral lift (PUL) is designed for lateral lobe obstruction only; for the same reason, patients with bladder neck obstruction are excluded.
2. PSA >10 ng per mL, a level which warrants a mandatory histologic examination.
3. History of urinary retention, decompensated detrusor, or compromised renal function, as these conditions make the tissue removal mandatory.
4. Concomitant urinary infection due to the risk of a colonization of the foreign body.

Practical considerations. Prostate size is important in patient selection for PUL. Although some data suggest that very large glands may be successfully treated with PUL, we recommend excluding patients with a prostate volume >50 mL, especially during the learning curve phase (55,56).

Preoperative evaluation of patients includes transrectal ultrasonography and cystoscopic examination to assess the dimension and the conformation of the prostate as well as laboratory tests including PSA and renal function determination with urinalysis (56).

The potential to treat a patient with PUL under local anesthesia on an outpatient basis, as well as the minimal learning curve with only one to two procedures required to be proficient and around five procedures to reach optimal implant placement (53), make this an attractive therapeutic option for the management of BPO (40). The reported 1-year IPSS improvement of 46% seems superior to the approximately 35% to 40% improvement usually achieved after a period of alpha blockers (57) and similarly superior to the 15% to 30% improvement usually achieved after a minimum of two treatments with 5-alpha reductase inhibitors (58). Conversely, these results are unparalleled to the 75% improvement in IPSS reported 1-year after traditional surgical intervention (e.g., HoLEP) (56,59). These clinically relevant improvements in urinary symptoms appear to be sustained in the short-to-medium term despite the limited data that has been published (7,53,54).

It has been shown that PUL does not compromise erectile or ejaculatory function (38), and the ideal candidate is a patient with interest in maintaining potency and with mild LUTS (56,60,61). RCTs are awaited for this procedure. The L.I.F.T. study demonstrated in a multicenter randomized blind trial that the PUL provided rapid and sustained improvement in AUASI and flow without compromise of ejaculatory or erectile function(62).

Botulinum Toxin A Injection into the Prostate

Botulinum toxin (BTX) is the exotoxin of the bacterium *Clostridium botulinum*. This toxin is the most potent neurotoxin known in humans. Experience with intraprostatic injections for the treatment of LUTS/BPO exists only for onabotulinum toxin A (BTX-A). The mechanism of action of BTX-A in the prostate is not fully understood. In addition to blocking the release of neurotransmitters from presynaptic nerves (63), BTX-A reduces LUTS by induction of apoptosis of prostatic cells, leading to tissue atrophy and prostate size reduction (64–67). BTX-A inhibits the sensory prostatic neurons and reduces afferent signals to the central nervous system (65), with relaxation of smooth muscle cells in the prostatic parenchyma and reduction of BPO (65,68). Downregulation of 1A-adrenergic receptors in the prostate may contribute to smooth muscle cell relaxation (66). The latter two mechanisms are summarized as chemical denervation that may have a negative influence on prostate growth (11).

BTX injection into the human prostate was first reported in 2003 (69) in a small randomized trial comparing BTX with saline injection into the prostate. These initial results at 2 months following treatment appeared promising, with a 65% reduction in symptom scores, a 51% decrease in PSA levels, and a 33% reduction in prostate volume. No side effects to BTX injection were reported (7).

BTX can be injected directly into the prostate using transurethral, transrectal, or transperineal approaches, although the transperineal technique under transrectal ultrasound guidance has been the most common approach (7).

Practical Considerations. BTX-A injections into prostatic parenchyma appear to be a promising and quick minimally invasive treatment modality with low morbidity for patients who are refractory to medical treatment or in urinary retention. Nevertheless, BTX-A has been injected into only a limited number of patients, and all trials have only short-term follow-up (11).

A small study looking specifically at sexual function in 16 sexually active men was unable to establish any impact of BTX treatment on erectile, orgasmic, or ejaculatory function (7,68). Based on the limited available data, botulinum injection treatment into the prostate for LUTS/BPO remains promising but experimental (7).

TREATMENT OUTCOMES

The ultimate assessment of the efficacy of a surgical treatment for LUTS/BPO is a measure of its treatment outcome (see Table 30.5 and 30.6). The AUA Clinical Guidelines Panel on LUTS/BPO assessed the literature on surgical therapies in order to define the treatment outcomes for particular interventions (3).

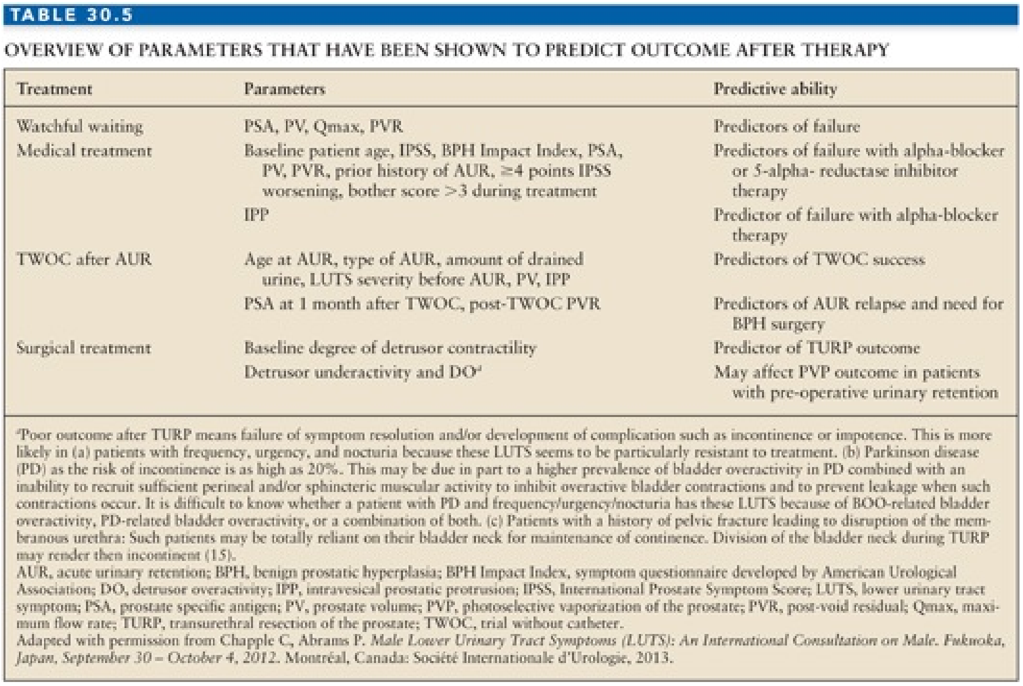

TABLE 30.5

OVERVIEW OF PARAMETERS THAT HAVE BEEN SHOWN TO PREDICT OUTCOME AFTER THERAPY

Treatment	Parameters	Predictive ability
Watchful waiting	PSA, PV, Qmax, PVR	Predictors of failure
Medical treatment	Baseline patient age, IPSS, BPH Impact Index, PSA, PV, PVR, prior history of AUR, ≥4 points IPSS worsening, bother score >3 during treatment	Predictors of failure with alpha-blocker or 5-alpha- reductase inhibitor therapy
	IPP	Predictor of failure with alpha-blocker therapy
TWOC after AUR	Age at AUR, type of AUR, amount of drained urine, LUTS severity before AUR, PV, IPP	Predictors of TWOC success
	PSA at 1 month after TWOC, post-TWOC PVR	Predictors of AUR relapse and need for BPH surgery
Surgical treatment	Baseline degree of detrusor contractility	Predictor of TURP outcome
	Detrusor underactivity and DO[a]	May affect PVP outcome in patients with pre-operative urinary retention

[a] Poor outcome after TURP means failure of symptom resolution and/or development of complication such as incontinence or impotence. This is more likely in (a) patients with frequency, urgency, and nocturia because these LUTS seems to be particularly resistant to treatment. (b) Parkinson disease (PD) as the risk of incontinence is as high as 20%. This may be due in part to a higher prevalence of bladder overactivity in PD combined with an inability to recruit sufficient perineal and/or sphincteric muscular activity to inhibit overactive bladder contractions and to prevent leakage when such contractions occur. It is difficult to know whether a patient with PD and frequency/urgency/nocturia has these LUTS because of BOO-related bladder overactivity, PD-related bladder overactivity, or a combination of both. (c) Patients with a history of pelvic fracture leading to disruption of the membranous urethra: Such patients may be totally reliant on their bladder neck for maintenance of continence. Division of the bladder neck during TURP may render then incontinent (15).

AUR, acute urinary retention; BPH, benign prostatic hyperplasia; BPH Impact Index, symptom questionnaire developed by American Urological Association; DO, detrusor overactivity; IPP, intravesical prostatic protrusion; IPSS, International Prostate Symptom Score; LUTS, lower urinary tract symptom; PSA, prostate specific antigen; PV, prostate volume; PVP, photoselective vaporization of the prostate; PVR, post-void residual; Qmax, maximum flow rate; TURP, transurethral resection of the prostate; TWOC, trial without catheter.

TABLE 30.6

RECOMMENDED PROSTATE SIZE FOR CURRENT BENIGN PROSTATIC OBSTRUCTION (BPO) THERAPIES

Current BPH therapies	Recommended prostate size
TURP	<80 mL
BNI	<30 mL
HoLEP	size independent
Open prostatectomy	>80 mL
532-nm vaporization	size independent

These are appropriate alternatives based on surgeon/patient preference. The durability of 532 nm could not be assessed, however.

BNI, bladder neck incision; HoLEP, holmium laser enucleation of the prostate; TURP, transurethral resection of the prostate.

Reprinted with permission from Chapple C, Abrams P. *Male Lower Urinary Tract Symptoms (LUTS): An International Consultation on Male. Fukuoka, Japan, September 30 – October 4, 2012*. Montréal, Canada: Société Internationale d'Urologie, 2013.

Surgical therapies remain a principal option in management of men with moderate to severe LUTS and/or those who are significantly bothered by these symptoms on maximal medical therapy. Open prostatectomy, TUIP, and M-TURP remain as gold standards by which newer transurethral approaches are compared (3). However, all laser therapies produce major improvements in the AUA Symptom Index scores. Although there are no direct comparisons between the various laser technologies, the improvements in symptom scores appear to be comparable to other surgical therapies and durable to 5 years (3). Laser therapies appear to offer similar improvements in postvoid residual and other urodynamic parameters compared to other surgical therapies such as TURP.

QoL data, a measure that is perhaps most important to the patient being treated, demonstrate equivalent improvements among all surgical technologies.

COMPLICATIONS

Endoscopic Surgery

One of the more common intraoperative complications for patients undergoing endoscopic surgical treatment of LUTS/BPO is bleeding, with hemorrhage requiring blood transfusion occurring in about 3% of cases (11). Due to the continuous irrigation flow and postoperative continuous bladder irrigation, it can often be difficult to estimate the magnitude of bleeding both during and following surgery. When bleeding is appreciated, a systematic inspection of the prostatic fossa will permit identification of the source, which can then be fulgurated with cautery or coagulated with the laser. If bleeding is refractory to these maneuvers, a Foley catheter placed on traction may be helpful.

Overaggressive resection may result in perforation of the prostatic capsule. Sequelae of this event may include extravasation of fluid into the retroperitoneum as well as electrolyte derangements. When a capsular perforation is encountered, it should be assessed. In the case of a small perforation, the procedure should be completed expeditiously. If a large perforation is identified, however, the procedure should be terminated. In the case of a retroperitoneal fluid collection, conservative management (catheter drainage and furosemide) is a reasonable approach because these contained collections generally reabsorb spontaneously. If the perforation is extensive, however, TUR syndrome may occur, although this is a rare event occurring in approximately 1% of cases (11). This condition, brought about by intravascular absorption of hypotonic irrigating solutions ultimately inducing a dilutional hyponatremia, can be associated with hypertension, mental confusion, and nausea and vomiting. TUR syndrome can be managed by diuresis and repletion with normal saline intravenous fluid or, in extreme circumstances, hypertonic (3%) saline in small (e.g., 100 mL) boluses.

Structures in the vicinity of the prostate may also be injured in the course of endoscopic surgical treatment. In some patients, the ureteral orifice may be close to the bladder neck and can be inadvertently ablated or resected. Should the ureteral orifice be injured, an attempt should be made to stent the ureter at the conclusion of the procedure. Stricture formation is the most concerning sequelae of this complication and occurs in about 4% of patients (11). The bladder neck may also be undermined, which can complicate the placement of a catheter at the conclusion of the procedure and lead to bladder neck contracture in approximately 5% of patients. In severe cases, the bladder and prostatic urethra can become completely dissociated. If the bladder neck is identified as being undermined, a Foley catheter should be placed with a catheter guide, or preferably over a wire, to ensure proper placement.

Transient urinary incontinence or urinary retention may occur following an endoscopic prostate resection or ablation. These symptoms generally resolve in the weeks following the procedure. Permanent stress urinary incontinence (11) or retention following these procedures is exceedingly rare. All patients who undergo any of these previously described procedures will experience retrograde ejaculation (11) and should be forewarned of this eventuality. In the analysis of 29 randomised controlled trials (RCTs), the incidence of erectile dysfunction (ED) following TURP was 6.5% (11), and this is thought to be caused by confounding factors (e.g., age) rather than being the direct consequence of TURP. Patients with preoperative urinary retention are at increased risk for postoperative complications (70).

Open Surgery

Severe bleeding following open prostatectomy has been documented to occur in up to 35% of patients; blood transfusion rates are similarly high (7,47). Urinary clot retention has been reported to occur following open prostatectomy procedures and may require both manual and, less commonly, cystoscopic evacuation of clot from the bladder. Urinary leakage from the cystotomy is not uncommon following catheter removal and generally resolves within 1 to 2 days. Transient urgency urinary incontinence occurs following open surgical prostatectomy, usually due to bladder overactivity, but this generally resolves within several weeks of surgery. Retrograde ejaculation occurs in all patients undergoing prostatic adenomectomy. ED ranks sixth after symptomatic improvement, incontinence, immediate surgical complications, mortality, and complications requiring surgery (7,71). Long-term complications from open surgery are incontinence, bladder neck contracture, and urethral stricture. The risk of developing stress incontinence is up to 10% (4), whereas the risk for developing bladder neck contracture and urethral stricture is about 6% (11,44–46). The etiology of bladder neck contracture is unclear, and treatment may require dilation or even incision of the bladder neck.

Conclusion

The choice of the surgical technique depends on prostate size, patient comorbidities, fitness for anesthesia, patient preferences, willingness to accept the respective surgery-specific side effects, availability of each treatment, and experience of the surgeon with these operative techniques. Transurethral resection remains the gold standard, but when available, new therapies could be considered. The best available evidence currently, based on RCTs, is for B-TURP, HoLEP, and GreenLight laser treatment with selective indications for open and minimally invasive simple prostatectomy (7).

CHAPTER 31 OPEN RADICAL RETROPUBIC PROSTATECTOMY

DAVID GILLATT AND SANDIP M. PRASAD

Until the last decade, open radical retropubic prostatectomy (RRP) had become the surgical procedure of choice to effect cure in men with clinically localized prostate cancer and a life expectancy that rendered them at risk of death from their cancer (1). In appropriately selected patients, total removal of the prostate gland with preservation of neurovascular bundles, where appropriate offers a high rate of cure of the cancer. In those men with risk factors suggesting a chance of microscopic breach of the prostatic capsule by the cancer, wider excision without neurovascular bundle (NVB) preservation is more appropriate. If other risk factors for disease progression are present, RRP should be combined with concomitant excision of pelvic lymph nodes.

Walsh and Donker (2) pioneered the anatomic understanding of the prostate and its surrounding structure, which allows us now to understand the nuances of a complex procedure where the surgeon is attempting to cure a cancer but retain both urinary and sexual function where possible. In order to perform this operation, the surgeon must have a mastery of this anatomy, including the periprostatic fascia, the position of the NVB, and the structure of the distal urethral sphincter mechanism. Subsequent modifications of the technique, which will be described in this chapter, have allowed improved visualization of the structures, improved hemostasis, and preservation of the anatomy while margin positivity rates have reduced (3).

The open retropubic approach for this procedure remains in common usage around the world, although in many Western countries, RRP is rapidly being superseded by laparoscopic or robot-assisted techniques. This chapter describes the open RRP operation and is based on our cumulative experience of >2,000 cases and the collective experience in the urologic literature.

INDICATIONS

The indications for any form of radical prostatectomy are largely the same. For the small number of men in whom access via the retropubic space is difficult or impossible, the perineal approach may be preferred. In the early days of the modern procedure, the prevailing paradigm was to treat all men with “curable” localized prostate cancer. However, this approach resulted in considerable overtreatment of men with cancers at low risk of progression in their lifetime given the long natural history of the disease (4). More recently, adoption of expectant management approaches to localized prostate cancer suggests that surgery may best serve younger men (younger than age 65 years) and those with intermediate risk disease (5). In general, for these men, a predicted life expectancy of 10 years or older is needed for the benefits of prostate cancer treatment to manifest.

PREOPERATIVE PREPARATION

Preoperative counseling for RRP is vitally important as men will have temporary and occasionally permanent effects on sexual and urinary function postoperatively. We recommend that this process occur over several visits to allow for an informed and participatory discussion between surgeon and the patient and his family. For men to be satisfied with their treatment decision, a thorough and informed consent is critical.

Given the low rate of rectal injury and lack of strong evidence favoring improved outcomes with mechanical bowel preparation, we do not routinely use bowel preparation except for an enema in certain clinical scenarios, namely, salvage surgery following radiation, brachytherapy, and high-intensity focused ultrasound or after previous rectal surgery (6). In the preoperative holding area, prophylactic antibiotics are started prior to incision. For prophylaxis against thromboembolism, we use a regimen of elastic compression stockings, sequential pneumatic compression devices, and subcutaneous heparin (5,000 units) prior to induction of the anesthesia and throughout the postoperative period until patients are routinely ambulating (typically postoperative day 1).

Patients are positioned supine on the operating room table with mild dorsiflexion with the break positioned just above the anterosuperior iliac spine to open the pelvis and improve access and visualization of the retropubic space. The patient's legs may be positioned on spreader bars to facilitate a second surgical assistant (Fig. 31.1). Typically, RRP is performed with general anesthesia, but some advocate for the use of epidural or spinal anesthesia (7). With the increasing adoption of minimally invasive approaches to radical prostatectomy with their shorter lengths of stay and postoperative narcotic requirements, proponents of RRP have incorporated more aggressive use of non-narcotic anesthesia (standing Tylenol and Toradol) and local anesthetic techniques (e.g., transabdominal plane [TAP] block) to reduce postoperative opiate use and facilitate early mobilization and discharge.

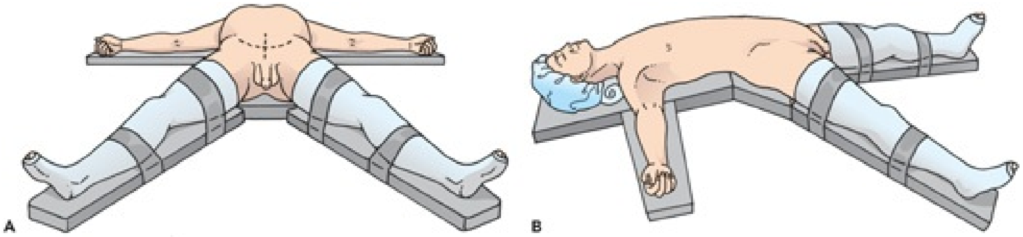

FIGURE 31.1 A and B: Positioning of the patient. Legs are separated on spreader bars. The operating table is flexed with the break just above the patient's anterosuperior iliac spine. OPERATIVE TECHNIQUE

Incision

Classically, an 8- to 10-cm lower midline incision is used. This allows access to the extraperitoneal retropubic space and the pelvic lymph nodes. The incision should commence over the superior aspect of the pubic bone and travel cranially. The skin and subcutaneous fat is incised and the rectus sheath opened along the linea alba. To facilitate identification of the linea alba, a retractor can be used at the apex of the incision with cranial retraction; the linea alba can then easily be palpated. The recti muscles can be parted in the midline with blunt dissection to create an extraperitoneal space which can give excellent access to the retropubic space of Retzius. Typically, the insertion of the recti abdominis muscles are divided with electrocautery to their attachment to the pubis. Blunt dissection is again performed to free the perivesical and periprostatic alveolar tissue from the pelvic side wall, and the external iliac artery and vein should be visualized bilaterally. A self-retaining retractor of appropriate size should be used; we prefer the Balfour or Bookwalter retractor for this incision.

It is possible to perform this operation through a standard Pfannenstiel incision although a randomized controlled trial did not demonstrate significant differences in need for postoperative analgesia and time to recovery compared with a standard vertical laparotomy (8). The Pfannenstiel incision may restrict access to the immediate retropubic space and make lymphadenectomy more difficult, although it allows for concomitant inguinal hernia repair.

Pelvic Lymphadenectomy (If Indicated)

Current National Comprehensive Cancer Network (NCCN) guidelines recommend the performance of pelvic lymph dissection in men with a predicted probability of lymph node metastasis greater than or equal to 2% (9).

The decision to perform standard versus extended pelvic lymph node dissection remains primarily driven by surgeon preference because the number of lymph nodes resected does not appear to affect disease-specific survival in men without positive nodes (10). In addition, a conversation should occur preoperatively with the patient with high-risk disease about his preferences regarding prostatectomy in the event that positive lymph nodes are found; if the patient would elect to forgo prostatectomy in the setting of metastatic disease, the pelvic lymph nodes should be sent for frozen section.

The surgical template for extended pelvic lymph node dissection extends from the bifurcation of the common iliac artery superiorly, the femoral canal inferiorly, and the obturator nerve and vessels and the hypogastric artery posteriorly. The standard template differs by exclusion of the lymphatic tissue overlying the hypogastric artery. Only those lymph nodes medial to the hypogastric vein should be removed and arterial branches from the external iliac, and obturator arteries should be preserved as these may supply the corpora cavernosa. Care should be taken to clearly identify, preserve, and avoid excessive traction to the obturator nerve.

Identification and Preparation of the Prostate

An often underrated step is the removal of fat and areolar tissue from the anterior surface and apex of the prostate in order to facilitate precise identification of relevant anatomy. This is best achieved by the use of a combination of blunt dissection with a peanut swab and limited use of electrocautery superficially when veins are encountered from prostatic apex to the bladder neck.

Incision of the Endopelvic Fascia

The endopelvic fascia is incised sharply or with electrocautery in the groove between the levator ani muscles and the lateral border of the prostate (Fig. 31.2). This groove can be clearly visualized with medial retraction of the prostate using a sponge stick. Inside the fascia, the lateral surface of the prostate is covered by a smooth membrane overlying the lateral portion of the Santorini plexus. Strands of the levator ani muscles are gently dissected off the prostate to the level of the urogenital diaphragm using a peanut swab. There is often a small vein just lateral to the puboprostatic ligaments, and this should be cauterized adjacent to the prostate. The endopelvic fascia should be opened from the apex to the base of the prostate, taking care to avoid the deeper veins of the DVC. There is often debate whether the puboprostatic ligaments should be divided or preserved at this point. If the decision is made to divide the puboprostatic ligaments, they should be divided close to the pubis to facilitate access to the dorsal vein complex (DVC) (Fig. 31.3).

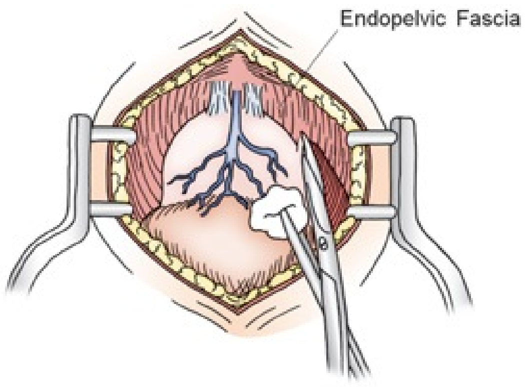

FIGURE 31.2 The endopelvic fascia is incised in the groove between the levator ani muscles and the lateral border of the prostate. (Adapted with permission from Han M, Catalona WJ. Ligation of the Dorsal Vein Complex

The DVC and urethra can be gently retracted medially allowing access to the plane between DVC and urethra. If the DVC is difficult to access, an atraumatic clamp such as a Babcock or Allis may be used to grasp the DVC (but not the urethra). Lifting this clamp anteriorly will open the space between DVC and urethra, facilitating subsequent suture placement. The fibers of the striated distal urethral sphincter should be observed wrapping around the urethra as part of the complex. A 2-0 absorbable suture on a CT-1 needle is typically used to suture ligate the DVC (Fig. 31.4). The needle should be pushed straight through the notch between the DVC and urethra as distally as can be placed and rotated only after the needle tip emerges on the opposite side. A simple ligation will usually suffice, but some surgeons advocate a figure-of-eight suture for control of a broader DVC or improved hemostasis. Occasionally, it may be useful to pass the needle through the periosteum of the posterior pubis just anterior to the DVC. If the suture is then tied, it will both control the DVC and anchor it to the periosteum, facilitating underrunning of any bleeding points after transection. A 3-0 absorbable suture on a 5/8 or UR needle is an excellent tool for dealing with bleeding in this area. A second caudal (Fig. 31.4) or “back-bleeding” suture on the anterior surface of the prostate (Fig. 31.5) may be used and is often best applied in a running inverted V over the anterior surface of the prostate for hemostasis. Once ligated, the DVC should be divided initially with a curved dissecting scissors, electrocautery, or scalpel (Fig. 31.6), allowing the curve to guide over the apex to the urethra just distal to the prostate. Lateral dissection around the urethra should be kept to a minimum to avoid the NVB at this point.

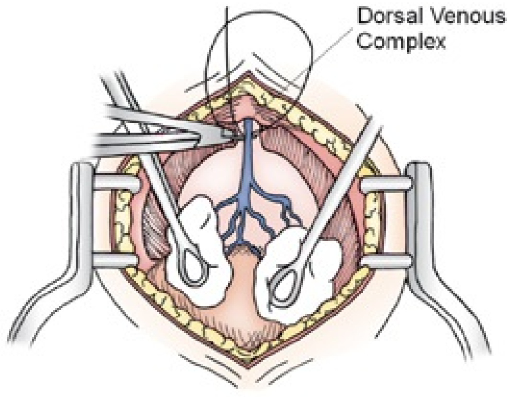

FIGURE 31.4 DVC is suture ligated with a 2-0 chromic catgut suture on a CT-1 needle. (Adapted with permission from Han M, Catalona WJ. Ch. 29, Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;514–527. Copyright © 2005 Elsevier Inc. All rights reserved.)

Dividing the Urethra

After complete hemostasis is achieved, the anterior urethra should be immediately visualized. It can be opened with a scalpel or dissecting scissors (Figs. 31.7 and 31.8), and the urethral catheter is delivered through the urethrotomy into the pelvis. The catheter can be divided between two Kelly clamps and will be subsequently used to gently retract the urethra (and later the prostate). At this point, urethral sutures for the vesicourethral anastomosis can be pre-placed. Perineal pressure by the assistant with a sponge forceps may facilitate placement (Fig. 31.9). Six 4-0 Monocryl sutures are inserted into the distal urethral margin, equally spaced circumferentially. The sutures should be anterolateral, lateral, and posterolateral on either side. These sutures should have a 5/8ths needle on either end which can be used later to place the sutures through the bladder neck to achieve the vesicourethral anastomosis. Following placement of the urethral sutures, the posterior wall of the urethra and the “rectourethralis” fibers are divided (Fig. 31.10).

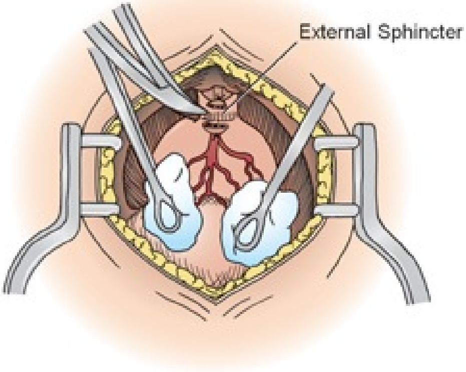

FIGURE 31.7 The circumurethral external sphincter muscle fibers are incised to expose the urethra. (Adapted with permission from Han M, Catalona WJ. Ch. 29, Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;514–527. Copyright © 2005 Elsevier Inc. All rights reserved.)

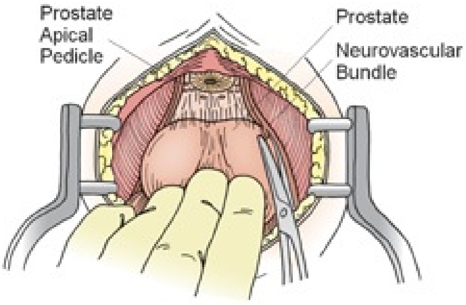

FIGURE 31.10 The apical pedicles of the prostate may require suture ligation. Fibromuscular bands tethering the apex of the prostate to the pelvic floor are incised using sharp dissection. The prostate gland is dissected from NVBs. (Adapted with permission from Han M, Catalona WJ. Ch. 29, Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;514–527. Copyright © 2005 Elsevier Inc. All rights reserved.)

Neurovascular Bundle Preservation (“Nerve Sparing”)

An understanding of the position and route of the NVB is critical to perform precise anatomic nerve sparing. In order to separate the NVB from the prostate and preserve it, the lateral pelvic fascia should be opened initially with sharp dissection from apex to the base of the prostate. We perform a high anterior release of the fascia because this is associated with an improved chance of preserving nerve fibers which are often spread across the anterolateral aspects of the gland as well as sitting in the groove between the prostate and rectum posterolateral. It is also important to gently sweep away the bundle from the apex of the prostate at the lateral aspect of the urethra in order to avoid damage. By gently teasing the bundles off the prostate, a plane should develop allowing the prostate to be dissected away from the rectum. Small vessels, mainly veins, may be controlled with clips or ties. The dissection continues toward the bladder neck until the fascia covering the vas and seminal vesicles (SVs) is identified and the prostatic vascular pedicles are isolated. This step can be more difficult if there is periprostatic fibrosis and anecdotally this seems more common in the era of transperineal biopsy and again more recently in the era of active surveillance, where men may undergo multiple biopsies prior to surgery. Prior to embarking on nerve sparing, a decision regarding its suitability should be made in light of each individual’s tumor type and location.

It is possible to mobilize the NVB at the apex just lateral to the urethra and sweep it away from the prostate at this point. This can be a useful maneuver when fibrosis is present in the lateral prostate. However, it does run the risk of entering veins constituting part of the DVC. Dissection toward the bladder will often reveal the prostatic vascular pedicles, which at this point can be suture ligated or clipped. This stage of the procedure can also be performed prior to division of the urethra resulting in lateral mobilization of the prostate and creating a “valley” laterally between prostate and rectum.

Posterior Mobilization

After mobilization of the NVBs and division of the urethra beyond the apex, the prostate should be mobilized from the rectum by gentle blunt dissection. It should be possible to insert a finger between the rectum and prostate in the midline. If mobilization of the NVB is complete, the prostate should lift completely away from the rectum. Anterior and cranial retraction of the prostate will expose Denonvilliers fascia over the ampullae of the vasa and SVs (Fig. 31.11). It is often necessary to clip and divide a few remaining posterolateral fibers to completely mobilize the lateral prostate.

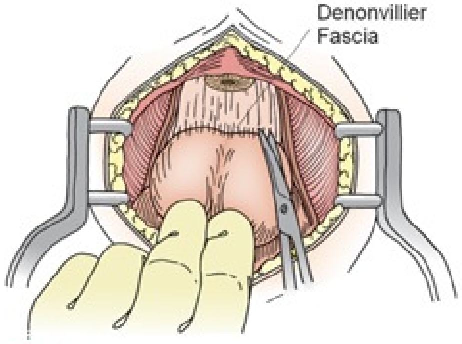

FIGURE 31.11 The dissection is carried cephalad until the portion of the Denonvilliers fascia covering the ampullary portions of the vasa deferentia and the SVs are exposed. The Denonvilliers fascia is incised with cautery to expose vascular pedicles at prostate base. (Adapted with permission from Han M, Catalona WJ. Ch. 29, Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;514–527. Copyright © 2005 Elsevier Inc. All rights reserved.)

Control of the Prostatic Vascular Pedicles

Vascular control of the prostatic pedicles is best achieved by using a right angle clamp passed medial to the pedicle, with the direction of control parallel to the prostatic surface from cranial to caudal and medial to the NVB. Initially, hemostatic clips are applied (Fig. 31.12) before division with sharp scissors, although often it is wise to also suture ligate the pedicle. The anatomy of the pedicles is quite variable and may require more than a single point of control.

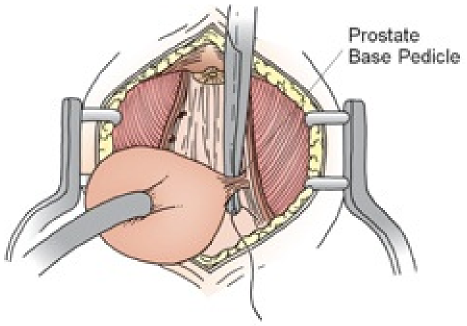

FIGURE 31.12 The prostate base pedicle is ligated or hemoclipped laterally, taking care to place the tie medial to the NVB. (Adapted with permission from Han M, Catalona WJ. Ch. 29, Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;514–527. Copyright © 2005 Elsevier Inc. All rights reserved.)

Opening of Denonvilliers Fascia and Dissection of the Seminal Vesicles

The prostate should now be mobile and easily delivered anteriorly toward the wound. The Foley catheter is in situ with the balloon inflated and a clamp across the tube distal to the prostatic apex and acts as a retractor and deflects the gland in appropriate directions to allow access to posterior structures. With the catheter holding the prostate in the midline and exposing Denonvilliers fascia, mobilization of the SVs can begin. At this point, Denonvilliers fascia has two layers. The layers should be incised over the SVs in the midline in a horizontal direction. Both layers should be incised to expose the vesicles laterally; the ampullae of the vasa deferentia will lie in the midline but in many cases will be obscured by the medial aspect of the SVs. In order to access the vasa, it may be necessary to sweep away the medial aspects of the SVs. A right-angle clamp should be passed behind the vas and blunt dissection used to free a 1- to 1.5-cm segment of each vas. The vas should be clipped away from the base of the gland and divided. The vas can subsequently be used to gain access to the medial and posterior aspects of the SVs. The SVs can be mobilized by blunt and sharp dissection. Typically, one will encounter several small perforating vessels, which require clipping. The vascular pedicle at the tip of each SV should be clipped and divided.

Transection of the Bladder Neck

Once the SVs are mobilized and the pedicles divided, the prostate is only attached to the bladder neck. There are several ways to deal with the bladder neck. The most straightforward is to take an anterior approach. In order to identify the “true bladder neck,” it may be useful to fix the intravesical portion of the urethral catheter with a Babcock-type atraumatic clamp taking the bladder wall and catheter en masse. By manipulating the catheter, the junction between bladder and prostate can be identified. Electrocautery is used to open the anterior bladder neck and to identify the catheter in the bladder. The catheter balloon is deflated and the intravesical portion is delivered out of the vesicostomy. The two ends of the catheter should be clamped together and again used for retraction (Fig. 31.13). The bladder neck defect can be widened with electrocautery, and the urothelial of the posterior bladder neck transected. Prior to this, the ureteric orifices should be identified and avoided. If, because of prior transurethral resection of the prostate or a large intravesical lobe they are close to the transection line, the surgeon may consider passing ureteric catheters or a 5Fr pediatric feeding tube to localize and protect the lower ureters. These should be kept in place until the bladder neck is reconstructed. Once the posterior bladder neck is safely transected, the muscular fibers between prostate and bladder can be divided with electrocautery to completely free the prostate for pathologic examination.

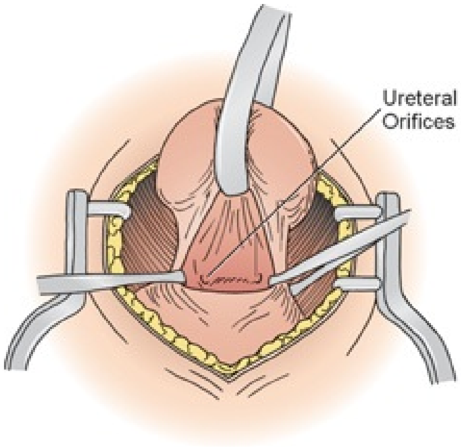

FIGURE 31.13 The anterior bladder neck is transected in the natural groove between the bladder and the prostate. The bladder neck opening is enlarged with scissors. The ureteral orifices are identified. (Adapted with permission from Han M, Catalona WJ. Ch. 29, Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;514–527. Copyright © 2005 Elsevier Inc. All rights reserved.)

Reconstruction of the Bladder Neck

It is useful to try and preserve the bladder neck where possible to promote an early return to continence and, if so, only minimal reconstruction should be necessary. If the bladder neck is approximately the diameter of a 22Fr or 24Fr catheter, then the surgeon may simply evert the mucosa by placing 4-0 absorbable suture at 5 or 6 points circumferentially around the bladder neck or with a continuous running everting suture circumferentially around the bladder neck (Fig. 31.14). These everting sutures should be between bladder mucosa and the outer surface of bladder muscle. When a wider defect is present, formal reconstruction of the bladder neck is appropriate. This is best performed in an inverted Y (“tennis racket”) fashion. A 3-0 Monocryl suture is placed at the posterolateral apex of the defect on either side and run until they meet in the midline. The remaining small anterior defect is the new bladder neck; infrequently, if this remains large, further closure can be performed anteriorly to create an appropriately sized bladder neck.

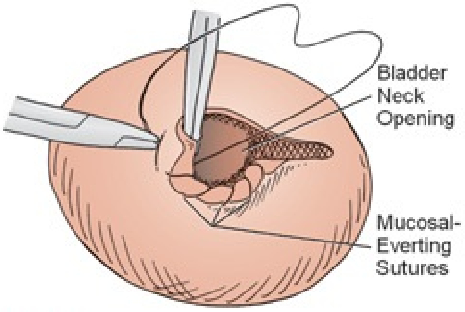

FIGURE 31.14 A continuous running mucosa-everting suture of 3-0 chromic catgut is placed for a distance of nearly the entire anastomotic circumference. (Adapted with permission from Han M, Catalona WJ. Ch. 29, Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;514–527. Copyright © 2005 Elsevier Inc. All rights reserved.)

Vesicourethral Anastomosis

The preplaced six 3-0 Monocryl sutures in the urethra are now placed into their corresponding locations in the bladder neck (Fig. 31.15). If double-armed suture is not available, a French eye needle may be used to place the suture inside-out through the bladder neck. An 18Fr catheter is passed down the urethra and delivered into the pelvis anterior to the posterolateral sutures. The bladder can then be “parachuted” down onto the urethra with a sponge stick to reduce tension, and the sutures are then tied carefully to bring bladder neck and urethra into apposition over the Foley catheter. Integrity of the anastomosis should be tested by filling the bladder with at least 180 mL saline to ensure that it is watertight.

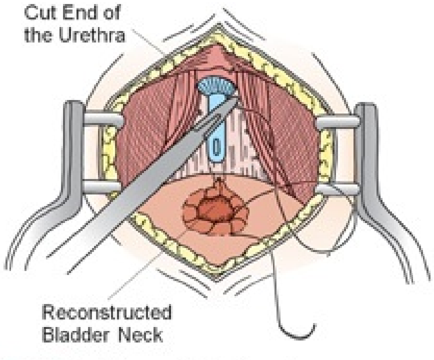

FIGURE 31.15 Double-armed 2-0 chromic catgut sutures are used for the vesicourethral anastomosis. (Adapted with permission from Han M, Catalona WJ. Ch. 29, Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;514–527. Copyright © 2005 Elsevier Inc. All rights reserved.)

Wound Closure

After full hemostasis is achieved, the wound may be closed. Typically, adjunct hemostatic agents (e.g., Surgicel, FloSeal) are not necessary. A continuous nonabsorbable running mass closure of the abdominal wall is appropriate. The skin may be closed with clips or an absorbable subcuticular suture. The wound should be infiltrated into the deep layers with local anesthetic. A small drain is left in the pelvis during the postoperative period and removed prior to discharge if there is no evidence of bleeding or urine leak.

POSTOPERATIVE CARE

The analgesic requirement following surgery varies but with a good wound block may be minimal. However, a significant proportion of men require opiate analgesia for the first 12 to 24 hours. To minimize this, we advocate for the standing use of non-narcotics such as acetaminophen and nonsteroidal anti-inflammatory medications such as Toradol or ibuprofen on every 6 hours basis. Adopting these non-narcotic pathways has been shown to result in similar low narcotic use and pain scores compared with minimally invasive approaches (11). The patient can start a normal diet as soon as he feels able. Early ambulation is critical and patients should be up and out of bed on the evening of surgery and walking on the first postoperative day. Most patients are discharged home on postoperative day 1 or 2, with the drain removed prior to discharge if there is no concern for urine leak.

The urethral catheter can be removed without a cystogram in 7 to 10 days.

COMPLICATIONS

Massive intraoperative hemorrhage was an early concern of RRP, with more recent high-volume centers reporting perioperative transfusion rates of 20% (12). Careful and meticulous technique during control of the DVC and prostatic pedicles reduces blood loss considerably. In the authors' last 500 cases, no patient has required transfusion. Significant hemorrhage should be an uncommon complication of modern RRP. The rectum can rarely be injured during RRP, particularly if there is marked fibrosis around the apex of the gland. If recognized and there is not gross spillage of stool into the wound, the defect can be repaired with two layers of 3-0 Monocryl and prophylactic antibiotics commenced in the immediate postoperative period. Ureteric injury can also rarely occur when there has been previous bladder neck surgery. If recognized, the ureter can be sutured to the bladder mucosa with 4-0 Vicryl and the bladder neck subsequently reconstructed while protecting the ureters with stents.

The most common postoperative complications of anatomic nerve-sparing RRP include anastomotic stricture (bladder neck contracture), thromboembolic complications (deep vein thrombosis and pulmonary embolism), and postoperative inguinal hernia. The rate of bladder neck contracture in expert series has been as low as 1% (13), although a large population-based analysis suggests that the rate is closer to 14% (14). Thromboembolic complications were seen in 2.2% of patients undergoing open radical prostatectomy in a recent large, multicenter prospective controlled trial (15); these were 4 times more common when lymph node dissection was performed and was 4 times more common with RRP than robot-assisted laparoscopic radical prostatectomy. In the Scandinavian Prostate Cancer Group 4 study, a prospective randomized study between RRP and watchful waiting with a follow-up of over 12 years, 9.3% of subjects developed inguinal hernia after RRP within 48 months as compared to 2.4% in a group of men managed without surgery (16).

A comprehensive discussion of urinary and erectile function is beyond the scope of this chapter and in the absence of a large head-to-head comparative randomized clinical trial is limited by the quality of the available comparative studies (17). This said, it appears clear that functional outcomes are improved with increasing cumulative number of RRP performed by the surgeon and hospital (18) and we would endorse dissemination of the techniques and processes of care described in this chapter to accelerate this process in low volume surgeons.

CHAPTER 32 RADICAL PERINEAL PROSTATECTOMY

SAM D. GRAHAM JR. AND THOMAS E. KEANE

Radical perineal prostatectomy, first performed in 1869 by Buchler and popularized in the United States by Young in 1903, remained the primary surgical approach to carcinoma of the prostate into the mid-1970s. With the recognition of the importance of assessing advanced (nodal) disease preoperatively, which if positive would halt the operative procedure, and the advantage that retropubic prostatectomy offered with the concomitant pelvic node dissection, perineal prostatectomy declined in popularity for the treatment of prostate cancer. The perineal approach, however, saw a resurgence in the 1990s for several reasons: (a) the trend toward minimally invasive surgery with a focus on reducing the morbidity and therefore hospital stay of patients, (b) the advent of laparoscopic surgery for lymph node assessment, (c) the introduction of prostate-specific antigen (PSA) for screening for prostate cancer with reduction in the numbers of patients with node-positive disease, (d) algorithms that may predict patients at high risk for positive lymph nodes, and (e) increased recognition of similar results compared to all other methods of radical prostatectomy. The procedure is also associated with reduced blood loss and low morbidity, and it can be modified to incorporate the neurovascular-sparing techniques for preservation of potency.

DIAGNOSIS

All patients who are potential candidates for radical perineal prostatectomy should undergo appropriate preoperative staging to ensure that they are operable candidates; preoperative imaging is rarely required in low- to intermediate-risk patients. Methods of differentiating local versus advanced disease include digital rectal examination, transrectal ultrasonography, radionuclide bone scan, assessment of pelvic lymph nodes, and pathologic indicators of progression such as Gleason sum and other markers.

PSA screening has made a significant impact on the preoperative stage of patients with prostate cancer. Patients presenting for surgery are generally younger, healthier, and more likely to have organ-confined prostate cancer than the population treated prior to PSA introduction, and in many ways, this attributes to the large increase in the number of radical prostatectomies done in the United States in the PSA era.

Digital rectal examination has a limited role in the clinical staging of prostate cancer. It is primarily used to crudely estimate the volume of the cancer. Transrectal ultrasonography is another modality that also has limitations in assessing local disease, but combined with digital rectal examination, it at least gives some gross assessment of the likelihood of extracapsular disease. Other modalities, such as fused-transrectal ultrasound and magnetic resonance imaging (MRI), computerized tomography (CT) scan, and pelvic MRI, have been shown to have limited usefulness. The new generation of MRI scanners and ProstaScint scanning using fusion technology with CT or MRI have the potential to improve prostate cancer staging. Radionuclide bone scans are useful in assessing advanced bone disease but generally are not positive in patients with PSAs below 20 and no other sign of advanced disease.

For the past 20 years, we have prospectively provided data that has been applied to an algorithm for the preoperative assessment of patients with prostate cancer developed through data on over 400 patients who had undergone pelvic node dissection. The current algorithm includes patients with a Gleason sum of 7, providing that the predominant pattern is 3, a low-volume cancer (T1b-c, T2a), and PSA of <10 ng per mL. Patients meeting all of these criteria have a <5% chance of positive lymph nodes, and therefore, we do not routinely perform pelvic lymph node dissections (1). Patients exceeding any one of the previously described criteria are considered to be in the high-risk group and have undergone pelvic lymph node dissections. Using this method of assessment, our overall PSA recurrence rate from 1986 to 1993 was 24%. This compares favorably to other series of retropubic prostatectomies from that time in which all patients had a node dissection; in those series, PSA recurrence rates were between 24% and 28% (2–5).

INDICATIONS FOR SURGERY

Patients who are candidates for radical prostatectomy must have clinically organ-confined prostate cancer (T1-2). Other factors that need to be taken into consideration are the patient’s life expectancy, other comorbidities, or any other factors that may affect the patient’s choice. We generally do not offer a radical prostatectomy to patients who have a <10-year expectancy. Over the age of 70, we offer a radical prostatectomy only in selected cases where we feel that the benefits that can be obtained from radical prostatectomy outweigh the potential risks, particularly when compared to alternative therapies.

ALTERNATIVE THERAPY

Alternatives to perineal prostatectomy include retropubic and laparoscopic or robot-assisted laparoscopic prostatectomies. The retropubic approach allows simultaneous node dissection and removal of prostate glands, although the length of hospitalization and immediate postoperative morbidity are higher in our institution. The robotically assisted laparoscopic approach allows some improvement in visualization compared to the retropubic or laparoscopic surgeries due to the magnification and three-dimensional visualization, but it has yet to show any significant advantages in terms of operative morbidity, length of stay, or reduction in long-term morbidity. There are few if any large comparisons with radical perineal prostatectomy, although results to date indicate that no significant differences exist.

Alternatives to radical prostatectomy include observation, active surveillance (AS), hormonal deprivation, and radiation therapy. Although we do not consider either observation or hormonal deprivation to be curative, these are good options only for patients with less than a 5-year life expectancy, patients who are >70 years old with a well-differentiated cancer, and patients who are at high risk for surgery and refuse radiation. Radiation therapy, however, may be definitive and has a 5- to 10-year survival rate equivalent to that of surgery. The recurrence rates with radiation therapy are bimodal, with initial recurrences within 1 to 2 years of treatment and a delayed peak at 5 to 7 years after treatment. The recognition that many low-risk cancers (low volume 3/3 Gleason grade) have a minimal risk of prostate cancer death or progression has led to the introduction of AS for many patients who would previously have chosen intervention. If the patient is young with a 15-year or longer outlook and has significant disease, we feel that our results would favor radical prostatectomy.

SURGICAL TECHNIQUE

The patient is placed in an exaggerated lithotomy position (Fig. 32.1). It is important that the patient's perineum be parallel to the floor because this directly affects exposure. We use a standard operating room table with seven folded sheets under the patient's sacrum supporting the patient's entire weight. Shoulder braces are not recommended, and if a patient tends to slide off the sheets, we will place the table in a slight reverse Trendelenburg position. The patient's legs are stabilized using candy cane or Allen stirrups, again taking precautions to prevent stretching the hamstring or causing pressure on the legs. Prior to putting the patient in position, the legs are wrapped with ACE bandages.

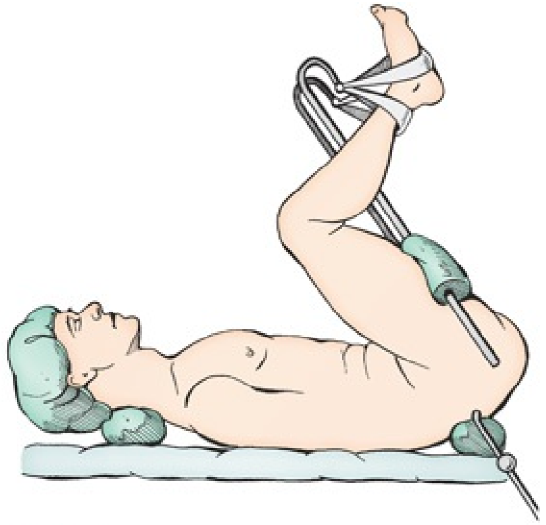

FIGURE 32.1 Positioning of the patient requires the perineum to be parallel to the floor. The sacrum supports the patient's weight, and the legs are positioned with no traction on the hamstrings. No shoulder braces are indicated.

Four instruments are significant in assisting the surgeon for this operation. These include the Lowsley curved tractor, the Young straight prostatic tractor, a Halogen head lamp, and an Omni-Tract Mini Wishbone retractor system. The curved Lowsley tractor is used to bring the prostate up into the perineum to allow dissection against the prostate while mobilizing the rectum from the prostate. The straight Young tractor is used to manipulate the prostate laterally as well as cephalad and caudad after the membranous urethra has been divided. The Halogen head lamp is important because it allows the surgeon to aim a strong light into the operative field, which may be too deep and narrow for standard operating lights to adequately illuminate the structures. The Omni-Tract Mini Wishbone allows virtually unlimited retraction in any direction. We have developed a posterior weighted speculum that is compatible with the Omni-Tract (Fig. 32.2). A further option is the harmonic scalpel, which allows coagulation and closure of vessels without transmission of electrical current, thereby reducing the risks to the neurovascular bundles.

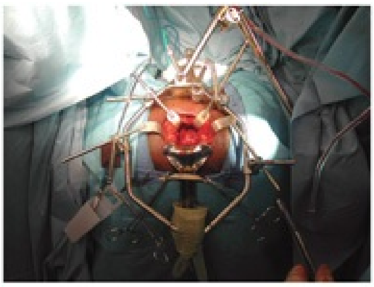

FIGURE 32.2 Mini Wishbone retractor set up for perineal prostatectomy.

It should be noted that in manipulating the prostate within the pelvis, the pelvis should be viewed as a cone with the apex of the cone being the incision (Fig. 32.3). To achieve better visualization, it is sometimes necessary to actually push the prostate further into the pelvis. Also note that traction is not placed directly on the bulb or membranous urethra, as this will decrease the likelihood of restoration of potency and potentially affect the patient’s continence postoperatively.

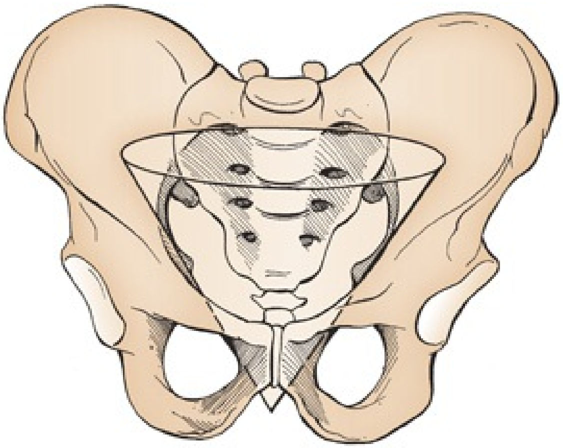

FIGURE 32.3 The bony pelvis is a cone with the apex at the incision. Better visualization can be obtained in many cases by actually pushing the prostate deeper into the pelvis.

The incision is made from the ischial tuberosity crossing the midline at the juncture between the squamous epithelium and the mucocutaneous border of the rectum (Fig. 32.4). The incision extends posteriorly to a line equal to the posterior portion of the anus. Using sharp dissection and electrocautery, the ischiorectal fossae are entered, and using blunt dissection, the central perineal tendon is identified and transected with electrocautery. At this point, we employ the Belt approach, dissecting down to the white fascia of the rectum and proceeding subsphincterically (Fig. 32.5). A transsphincteric or suprasphincteric approach is also an option. Using predominantly careful dissection with an index finger in the rectum, the rectal sphincter and levator ani sling can be dissected free of the rectum with minimal bleeding (Fig. 32.6). The blades from the Mini Wishbone retractor are then used to retract these muscles anteriorly and laterally. With tension on these muscles and tension on the rectum, the rectourethralis is identified and divided, allowing the surgeon to dissect the rectum free of the apex of the prostate (Fig. 32.7). The assistant presses down on the handle of the Lowsley curved tractor, which elevates the prostate into the wound and facilitates mobilization of the rectum off the prostate.

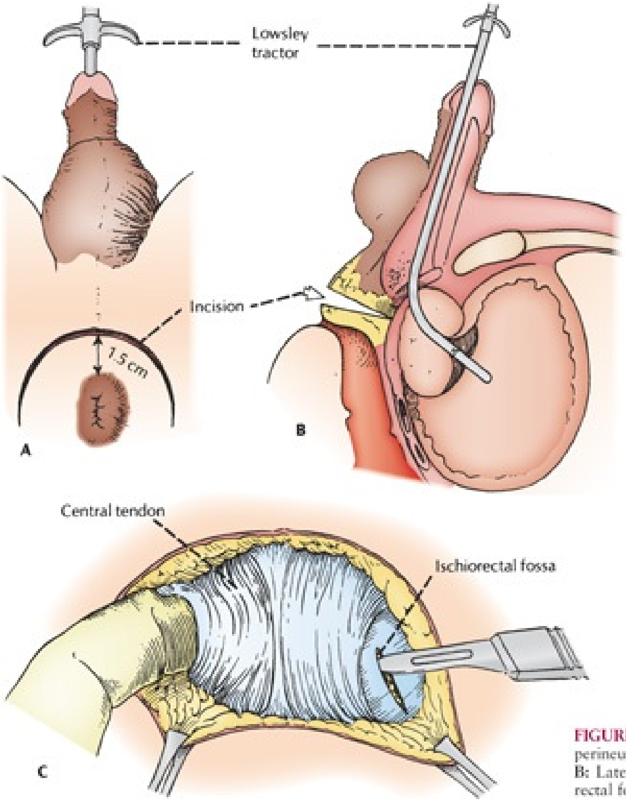

FIGURE 32.4 A: An inverted U-shaped incision is made in the perineum extending from one ischial tuberosity to the other. B: Lateral view of incision. C: Access is gained to the ischiorectal fossa bilaterally and the central tendon is divided.

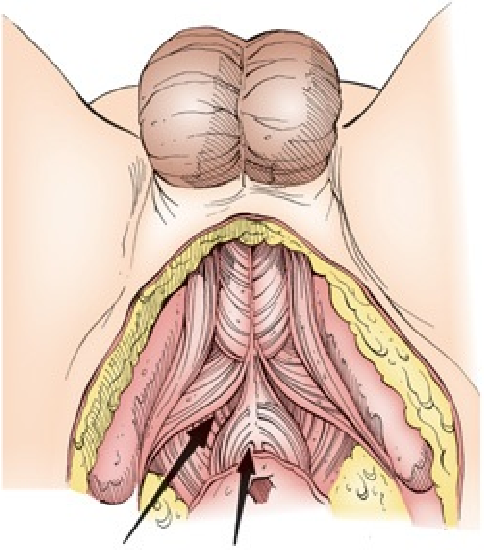

FIGURE 32.5 The dissection is carried along the rectal fascia (*lateral arrow*), sparing the anal sphincter (*mid arrow*).

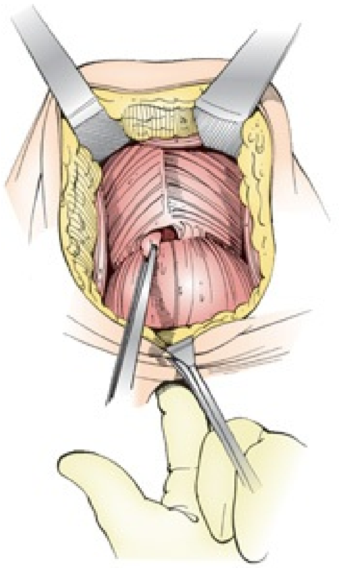

FIGURE 32.6 The levator ani and the anal sphincter are retracted to expose the rectourethralis.

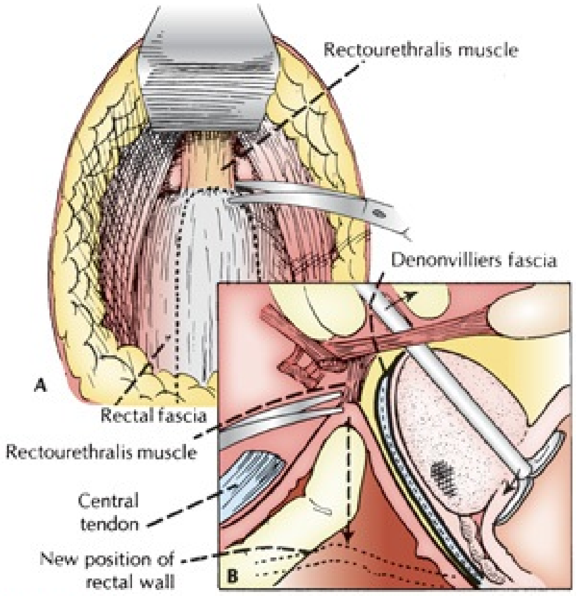

FIGURE 32.7 Dissection of the rectum from the prostate after division of the rectourethralis is facilitated with the surgeon's finger in the rectum.

In patients who are undergoing nerve-sparing surgery, the dissection is carried down to approximately 1.5 to 2.0 cm from the apex, at which point the external layer of the Denonvilliers fascia is divided and dissection is carried between the two layers of the Denonvilliers fascia (Fig. 32.8). Care is taken not to damage the neurovascular bundles that course along the lateral posterior prostate on either side (Fig. 32.9).

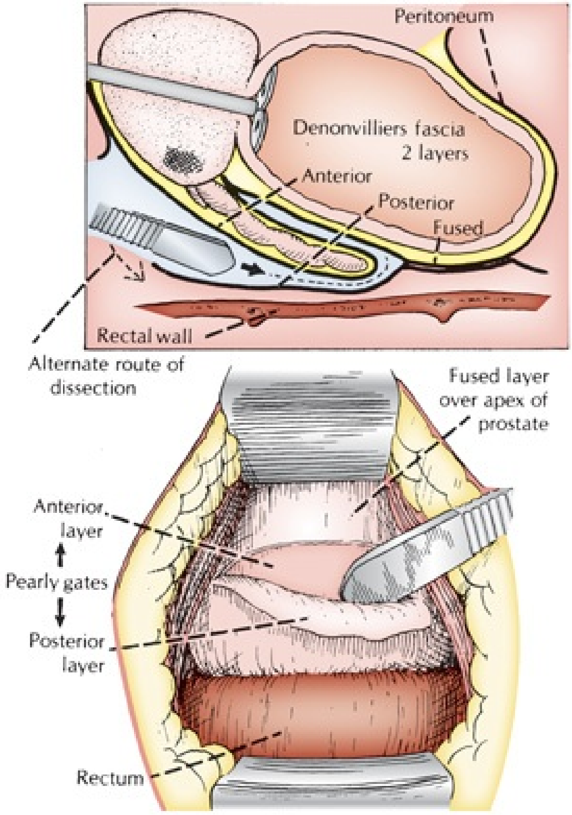

FIGURE 32.8 An incision into the posterior layer of the Denonvilliers fascia allows the dissection to continue between the two layers. For a nerve-sparing technique, this incision is made transversely 1 to 2 cm proximal to the apex of the prostate, avoiding carrying the incision into the neurovascular bundles.

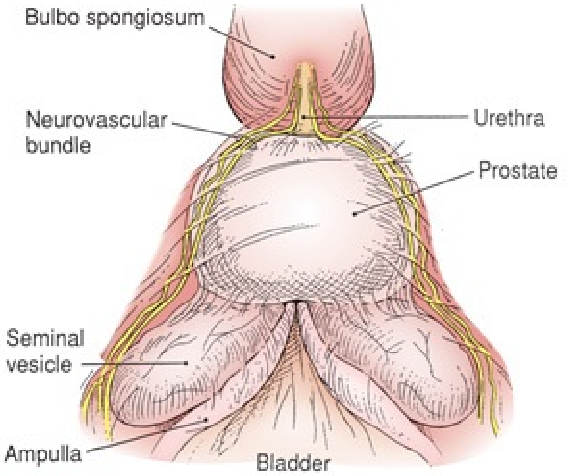

FIGURE 32.9 Anatomic view of the neurovascular bundles from the posterior view of the prostate. The vessels course along the lateral and posterior prostate and cross the apex to enter the urogenital diaphragm posterior to the membranous urethra.

The distal portion of the Denonvilliers fascia is then incised in the midline with scissors, and the tag is used to facilitate dissection of the neurovascular bundle from the prostate (Fig. 32.10); the inferior pedicle, if present, is then ligated and divided (Fig. 32.11). If the dissection is in any way impaired by fibrosis such that there is a potential for prostatic tissue to be left behind, the neurovascular bundle is sacrificed on that side.

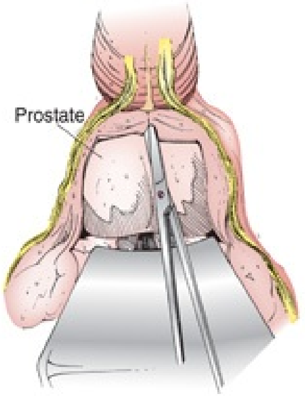

FIGURE 32.10 Incision of the distal posterior layer of the Denonvilliers fascia in the midline. This is best done *without* electrocautery if a nerve-sparing technique is planned.

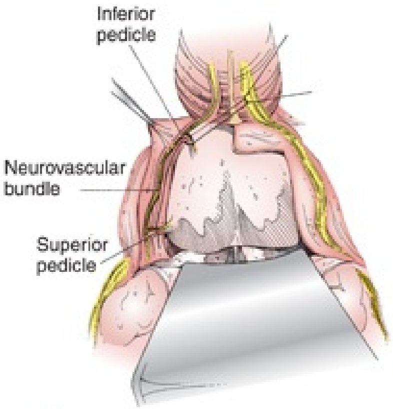

FIGURE 32.11 Using the wings of the distal posterior layer of the Denonvilliers fascia to aid in dissection, the inferior branch from the neurovascular is isolated and divided.

It should be noted during this dissection that the neurovascular bundle actually courses across the posterior surface of the prostate at the apex and enters the urogenital diaphragm just posterior to the membranous urethra. This proximity is important in that the vesicourethral anastomosis may incorporate the neurovascular bundle if the surgeon is not precise with the placement of sutures in the posterior urethra. Very gentle and careful retraction of the neurovascular bundle on either side thereby exposes the proximal membranous urethra for placement of such sutures during urethrovesical anastomosis.

A right-angle clamp is placed around the membranous urethra and generally meets little resistance if one stays posterior to the endopelvic fascia (Fig. 32.12). The Lowsley tractor is removed and the membranous urethra divided. The Young tractor is then placed into the bladder through the prostatic urethra, and the endopelvic fascia can be pushed away superiorly or divided with the harmonic scalpel.

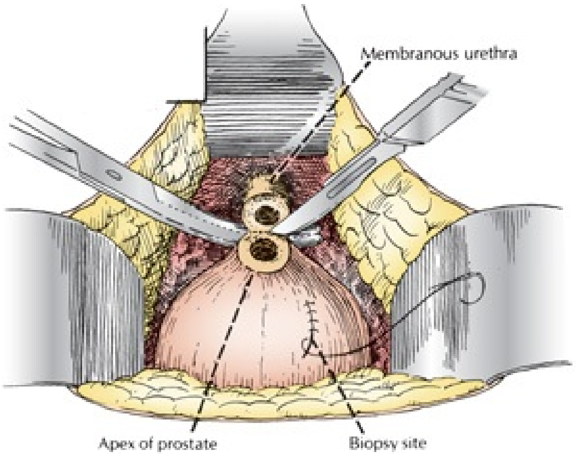

FIGURE 32.12 Division of the membranous urethra at the apex of the prostate.

The anterior prostate is dissected free of the bladder (Fig. 32.13). It should be noted that there are generally two small arteries that enter the prostate along the anterior bladder at 10 and 2 o'clock positions that should be cauterized and divided. The groove between the prostate and bladder is identified, and the prostate and bladder can be separated with either sharp or blunt dissection. If the plane between the prostate and bladder is not easily developed, the dissection should be performed sharply and biopsies taken of the bladder neck to ensure that there is no invasion of the bladder neck by the cancer. In patients who have had prior transurethral resections of the prostate, palpation of the blades of the Young tractor can be used to identify the bladder neck. Care should be taken during the anterior dissection because this is a common area for a positive margin.

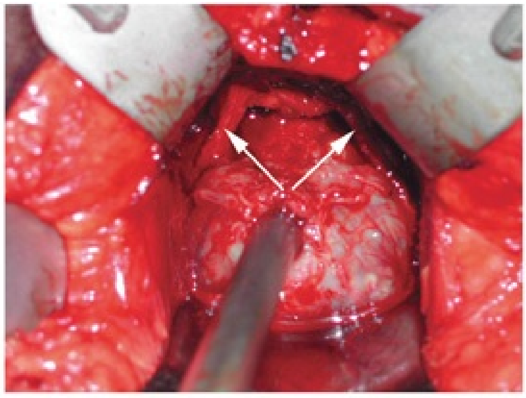

FIGURE 32.13 Urethra divided and anterior prostate demonstrated with neurovascular bundles mobilized (*arrows*).

In most cases, there is insignificant bleeding from the dorsal venous complex in the endopelvic fascia. However, if there should be communicating veins, they may be suture-ligated using 3-0 Vicryl. The prostate is dissected from the bladder anteriorly to posteriorly to the 5 and 7 o'clock positions, respectively, on the patient's left and right, and the bladder neck is divided over the Young tractor prior to removal of the Young tractor; a stay suture may be inserted in the bladder neck at this point and a Penrose drain can be inserted through the vesicostomy and passed through the Young tractor blades and then brought out the prostatic urethra while removing the young tractor thus establishing through and through traction on the prostate (Fig. 32.14). The bladder is evacuated of any urine, and the posterior bladder neck is divided. The prostate is then dissected free from the posterior bladder. A plane is entered after dividing the posterior bladder neck, which is anterior to the seminal vesicles and the ampulla of the vas but posterior to the bladder. The superior pedicles lie in the lateral aspect of this plane and can be divided. At this point, a median lobe can be encountered. The mucosa can be divided on the bladder side of the lobe and the lobe mobilized with the prostate to identify the true bladder neck. Care is necessary to avoid ureteric damage.

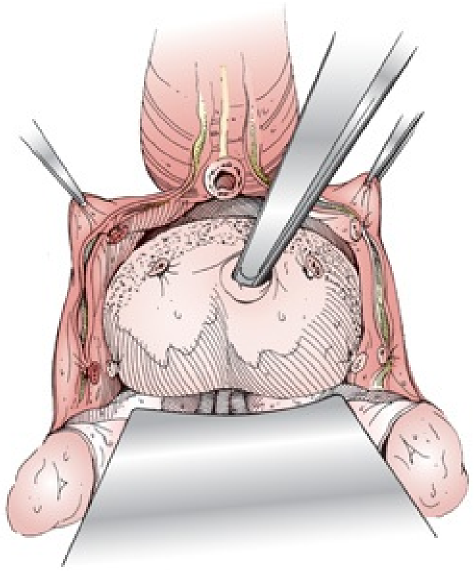

FIGURE 32.14 A Young prostatic tractor is used to manipulate the prostate and to identify the vesical neck.

Attention is then directed to the posterior surface of the prostate. The rectum is swept free of the neurovascular bundles, which also allows identification of the superior pedicles of the prostate as well as the seminal vesicles. The superior pedicles can be divided with the harmonic scalpel at this point, if not done earlier. The seminal vesicles are dissected to their tips with blunt dissection, and the artery from the seminal vesical is divided by clips or harmonic scalpel. The vasa deferens are likewise divided. Any remaining fibrolymphatic tissue is then divided, allowing removal of the prostate.

After ensuring complete hemostasis, the bladder neck may be reconstructed if necessary using 3-0 Vicryl on an SH needle beginning posteriorly to anteriorly (Fig. 32.15). This direction of the closure, beginning in the posterior bladder, is done to facilitate the closure without injury to the ureters and also to take advantage of the anatomic relationship between the bladder neck and the membranous urethra with a shorter distance being anteriorly. The anastomosis is performed using 3-0 Vicryl simple sutures and an RB-1 controlled-release needle (Fig. 32.16). The anastomosis is performed around a 20Fr, 10-mL Silastic catheter, and generally seven to eight sutures are used. Care should be taken that the membranous urethra is clearly identified and the neuromuscular bundle is not incorporated in the anastomosis. The continence mechanism should be left undisturbed. These measures will contribute to potency and continence.

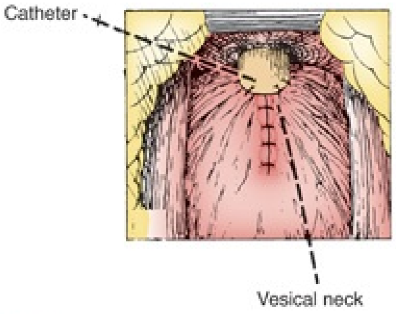

FIGURE 32.15 Reconstruction of the posterior bladder neck is carried from posterior to anterior, leaving an opening of approximately 22Fr.

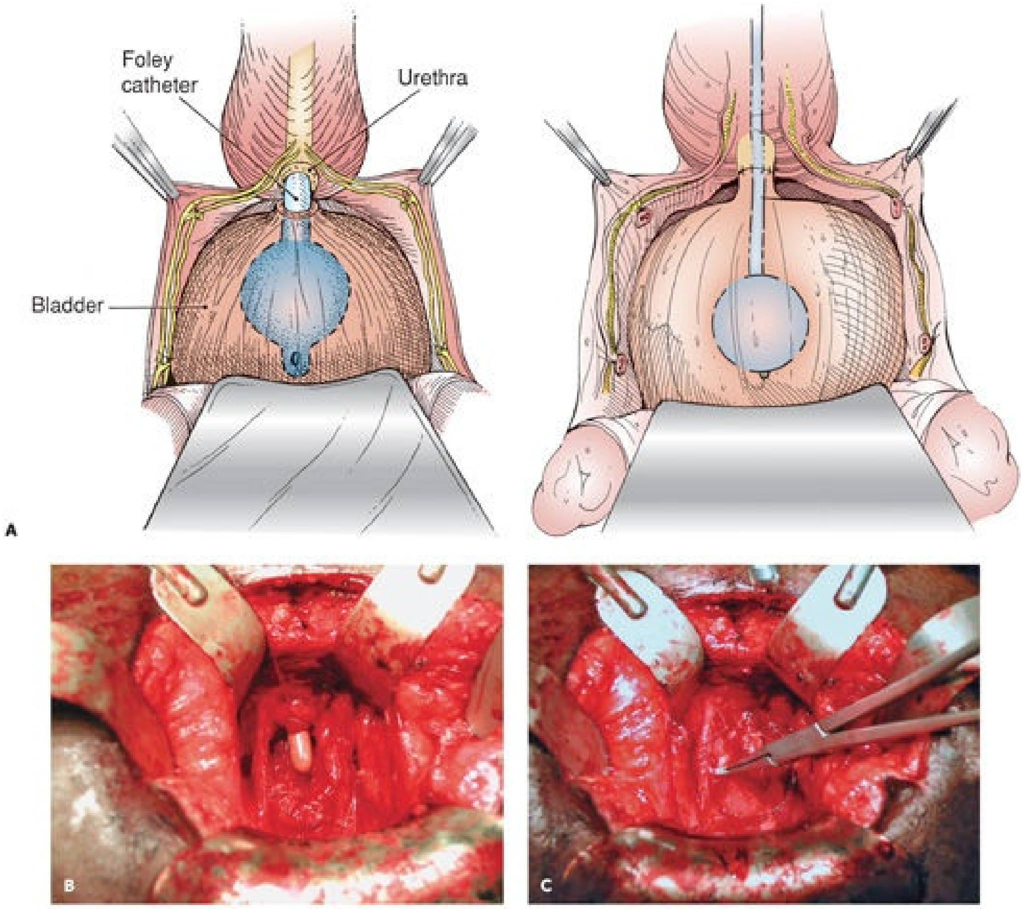

FIGURE 32.16 A: Anastomosis of the urethra to the bladder is performed over a 22Fr Foley catheter. B: Anastomosis of urethra to bladder neck with preserved neurovascular bundles. C: Completed anastomosis of bladder to urethra with intact right neurovascular bundle demonstrated.

The rectum is then inspected, the Foley balloon inflated, and a Penrose drain placed in the left ischiorectal fossa and brought to the skin either out the lower end of the wound or through a separate stab incision. The incision is closed with a 3-0 Vicryl to the deep layers and 0 chromic for the skin. One or two sutures are placed to reapproximate the central tendon, and the remainder of the sutures is used to close the skin in a horizontal mattress fashion (Fig. 32.17).

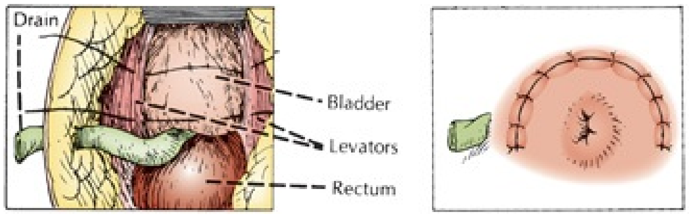

FIGURE 32.17 Closure of the incision.

Postoperatively, patients have a very low requirement for pain medication. Most patients either do not require parental pain medication or are off the parental medications within 12 to 24 hours. Average time to discharge is less than 24 hours from the time of surgery (Table 32.1). The patient’s catheter is removed on day 7 to 8. The Penrose drain is removed prior to discharge.

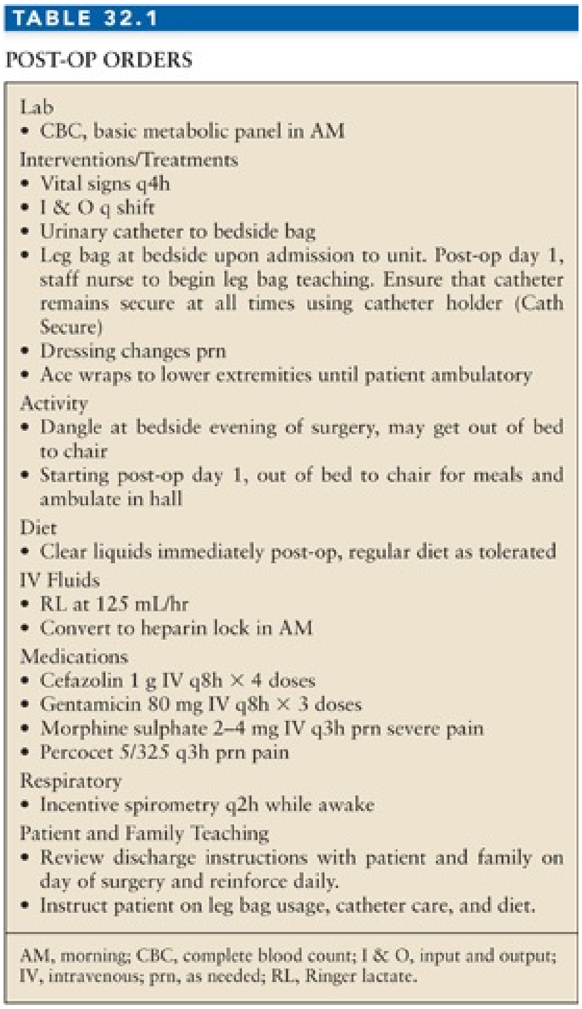

TABLE 32.1

POST-OP ORDERS

Lab
- CBC, basic metabolic panel in AM

Interventions/Treatments
- Vital signs q4h
- I & O q shift
- Urinary catheter to bedside bag
- Leg bag at bedside upon admission to unit. Post-op day 1, staff nurse to begin leg bag teaching. Ensure that catheter remains secure at all times using catheter holder (Cath Secure)
- Dressing changes prn
- Ace wraps to lower extremities until patient ambulatory

Activity
- Dangle at bedside evening of surgery, may get out of bed to chair
- Starting post-op day 1, out of bed to chair for meals and ambulate in hall

Diet
- Clear liquids immediately post-op, regular diet as tolerated

IV Fluids
- RL at 125 mL/hr
- Convert to heparin lock in AM

Medications
- Cefazolin 1 g IV q8h × 4 doses
- Gentamicin 80 mg IV q8h × 3 doses
- Morphine sulphate 2–4 mg IV q3h prn severe pain
- Percocet 5/325 q3h prn pain

Respiratory
- Incentive spirometry q2h while awake

Patient and Family Teaching
- Review discharge instructions with patient and family on day of surgery and reinforce daily.
- Instruct patient on leg bag usage, catheter care, and diet.

AM, morning; CBC, complete blood count; I & O, input and output; IV, intravenous; prn, as needed; RL, Ringer lactate.

OUTCOMES

Complications

Perioperative complications include hemorrhage, wound infection, cardiovascular complications, and rectal injury. The instance of rectal injury is <1% with current techniques and antibiotics or preoperative bowel preparation (two Fleet enemas, the night before and morning of surgery). The rectal injury is closed primarily in two layers without the need to perform a diverting colostomy. Wound infection rates are <1%, and cardiovascular complications are approximately 1% to 2%. The average blood loss in these patients is approximately 300 to 400 mL, and our transfusion rate is <1%. Deep venous thrombosis is extremely uncommon.

Long-term complications include incontinence and impotence. Incontinence requiring intervention such as pads, clamps, or inflatable devices occurs in 2.8% of patients. We have found that incontinence generally occurs in patients who are older, obese, and have had prior radiation therapy. Potency following nerve-sparing perineal prostatectomy is dependent upon the patient’s age and preoperative status. Patients under the age of 60 who are fully potent and have both neurovascular bundles spared have approximately a 60% to 70% potency rate. Patients who are over the age of 60 have a reduced rate of potency (~40% to 50%), and we have only had 5% to 10% of patients over the age of 70 who have spontaneously regained potency. Patients who are having difficulties with potency prior to surgery and patients in whom the neurovascular bundles could not be spared will likely be impotent. We generally advocate early use of pharmacotherapy and vacuum erection device or other means of assistance in these patients.

Results

Following radical prostatectomy, recurrence can be measured using PSA, which is exquisitely sensitive. Any patient who undergoes a radical prostatectomy can expect his PSA to fall below detectable levels (less than 0.1 ng per mL). Failure to do so generally means that the patient has significant residual disease, either locally or distantly. Another group of patients will have an initial drop of their PSA to undetectable levels and then a return to measurable levels. These patients may have local and/or distant recurrence of their disease, or possibly residual malignancy (6). Occasionally, the PSA will rise to between 0.1 and 0.2 and then stabilize again. Generally, we do not use salvage radiation therapy until the PSA has risen over 0.2 ng per mL. Additionally, if the PSA is going to rise, it will do so within 2 years in 90% of patients and within 4 years in virtually every patient. Based on PSA, we can now predict disease recurrence earlier, and depending on the PSA doubling time, we can identify those patients with higher risk recurrence who require urgent aggressive intervention.

Using this technique and a clinical care pathway, we have seen better pain control, earlier ambulation, quicker short-term recovery, and earlier discharge at considerably lower cost than in patients undergoing any other form of radical prostatectomy. This has been confirmed in other studies and will lead to a lower cost of care (2,7).

CHAPTER 33 ROBOTICALLY ASSISTED LAPAROSCOPIC RADICAL PROSTATECTOMY

SANDIP M. PRASAD, DAVID GILLATT, AND MAGNUS ANNERSTEDT

Until the past two decades, radical prostatectomy for clinically localized prostate cancer was traditionally performed through a retropubic or perineal approach. Since the first reported laparoscopic radical prostatectomy (LRP) performed by Schuessler and colleagues (1) in 1997, the use of this minimally invasive approach gained favor in certain centers for the reported improvements in perioperative outcomes including blood loss and length of stay with similar functional and oncologic outcomes in high-volume centers (2). However, the technical challenges associated with this approach, including intracorporeal suturing of the vesicourethral anastomosis, limited range of motion, and two-dimensional optics, limited its widespread adoption to skilled laparoscopists.

One decade following the first LRP, Abbou and colleagues (3) first reported the use of a robotic system to perform the critical steps of radical prostatectomy in 2001. They used the da Vinci surgical system, which remains to this day the only commercially available surgical robot used for radical prostatectomy. Since that time, robotically assisted laparoscopic radical prostatectomy (RALP) has become the standard of care for radical prostate cancer surgery in most western countries accounting for the majority of all such procedures.

The aim of this chapter is to describe the use of the da Vinci surgical system to deliver RALP and to outline some of its potential advantages and pitfalls.

BENEFITS OF ROBOTIC-ASSISTED SURGERY

The da Vinci system is a precise master-slave surgical assistance device with high-quality, three-dimensional, magnified optics. It offers the surgeon the opportunity to operate in narrow spaces with difficult access through the use of three (in earlier generations) and four multijointed robotic arms. In addition, the robotic platform offers the surgeon the additional benefits of motion scaling to allow precise dissection and tremor filtration to facilitate delicate movements (4). The instrumentation articulates about a “wrist” allowing 7 degrees of movement exceeding that of the human wrist. It is particularly effective for difficult dissection and for suturing in tight spaces.

INDICATIONS FOR SURGERY

The indications for RALP are the same as those for open or laparoscopic approaches. Patients should have clinically localized prostate cancer and a life expectancy exceeding 10 years. As experience with RALP has grown, previously stated contraindications such as prior abdominal surgery and obesity are rarely an obstacle to performing RALP with reasonable short- and long-term outcomes in the hands of experienced surgeons (5,6).

PREPARATION

Standard preoperative assessment is appropriate, including a type and screen. Blood products are uncommonly administered given the low rate of blood transfusion with RALP (7). We use a clear liquid diet the day before surgery and a mild mechanical bowel prep the evening prior to surgery. Some surgeons use a preoperative enema to cleanse the rectum; however, in our practices, this is only employed in those undergoing salvage surgery postradiation given the increased rate of rectal laceration in these patients (8).

On the morning of surgery, patients receive perioperative antibiotic prophylaxis with a cephalosporin and deep venous thrombosis prophylaxis with subcutaneous heparin and sequential pneumatic compression devices prior to induction per AUA recommendations (9,10).

ANESTHETIC CONSIDERATIONS

General anesthesia is essential for this operation. The patient requires relaxation and will be positioned in extreme Trendelenburg for a prolonged period. This position, coupled with pneumoperitoneum, may produce cardiopulmonary derangements in certain patients. In addition, a history of glaucoma or intracranial pathology such as arteriovenous malformation or cerebral aneurysm should be reviewed, as this position results in increased intraocular pressure and cerebral blood volume (11,12). Typically, an arterial line or central venous access is not routinely needed except in selected patients at higher risk of complication. In addition, to avoid periorbital and laryngeal edema, judicious fluid administration should be delivered while the patient is in Trendelenburg position (13).

SURGICAL TEAM

The surgical team is composed of one surgeon at the robotic console and one bedside assistant. To facilitate efficiencies in preparation for and performance during robotic surgery, we endorse the use of a dedicated “robot team” for nursing and surgical assistants.

POSITIONING

The patient is positioned in a lithotomy position with the arms tucked. The operating table needs to allow the legs to be separated and the hips to be flexed/extended. It should allow Trendelenburg positioning. The hips should be slightly flexed and the thighs supported to reduce stress on the anterior thigh muscles. The legs should be bandaged to the leg supports in order to fix their position. Once the ports are in place, the patient will be tilted into Trendelenburg to an angle of approximately 30 degrees. The legs may then be brought downward by extension at the hip to allow access for the da Vinci robot between the legs. At all times, care must be taken to avoid tension on the thigh muscles and any excess pressure on calves and thighs. Positioning injuries, although uncommon, can lead both to nerve impairment and rhabdomyolysis (14,15). Once the patient is prepped and draped, an 18Fr Foley catheter is placed sterilely on the field.

PORT PLACEMENT AND DOCKING

Pneumoperitoneum is obtained by surgeon preference; we employ the Veress needle through the anticipated camera port immediately cranially or inferiorly to the umbilicus. Pneumoperitoneum is established to 15 mm Hg with CO_2. The 12-mm camera port is then introduced directly through this incision and then the 0-degree camera (used for the entire case) is passed into the peritoneum and accessibility including the presence of adhesions is assessed. In the setting of prior upper abdominal surgery or umbilical hernia repair, we use an optical trocar or the open Hasson technique to gain access into the peritoneum.

The anticipated location of each port is infiltrated with local anesthetic without epinephrine. All ports are then placed under direct vision, with laparoscopic adhesiolysis performed as needed to facilitate port placement. Three 8-mm da Vinci reusable ports are then placed. Two are positioned laterally 8 to 10 cm from either side of the midline just below the camera port and the third laterally approximately 8 cm from the medial robotic port at least two fingerbreadths above the anterior superior iliac spine (ASIS). The right-handed robotic port will house the scissors/shears; the left-handed robotic port uses the bipolar forceps (fenestrated or Maryland); and the third robotic port exclusively uses the ProGrasp forceps. This third arm is placed on the right or left side of the patient per surgeon preference. It is critical that the ports are separated by a minimum of 8 cm so that the da Vinci arms do not clash outside the patient during the procedure.

In addition, two conventional laparoscopic assistant ports are placed on the opposite side to the third arm. A 12-mm port is placed laterally, at least 2 cm anterior and superior to the ASIS, and a 5-mm port is placed above and just medial to the medial robotic port below the costal margin. These ports are used for retraction, suction, introduction of sutures, and other laparoscopic assistance by the bedside assistant.

Prior to docking, the patient is placed in extreme Trendelenburg at an angle of approximately 30 degrees and the legs are dropped by extending the stirrups at the hip joints. Once the ports are in position, the da Vinci system should be guided over the patient's abdomen by being driven in a straight line between the patient's legs. When the central arm is over the camera port in the "sweet spot," the four da Vinci arms can be positioned and locked on to their respective ports. The camera and its port are positioned to view the lower abdomen and pelvis. The instruments are inserted under vision and locked into their respective ports.

With experience, the steps from Veress insertion to docking the robot can be achieved in less than 15 minutes.

THE OPERATION

There are two traditional surgical approaches to RALP—the "anterior" and "posterior" approach. This specifically refers to the approach for dissection of the vasa and seminal vesicles (SV). If the posterior approach is employed, this is the first step in the procedure and is described in the following text. In the anterior approach, dissection of the seminal vesicles is performed following division of the posterior bladder neck. If indicated, we also advocate performing pelvic lymph node dissection (PLND) prior to beginning radical prostatectomy, as the therapeutic benefit of prostatectomy is unknown in the setting of positive regional lymph nodes.

Dissection of the Vasa and Seminal Vesicles (Posterior Approach Only)

Adhesions of the large and small bowel to the lateral pelvic side walls are common and adhesiolysis is performed to allow for exposure of the planned PLND and for allowing mobilization of the sigmoid colon out of the pelvis. The peritoneum overlying the vas deferens is divided in the pouch of Douglas 3 to 4 mm above the insertion of the sigmoid colon into the posterior peritoneum. Once the vas is identified, it is dissected to the base of the prostate and laterally to an anatomic "bend" that can be visualized at the lateral edges of the posterior peritoneum overlying the pouch of Douglas and then divided laterally. Once the vas is freed, it is retracted anteriorly and the SV can be identified posteriorly. Dissection of the SV occurs in a medial to lateral direction posteriorly, with a combination of sharp and blunt cold dissection to free the SV from surrounding tissues. Hem-O-Lok clips can be used to isolate and divide perforating arteries that are present posteriorly and at the tip of the SV. This process is repeated on the other side and once the vasa and SVs are divided, they are retracted anteriorly. Denonvilliers fascia is then visible under these structures and can be sharply incised just below the SVs and a plane can be developed using sharp and blunt dissection posterior to the prostate up to the apex. Some surgeons will choose to start this plane and then complete the posterior dissection following bladder neck division, but the entire posterior dissection to the prostatic apex can be performed at this time.

Bilateral Pelvic Lymph Node Dissection (If Indicated)

The standard PLND boundaries are the bifurcation of the common iliac artery proximally, the node of Cloquet posteriorly, the bladder medially, the obturator nerve posteriorly, and the pelvic side wall laterally. The fourth arm is used to mobilize the sigmoid colon to the contralateral side of PLND to visualize the bifurcation of the common iliac artery. The peritoneum is divided along the visualized path of the external iliac artery from the bifurcation of the common iliac artery to the internal inguinal ring. The lateral aspect of the lymph node package is developed by opening the fibroadipose tissue from the anterior and medial surface of external iliac vein until the pelvic side wall is identified. We find this easiest at the level of the pubis where the obturator nerve can be identified and then carried out proximally.

The medial aspect of the PLND is then performed by grasping the obliterated umbilical artery and retracting it medially. There is a fibroalveolar plane lateral to the bladder that can be carried bluntly to the obturator nerve. Once the obturator nerve is identified, the closed scissors is used to bluntly and gently strip nodal tissue off the nerve along the entire length of the nodal packet. The lymph node packet is then divided distally beyond the node of Cloquet. Clips or bipolar energy are recommended for larger lymphatic vessels to avoid postoperative lymphatic leak. Anterior retraction of the packet facilitates proximal dissection to the iliac artery bifurcation. Lymph nodes are placed into a 10-mm laparoscopic specimen retrieval bag and removed through the assistant 12-mm port. We do not routinely send frozen sections unless there is high clinical suspicion intraoperatively or by preoperative imaging.

Mobilizing the Bladder

The scissors are used to incise the medial umbilical ligaments up to the anterior abdominal wall (Fig. 33.1). The incision is made by using the outer part of the blades of the monopolar scissors. The tips of the scissors then incise the peritoneum on each side from each medial umbilical ligament to the ipsilateral vas deferens, which can be divided or left in situ per surgeon preference. To open the lateral space of Retzius, both right- and left-sided instruments are used to part the bladder from its attachments to the pelvic side wall in a “breaststroke” motion and this blunt dissection should continue under the pubic bone until the endopelvic fascia is exposed. This process should happen one side at a time. The two incisions in the medial umbilical ligaments can then be joined by similar monopolar and bipolar dissection continued anteriorly above the bladder, dropping it away from the anterior abdominal wall until the prostate and dorsal vein complex (DVC) are identified.

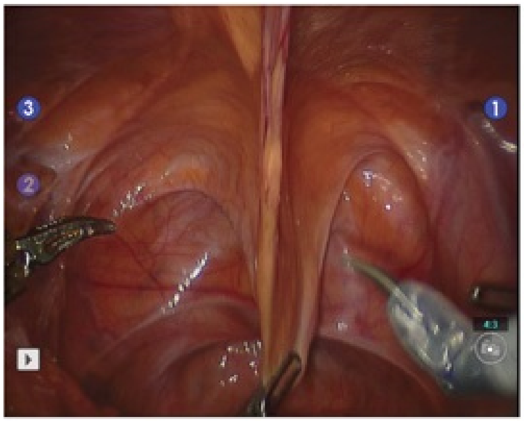

FIGURE 33.1 The robotic fourth arm grasping the right medial umbilical ligament

Exposure of the Prostatic Apex

The fourth arm is used to pull the urachus toward the patient's head, facilitating exposure of the prostatic apex. By blunt dissection, the fat lying over the anterior prostate should be swept away cauterizing any vessels entering laterally. The fat can be sent for histology in the setting of high-risk disease. The endopelvic fascia is opened by making a small incision lateral to the mid part of the prostate. This is extended cranially lateral to the bladder neck and caudally to the puboprostatic ligaments to expose the apex of the prostate (Fig. 33.2). Care should be taken at the apical end of the incision to avoid opening vessels either in or adjacent to the DVC. Once the fascia is incised, blunt dissection with the bipolar forceps can sweep the levator muscles away from the prostate, exposing the DVC and the prostatic apex and urethra. Occasionally, partial division of the puboprostatic ligaments helps to visualize the junction between urethra and DVC if needed.

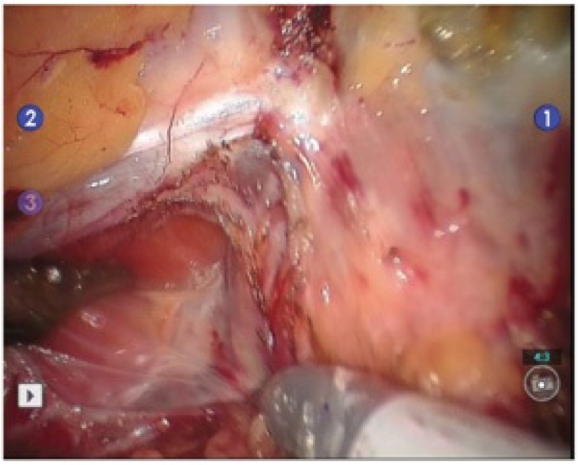

FIGURE 33.2 Incision of the endopelvic fascia

Ligation of the Dorsal Vein Complex

It is debatable as to whether the DVC should be ligated at this point. It is possible that by not ligating the DVC and dividing it sharply later in the procedure, a more accurate apical dissection will reduce the risk of positive margins at this site. However, we prefer to suture ligate the DVC at this time. This can be achieved by using a 0-Vicryl suture on a CT-1 needle measured to 10 inches. We begin DVC ligation by passing the needle medial to lateral through the apex of the right puboprostatic ligament. The suture is then passed horizontally 2 cm distally from the prostatic apex from right to left in the notch between the DVC and urethra (Fig. 33.3). The suture is then passed through the left puboprostatic ligament from left to right and the suture is then tied with a slip knot to secure the DVC. Securing the DVC stitch to the apex of each puboprostatic ligament ensures that the knot is tied distally and is unlikely to be inadvertently divided with the dorsal vein. We then perform a "back-bleeder" stitch with the remaining suture, placing the needle midway between the apex and base of the prostate between each cut edge of the endopelvic fascia.

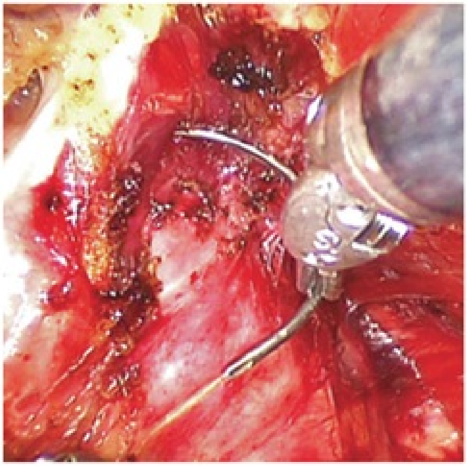

FIGURE 33.3 Distal placement of the dorsal vein ligation suture

Stapling of the DVC has been described, but we believe that this may limit the ability to perform more accurate apical dissection later in surgery.

Bladder Neck Dissection

At this time, some surgeons prefer to change the camera to a 30-degree lens in a downward orientation, although the procedure can be continued without significant challenges using the 0-degree camera. The anterior bladder neck is identified through a series of visual cues (Fig. 33.4): (a) asking the assistant to put gentle traction on the urethral catheter to "bounce" the balloon at the bladder neck; (b) identifying the area where loose fat cannot be bluntly dissected off the prostate; and (c) identifying the prostatovesical junction laterally where the endopelvic fascia has been opened. These maneuvers (in addition with preoperative magnetic resonance imaging [MRI], when available) may also suggest the presence of a median lobe. The anterior bladder is incised horizontally with diathermy until the bladder is entered (Fig. 33.5). The urethral catheter balloon is deflated and the catheter pulled out of the bladder defect. The ProGrasp forceps (third arm) or the assistant can grab the catheter by its "eye" and pull it up toward the anterior abdominal wall. The assistant can then apply traction to the catheter outside the body putting the bladder neck under traction and exposing the posterior bladder neck. At this point, the ureteric orifices can be identified and avoided. The posterior bladder neck can now be incised. However, there are two situations that may make this part of the operation tricky and demand particular attention at this point of the surgery:

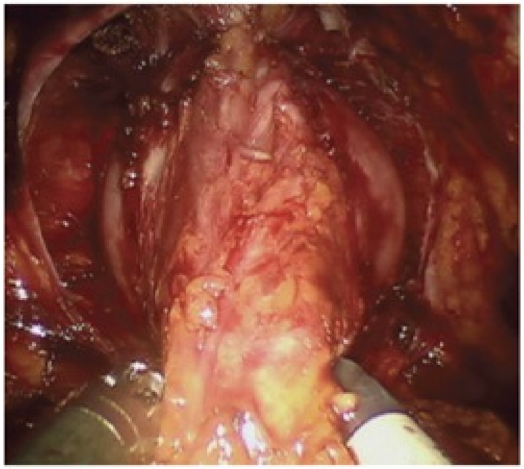

FIGURE 33.4 "Pinching" the bladder to identify the prostatovesical junction laterally

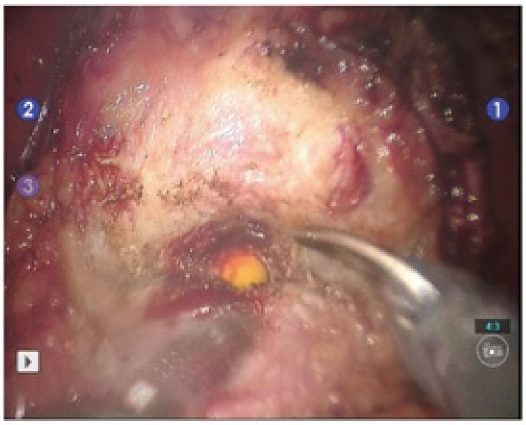

FIGURE 33.5 Incision of the anterior bladder neck, revealing the urethral catheter intravesically

1. Previous transurethral prostatectomy: The scarring left by surgery may make the ideal place to incise the posterior bladder neck difficult to judge. In addition, the ureteric orifices may lie closer to the incision than in a virgin bladder neck. It is important to identify the ureters (using methylene blue or indigo carmine if needed) and if necessary, intubate them with stents or feeding tubes until the bladder neck is mobilized and reconstructed. The incision should be distal to the ureters and continue through the bladder neck and any associated fibrosis.
2. The presence of a median lobe (Fig. 33.6): A median lobe may be deceptive and not always obvious when the anterior bladder neck is opened. The forceps via the third arm should be used to deflect the median lobe caudally in order to identify the posterior bladder neck and ureters. Occasionally, for larger median lobes, a figure-of-eight suture may be placed through the median lobe and the fourth arm can be used to retract and elevate the median lobe directly to facilitate exposure. The incision of the posterior bladder neck can then continue.

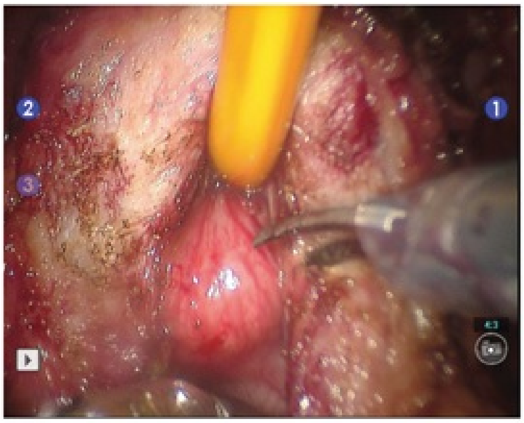

FIGURE 33.6 Identifying the presence of a median lobe with anterior retraction of the urethral catheter

The posterior bladder neck is incised with diathermy and sharp dissection (Fig. 33.7). Once divided, the curve of the scissors can be used to dissect behind the bladder neck exposing the anterior layer of Denonvilliers fascia which can be divided in the midline to expose the ampullae of the vasa and SV (anterior approach) or the previously dissected posterior plane. Prior to mobilizing the SV, access can be improved by widening the tissue lateral to the posterior bladder neck and clipping and dividing the lateral prostatic pedicles.

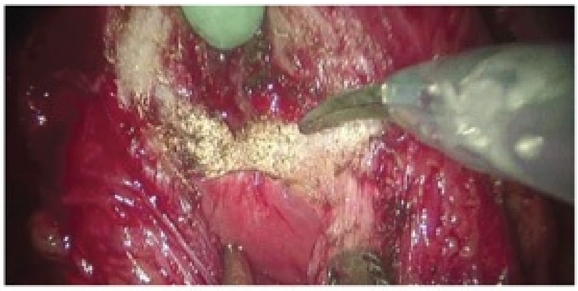

FIGURE 33.7 Incision of the posterior bladder neck

Dissection of the Vasa and Seminal Vesicles (Anterior Approach Only)

On each side, the fascia over the vas is incised. Each vas can be grasped and retracted out of the space anteriorly and mobilized before being clipped, along with its attendant vessels, and divided. This maneuver allows access to the posteromedial aspect of the SV. The SV should be fully mobilized along its medial aspect and posteriorly as far as its base. The dissection of the SV continues to its tip and the vessels in this area are clipped and divided, avoiding the issue of electrocautery near the neurovascular bundles (Fig. 33.8).

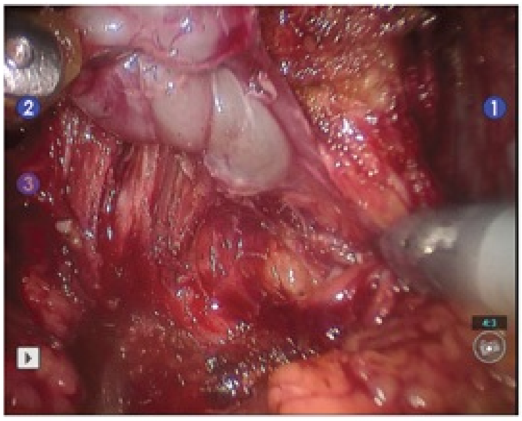

FIGURE 33.8 Dissection of the tip of the right seminal vesicle (being retracted anteriorly)

Posterior Dissection between Prostate and Rectum

Once free, the SV and vas on either side are retracted anteriorly to expose the posterior Denonvilliers fascia before entering the space behind the prostate and anterior to the rectum. The posterior layer of Denonvilliers fascia is incised horizontally just below the base of the SV to expose the perirectal fat. A combination of sharp and blunt dissection is used to mobilize the prostate from the rectum in the midline, extending out laterally toward the outer margins of the gland. It is critical to free the prostate from bladder neck to apex and to its lateral margins. Depending on the risk of extracapsular extension, the posterior layer of Denonvilliers fascia may be taken with the prostate or left on the rectum.

Vascular Control of the Lateral Pedicles and Nerve-Sparing Technique

The lateral pedicles are clipped with Hem-O-Lok clips close to the prostate and divided using electrocautery judiciously (Fig. 33.9). Following this step, it is important to avoid electrocautery whenever possible. The timing of nerve preservation is debatable. The dissection can take place either before the bladder neck is opened or as late as following posterior prostatic mobilization. The principle, however, is the same. The neurovascular bundle (NVB) is enclosed within the two thin layers of the periprostatic fascia. The fascia on the lateral prostate should be incised on the anterior lateral part of the gland, parallel to the NVB. The fascia is swept laterally away from the gland and the dissection is continued proximally to the junction between bladder and prostate and distally to the prostatic apex (Fig. 33.10). If the appropriate plane is entered, this is a mostly avascular dissection although several perforating micropedicles are often encountered entering the prostate. Bleeding here is typically self-limited but can be controlled with a 4-0 Monocryl suture if needed on the NVB precisely and superficially. Gentle sharp and blunt dissection are used to free the fascia and the NVB along its entire length from apex to bladder neck. Care must be taken to avoid traction injury to the NVB during this step.

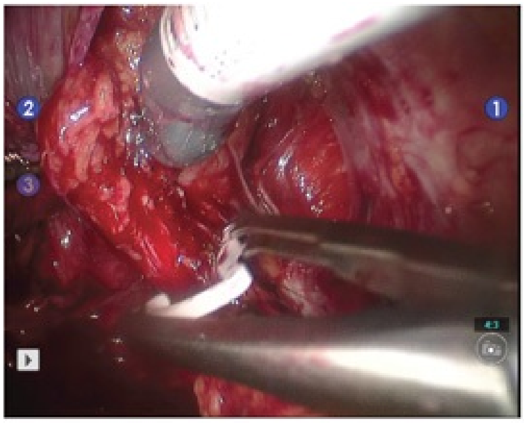

FIGURE 33.9 Control of the prostatic vascular pedicle with placement of Hem-o-lok (Weck) clip

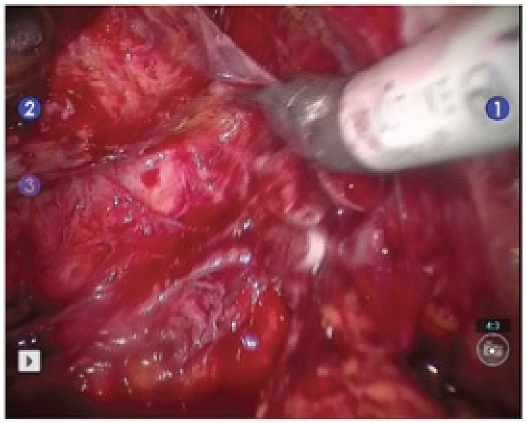

FIGURE 33.10 Nerve-sparing technique with athermal lateral displacement of the right neurovascular bundle

Division of the Dorsal Vein Complex and Urethra

If the 30-degree camera was used for the bladder neck dissection, it should be changed to a 0-degree camera at this time. The prostate by now is fully mobilized apart from the urethra/DVC complex. The fourth arm is used to provide gentle caudal traction on the “back-bleeder” suture on the prostate. The DVC is divided using electrocautery (Fig. 33.11) and the urethra is identified. The anterior urethra is then opened 1 to 2 mm distal to the apex using the cold scissors and the urethral catheter exposed (Fig. 33.12). Using the bipolar forceps, a plane posterior to the urethra and anterior to the rectourethralis muscle is identified and sharply divided. Remaining attachments to the posterior apex from the rectourethralis are divided and the specimen is delivered into a 10-mm laparoscopic specimen catch bag.

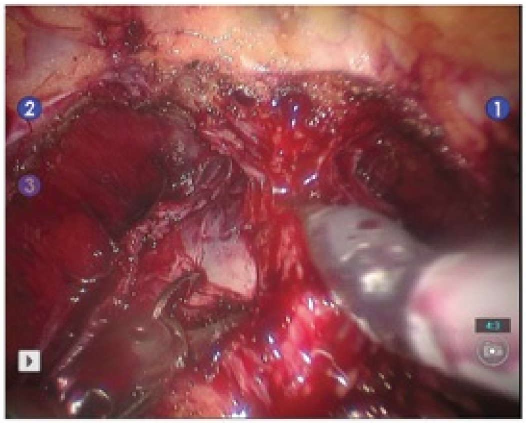

FIGURE 33.11 Division of the ligated dorsal vein complex using electrocautery

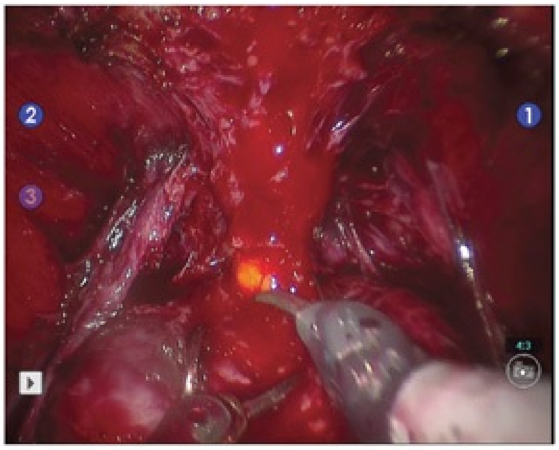

FIGURE 33.12 Incision of the anterior urethra with cold scissors

Vesicourethral Anastomosis

A posterior reconstruction of the musculofascial tissue is commonly performed using the “Rocco” technique, which has been demonstrated to markedly shorten the time to continence (16). Some surgeons advocate for additional techniques that may speed the return to continence such as anterior reconstruction or a periurethral suspension stitch, but we do not routinely perform these given the very high rates of continence with the Rocco technique alone. A 3-0 barbed monofilament suture is used to reapproximate the remnant of Denonvilliers fascia and the tissue of the posterior bladder wall cranial to the bladder neck. This maneuver reduces tension on the anastomotic suture by reducing the distance between the bladder and the urethra and promotes hemostasis by securing the bladder to the prostate bed.

There are a number of described approaches to the vesicourethral anastomosis. Typically, the anastomosis is performed with a double-ended barbed 3-0 monofilament suture commencing posteriorly at six o’clock. The suture continues between the bladder neck and the urethra in both clockwise and counterclockwise directions (Fig. 33.13) until the ends meet at 12 o’clock, where the suture is tied (Fig. 33.14). On completion, the integrity of the anastomosis is tested by passing a new 18Fr Foley catheter and filling the bladder with 240 mL of sterile water. If the anastomosis is water tight, no drain is required. If a drain is used, it can be placed through the fourth robotic port and secured following port removal.

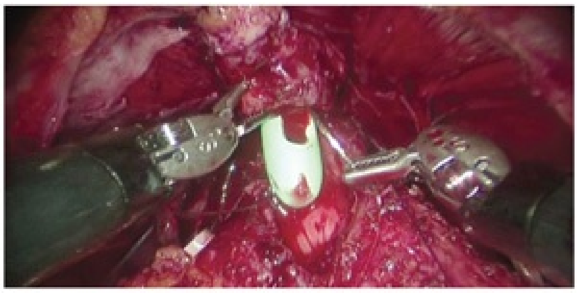

FIGURE 33.13 Placement of vesicourethral anastomotic sutures

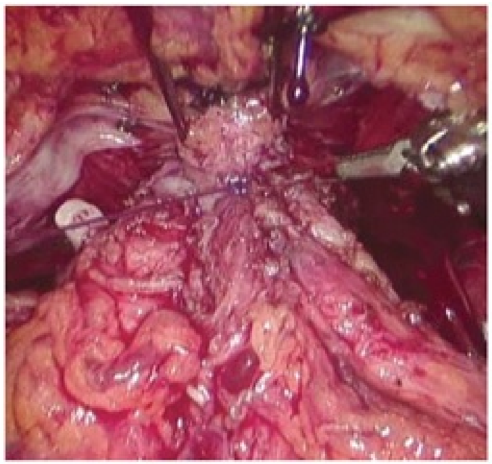

FIGURE 33.14 Completion of the vesicourethral anastomosis

Specimen Retrieval and Port Closure

The robot is undocked and the fascia of the lateral assistant port is closed using the Carter-Thomason technique with a 0-Vicryl suture under laparoscopic guidance. This port is then reintroduced and the camera is then located here so that the sutures to the Endocatch bags containing the prostate and pelvic lymph nodes can be brought through the midline camera port. This port is enlarged slightly to facilitate delivery of the pathologic specimens. The extraction site is closed with multiple 0-Vicryl sutures on a UR needle in a figure-of-eight fashion. Insufflation is then reestablished and the abdomen and pelvis is inspected one final time for hemostasis and to ensure that all fascial closures are intact. Incisions are closed with 4-0 Monocryl suture and Dermabond.

Postoperative Care

The patient usually requires minimal analgesia in the postoperative period. Our postoperative pathway consists of standing Tylenol and Toradol with breakthrough narcotic as needed. The majority of patients will not use narcotics in the postoperative period.

The patient can eat and drink immediately and should be ambulating in the early postoperative period. Most patients are discharged either on the day of surgery or day 1. The urethral catheter is left in situ for 5 to 7 days and removed. Routine cystogram is unnecessary.

Postoperative Complications

Bleeding is usually minimal with average blood loss of less than 200 mL. In the authors' cumulative experience of several thousand cases, transfusion rates are close to 0 and return to the operating room for bleeding occurs in less than 0.1% of cases. Significant infections are uncommon and other than perioperative antibiotics, no additional antibiotics are prescribed. Port site hernias are uncommon with meticulous closure technique and laparoscopic inspection of the extraction site closure prior to completion of surgery.

Bowel injury is potentially the most serious complication, albeit rare. Any tears, partial or full-thickness, in colon or small bowel can be repaired with a two-layer closure. If rectal injury is suspected, a soft 20Fr tube can be inserted into the rectum and then the injury can be identified by filling the pelvis with saline and blowing air into the rectum. If a rectal injury is found and there is minimal contamination, it should be repaired with a running two-layer closure and broad-spectrum antibiotic coverage should be commenced. A colostomy is only required if there is significant fecal contamination or signs of sepsis.

Initially, perioperative outcomes in regard to blood loss, transfusion requirement, length of stay, narcotic usage, and catheter duration following RALP were considerably shorter than were seen with open techniques. One major result of this technology has been that open surgeons have adopted RALP postoperative pathways for discharge and catheter duration, mitigating some of these differences (17,18). Long-term functional outcomes for urinary control and erections following RALP appear to be similar to those of open and laparoscopic surgery and are likely to vary more by surgeon and experience than by surgical approach (19,20).

CHAPTER 34 BRACHYTHERAPY FOR LOCALIZED PROSTATE CANCER

EVA MARIE SUAREZ, HARRY S. CLARKE, AND DAVID T. MARSHALL

The term *brachytherapy* describes the process of placing a radioactive source directly inside or in close proximity to the intended target. The use of brachytherapy in prostate cancer was first reported by Pasteau and Degrais in 1913 (1), and various techniques have been explored since. Retropubic implantation of radioactive sources was used initially until the introduction of the transrectal ultrasound (TRUS) probe in the early 1980s (2). Significant advancements in ultrasound technology have led to ultrasound-guided transperineal prostate brachytherapy as the currently accepted technique used for prostate brachytherapy and has experienced substantial growth over the last 20 years.

Brachytherapy offers several advantages over radical prostatectomy, including patient convenience, no surgical incision, decreased anesthesia requirement, minimal blood loss, rapid recovery, and less risk of incontinence. Brachytherapy also offers advantages over external beam radiation therapy (EBRT). Proper brachytherapy technique can lead to decreased radiation dose to surrounding structures, thereby limiting normal tissue toxicity. Evidence continues to accumulate demonstrating the importance of dose escalation in prostate cancer. In order to deliver an acceptable dose via EBRT, patients may undergo several weeks of treatment, whereas brachytherapy can be completed during an outpatient procedure or a short hospitalization. Finally, the position of the prostate and surrounding critical organs may be difficult to reproduce daily during a protracted course of treatment, which may lead to an increased dose to normal tissues or a decreased dose to the prostate. Potential disadvantages to brachytherapy compared to external beam radiotherapy are that it may take longer to develop brachytherapy skills, is at least minimally invasive with a higher risk of urinary retention, and requires anesthesia. Compared to surgery, the risk of bowel changes and toxicity may be greater with brachytherapy.

Three isotopes (^{125}I, ^{103}Pd, and ^{131}Cs) are now available for low-dose-rate (LDR) brachytherapy. The majority of the radiation dose is delivered over 2 to 10 months, depending on which isotope is used. The timing and severity of acute side effects have been described regarding the different sources; however, no convincing evidence is available to recommend one source over another. LDR brachytherapy involves the transperineal placement of radioactive seeds into and around the prostate. The seeds remain in place permanently but lose radioactivity over time. High-dose-rate (HDR) brachytherapy has been increasingly utilized as well. Catheters are placed within the prostate as described in the following text for LDR needles, and a dosimetric plan is developed with computerized tomography (CT) or TRUS imaging and computer planning. An iridium-192 source can then be moved in and out of each catheter remotely via a computer-controlled robotic device. The time the radioactive source spends in each catheter and at each dwell position within each catheter can be manipulated via computer control to achieve a conformal radiotherapy plan. HDR brachytherapy typically requires a short hospital stay and 2 to 10 treatments over a 1- to 5-day period.

DIAGNOSIS

The diagnosis and risk stratification of prostate cancer is via 12 to 16 core prostate biopsies following an elevated prostate-specific antigen (PSA) or abnormal digital rectal exam. Patients with high risk of seminal vesicle involvement, such as those with large nodules on exam or perineural invasion seen on prostate biopsy, should undergo TRUS-guided biopsy of the seminal vesicles. Magnetic resonance imaging (MRI) can also be used to detect otherwise occult seminal vesicle involvement or extracapsular extension. Pelvic lymphadenectomy is not commonly performed for patients with low-risk disease. Patients with high risk of lymph node involvement (patients with seminal vesicle involvement, Gleason score >7, PSA >20) may benefit from laparoscopic pelvic lymph node dissection as nodal involvement changes treatment recommendations.

INDICATIONS FOR SURGERY

When considering brachytherapy as monotherapy for prostate cancer, it is critical to carefully select patients with low-risk disease or those with favorable intermediate risk disease. A number of tools have been developed to aid the physician when making this selection, including the Partin tables (3) and the Roach formulas (4,5). These tools can help estimate the risk of extraprostatic extension, seminal vesicle invasion, and pelvic lymph node involvement. Recommendations have been made regarding classification of patients into low-, intermediate-, and high-risk categories as illustrated in Table 34.1. Low-risk prostate cancer can be summarized as PSA <10, Gleason score <7, and clinical stage <T2b. Other risk factors, such as presence of perineural invasion or lymphovascular space invasion, and number of cores positive on biopsy, should be considered when stratifying patients and choosing appropriate treatment modalities. Recent literature also demonstrates acceptable outcomes when treating patients with favorable intermediate risk disease with brachytherapy as monotherapy. Typically, patients who have only one intermediate risk factor are considered (6,7), but data is emerging demonstrating excellent control rates for higher risk patients with or without a short course of androgen deprivation therapy (ADT) (6,8,9).

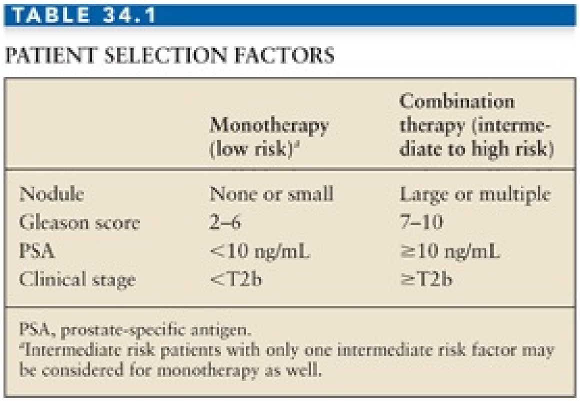

TABLE 34.1

PATIENT SELECTION FACTORS

	Monotherapy (low risk)[a]	Combination therapy (intermediate to high risk)
Nodule	None or small	Large or multiple
Gleason score	2–6	7–10
PSA	<10 ng/mL	≥10 ng/mL
Clinical stage	<T2b	≥T2b

PSA, prostate-specific antigen.

[a] Intermediate risk patients with only one intermediate risk factor may be considered for monotherapy as well.

Brachytherapy alone is not generally recommended as monotherapy for higher intermediate or high-risk patients. However, there is a growing body of evidence supporting the use of brachytherapy as a boost when combined with EBRT and ADT for higher risk disease (10–14). Brachytherapy is used in this situation as a very effective method of dose escalation. One recently reported trial from Canada, called the Androgen Suppression Combined with Elective Nodal and Dose Escalated Radiation Therapy (ASCENDE-RT) trial, randomized patients to dose-escalated EBRT with short-course ADT versus EBRT plus LDR brachytherapy with short-course ADT (15). In preliminary reports, LDR brachytherapy was shown to improve PSA control. Nine-year Kaplan-Meier relapse-free survival estimates were 63% for dose-escalated EBRT versus 83% for EBRT plus LDR brachytherapy.

ALTERNATIVE THERAPY

Prostate brachytherapy can be an ideal treatment for men with localized, low-risk prostate cancer, but good alternatives exist and may be more appropriate in certain situations. Men with high International Prostate Symptom Scores (IPSS), large prostate volume, or history of previous transurethral resection of the prostate (TURP) may tolerate EBRT or prostatectomy better than brachytherapy while achieving a similar therapeutic outcome. High IPSS before treatment predicts significant risk of severe lower urinary tract symptoms (LUTS) and acute urinary obstruction following brachytherapy (16). Similarly, large prostates have been shown to be at increased risk for urinary retention (17), although the absolute risk may still be low depending on the technique used (18). Patients with a history of prior TURP may be at increased risk for significant toxicity, including incontinence, if LDR brachytherapy is used (19,20), especially if the residual TURP deficit is large. This risk may be less with HDR brachytherapy (20a).

LOW-DOSE-RATE BRACHYTHERAPY

Selection of Isotope

Three isotopes (^{125}I, ^{103}Pd, and ^{131}Cs), as noted earlier, are currently being used for LDR prostate brachytherapy. Each delivers radiation to a volume of tissue within millimeters of each source. They differ in initial activity, dose rate, and half-life, as illustrated in Table 34.2. Some investigators believe ^{103}Pd may be more effective than ^{125}I at eradicating more rapidly proliferating tumors due to higher initial activity (20 to 25 cGy per hour and 7 to 10 cGy per hour, respectively). This belief has been propagated by convincing mathematical models and has led to the emergence of ^{131}Cs (32 cGy per hour) as another option. However, no conclusive clinical evidence proving this theory has yet been published, and one clinical trial has shown equivalence between ^{125}I and ^{103}Pd regarding PSA control at 3 years (21). The current recommended doses for the three isotopes in monotherapy and in combination with external beam therapy are shown in Table 34.3.

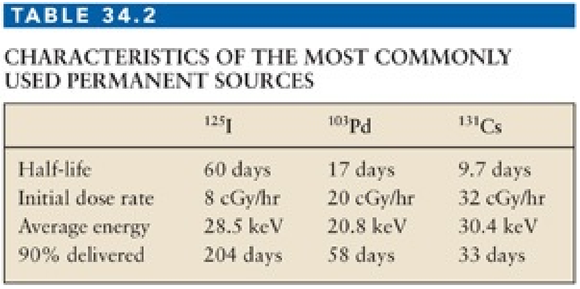

TABLE 34.2

CHARACTERISTICS OF THE MOST COMMONLY USED PERMANENT SOURCES

	^{125}I	^{103}Pd	^{131}Cs
Half-life	60 days	17 days	9.7 days
Initial dose rate	8 cGy/hr	20 cGy/hr	32 cGy/hr
Average energy	28.5 keV	20.8 keV	30.4 keV
90% delivered	204 days	58 days	33 days

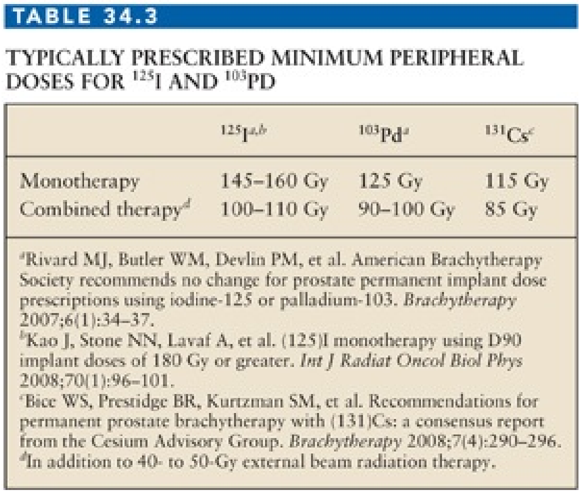

TABLE 34.3

TYPICALLY PRESCRIBED MINIMUM PERIPHERAL DOSES FOR ^{125}I AND ^{103}PD

	$^{125}\mathrm{I}^{a,b}$	$^{103}\mathrm{Pd}^{a}$	$^{131}\mathrm{Cs}^{c}$
Monotherapy	145–160 Gy	125 Gy	115 Gy
Combined therapy[d]	100–110 Gy	90–100 Gy	85 Gy

Treatment Planning

Prostate LDR brachytherapy has evolved significantly over the years, and two methods now predominate: preplanned implant as popularized by the Seattle Prostate Institute and intraoperative planning as developed at Mount Sinai School of Medicine (MSSM) in New York.

Preplanning Approach

With this approach pioneered in Seattle (22), the patient is placed in the dorsal lithotomy position (Fig. 34.1) and an imaging study of the prostate is performed using TRUS (Fig. 34.2) 1 to 2 weeks before the implant. This image data set is imported into the brachytherapy planning software and utilized to develop an optimized plan. The number of seeds ordered for the procedure is then determined from this preplan. The patient is taken to the operating room (OR) on the day of the procedure and is positioned as he was on the day of planning. It is critically important that the patient's preplanning position is reproduced as accurately as possible in the OR. Seeds are then placed within the prostate with TRUS guidance (Fig. 34.3) using needles preloaded with seeds or strands of connected seeds according to the previously developed plan. Alternatively, seeds may be placed with a gun-type applicator, such as the Mick applicator (Mick Radio-Nuclear Instruments, Mount Vernon, New York), based on the planning study completed earlier. With the preplanned approach, the Mick applicator allows the practitioner to make minor adjustments to more accurately reproduce the preplanning study. A combination of preloaded needles and free seeds placed with the Mick applicator can also be used.

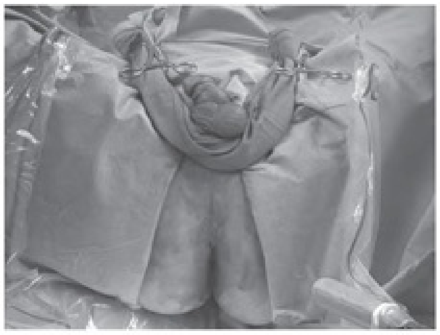

FIGURE 34.1 Patient prepared for TRUS in the dorsal lithotomy position.

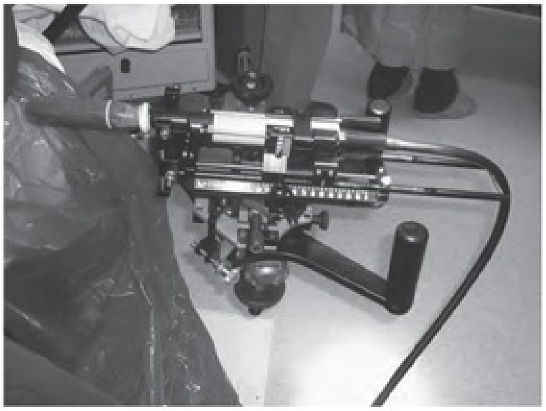

FIGURE 34.2 TRUS probe in ratcheting cradle/stepper.

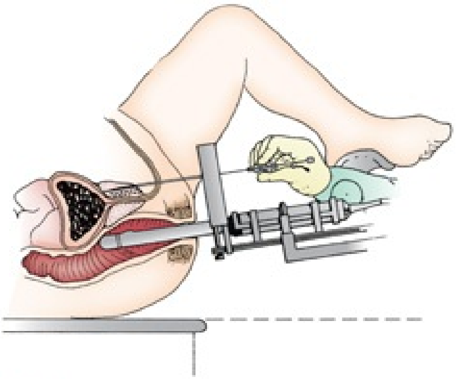

FIGURE 34.3 Schematic of the closed, ultrasound-guided implantation technique.

Real-time Intraoperative Planning Approach

With this approach developed by Stock et al. at MSSM (23), no preplanning study is acquired; however, the prostate volume is measured via a CT, MRI, or TRUS study at some point prior to the day of the implant in order to determine how many seeds to order for the procedure. This can be the volume determined at TRUS done for the initial biopsy. The patient is then brought to the OR and placed in the dorsal lithotomy position. TRUS is used to localize the bladder, urethra, prostate, seminal vesicles, and anterior rectal wall in three-dimensional space, and these data are recorded in the intraoperative treatment planning software (Fig. 34.4). An initial intraoperative plan is then developed based on a prostate volume-to-activity nomogram developed at MSSM. Needles are placed in the periphery of the prostate at approximately 1-cm intervals (Fig. 34.5). Once the needles are placed, images are reacquired to account for changes in size, shape, and position of the prostate that occurs with the inflammation induced by multiple needle placement (Fig. 34.6). The plan is optimized for actual position of the needles and for any changes in shape of the prostate due to needle placement. Longitudinal views on the TRUS are used to observe placement of the seeds into the prostate according to the intraoperative plan (Fig. 34.7). Seeds are most often placed using a Mick applicator. Typically 75% of the required activity is placed in the periphery of the gland, while 25% is placed in the interior of the gland. Then needles are placed in the central portion of the gland and the Mick applicator is then used to place the remaining 25% of the required activity in the gland according to the intraoperative plan. The majority of the inner seeds are placed at the apex and base of the gland in order to "cap" the prostate. Using modern treatment planning software and TRUS, the actual seed location can be documented as the seeds are placed and the intraoperative plan can better reflect reality, allowing for dosimetric inadequacies to be detected and corrected during the procedure.

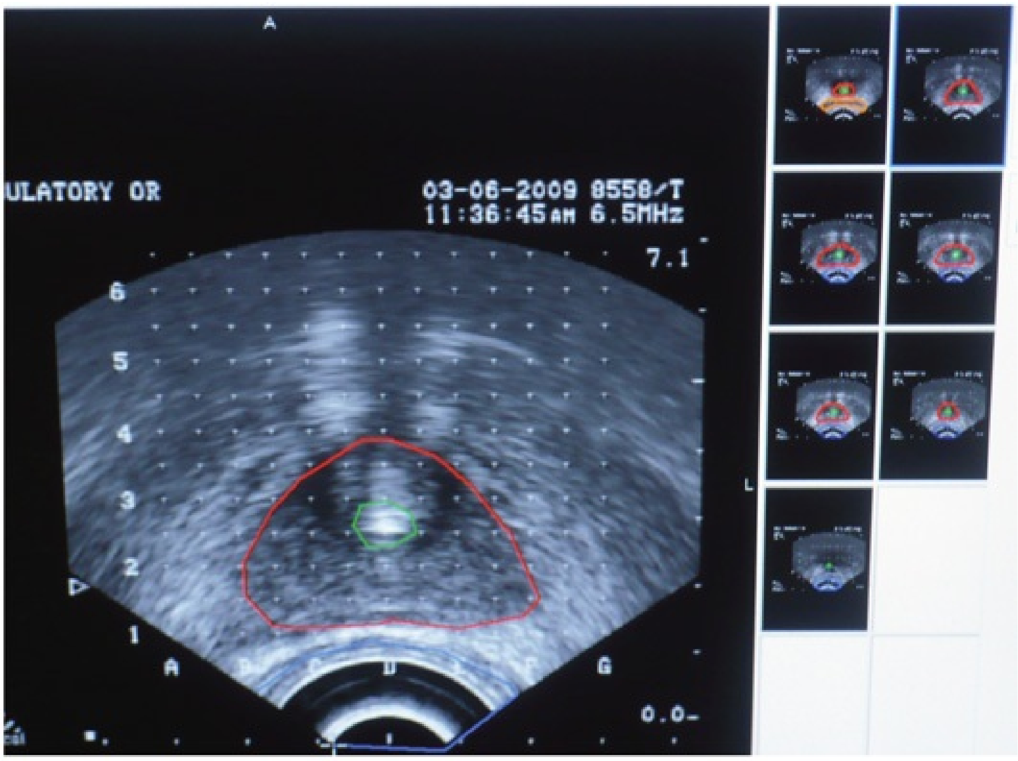

FIGURE 34.4 Ultrasound imaging of the prostate, urethra, seminal vesicles, and rectum in the intraoperative treatment planning system before needle placement. This data set is used to create the "preplan" in the OR.

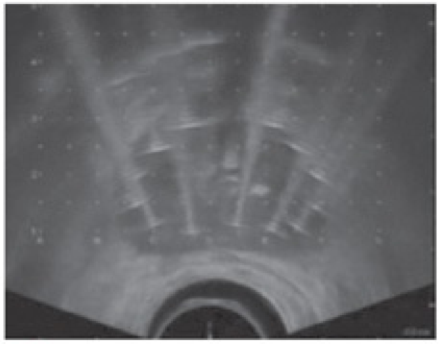

FIGURE 34.5 Axial ultrasound image of the prostate after peripheral needles have been placed.

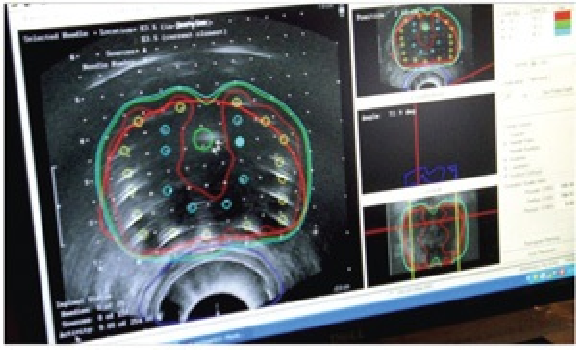

FIGURE 34.6 Treatment planning transverse and axial images of the prostate showing preliminary isodose lines for a ^{103}Pd implant (prescription dose = 100 Gy).

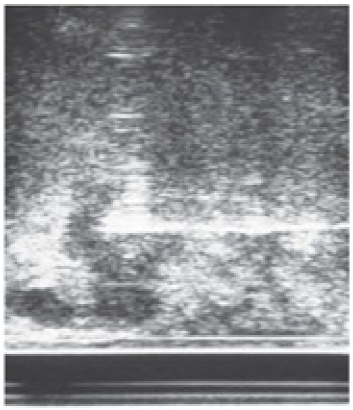

FIGURE 34.7 Longitudinal ultrasound view of seeds being deposited in the prostate.

This approach offers many advantages over the previously described technique as well as some disadvantages. The most significant advantage is that intraoperative planning allows for real-time optimization of the plan as each seed placed in the prostate is accounted for in the planning software and the resultant isodose lines are generated. No preplan is needed. Three variables unaccounted for with the preplanned technique, including changes in prostate size and shape with needle placement, needle deviation from planned position, and seed movement from initial placement, can be actively detected in the intraoperative treatment planning software and therefore corrected with subsequent seed deposition. Disadvantages include potentially longer procedure duration and Mick applicator utilization, which some practitioners may find unwieldy. Although the Mick applicator requires significant operator skill, in practiced hands, this applicator allows precise placement of individual seeds and significant flexibility. Some investigators have noted seed migration when seeds are placed individually in the prostate and surrounding tissues and have therefore argued for the use of stranded seeds. In fact, seeds have been observed to move significant distances and even to the lungs or other remote locations. When compared to stranded or linked seeds, single seed placement has been documented to result in increased overall seed migration (24,25). However, this has not been definitively shown to affect overall dosimetric outcome or toxicity (26–28).

Hybrid Approach with Real-time Planning and Linked Seeds

A novel technique has been developed and is currently being pursued at several institutions in an attempt to combine the advantages of real-time intraoperative planning and linked seeds (29–32). This technique is very similar to the intraoperative planning technique described earlier; however, strands or links of seeds are formed in the OR at the time of implant in response to real-time treatment planning. As before, an imaging study is obtained before the date of implant to determine the prostate volume, and an appropriate number and activity of seeds are ordered according to a nomogram. On the day of implant, the patient is placed in the dorsal lithotomy position and TRUS is utilized to build a three-dimensional model of the prostate, bladder, and anterior rectal wall within the treatment planning system as described earlier in the intraoperative planning approach. An initial intraoperative plan is then developed by the radiation oncologist while the urologist places needles in the periphery of the prostate at approximately 1-cm intervals under TRUS guidance (as in Fig. 34.5). Once the needles are placed, images are reacquired and the plan reoptimized. Longitudinal views of each individual needle are used to calculate the distance each needle traverses through the prostate. A device such as the QuickLink push-button delivery system (C. R. Bard, Inc, Covington, Georgia) or other method of linking seeds is then used to construct links of the appropriate number of seeds for the length measured along the longitudinal path of each needle in the prostate (Fig. 34.8). Each strand can be customized according to the number of seeds needed, and the overall length of the needle path in the prostate via custom-sized linkers or spacers. The linked seeds are then transferred to the prostate via the appropriate needle in a manner similar to that used with a preloaded needle in a preplanned approach (Fig. 34.9). The process is then repeated until all peripheral seeds have been placed. The inner needles are then placed (usually five to seven). The plan is then reoptimized to determine placement of the remaining required activity. Once the plan has been approved, the remaining interior links of seeds are constructed and placed within the prostate as described earlier. Multiple studies have demonstrated this hybrid planning approach provides similar quality of dosimetry and OR times, once the learning curve has been met, as compared to the traditional gun method (30,31,33).

FIGURE 34.8 Custom-constructed linked seeds. Note asymmetrical seed pattern that can be constructed in the OR according to the real-time plan.

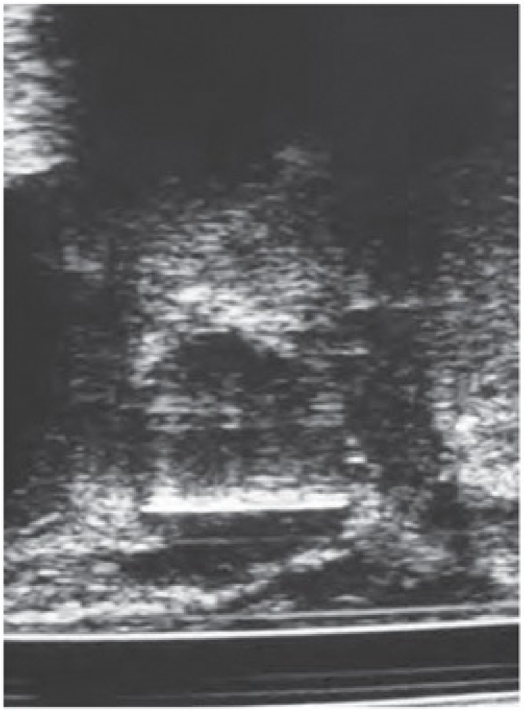

FIGURE 34.9 Longitudinal ultrasound image of linked seeds in prostate after implantation.

Postimplant Visualization

Following prostate seed implantation, flexible cystoscopy may be performed to verify an intact urethra and bladder wall and to account for any misplaced seeds in the bladder or protruding through the urethral wall. C-arm radiography may also be performed to verify seed position and to document the presence or absence of loose seeds in the bladder.

Postimplant Dosimetry

Postimplant dosimetry should be obtained at a consistent interval following prostate seed implant; however, the most appropriate interval is yet to be determined. Many institutions have patients return at 1 month following the implant for CT imaging. This image data set can then be imported into the treatment planning system, allowing for determination of dosimetric end points. Using this study, seed count should be verified, and isodose curves at 50%, 80%, 90%, 100%, 150%, and 200% of the prescribed dose should be displayed on axial images of the prostate, urethra, bladder, and rectal wall. The prostate D90, or minimum dose delivered to 90% of the prostate, as well as normal tissue doses, such as rectal V100 (volume of rectum receiving 100% of the prescribed dose) and urethral D30 (dose to hottest 30% of the urethra), should be recorded (34).

HIGH-DOSE-RATE BRACHYTHERAPY

HDR brachytherapy was initially developed in the mid-1990s to provide an alternative to LDR brachytherapy as a boost to EBRT. It has gained popularity since its introduction given the multiple potential advantages HDR may offer. It eliminates radiation exposure to medical personnel and the need for patients to follow radiation precautions because they are not radioactive after their treatment. HDR brachytherapy also provides a greater number of dwell positions than the number of seeds typically used for an LDR case. More dwell positions in conjunction with adjustable dwell times allow for conformal planning, including potentially better urethral avoidance, and the ability to plan a concomitant boost if needed. Biologically, HDR also theoretically provides the advantage of delivering a high dose per fraction, which results in a greater biologic effective dose for a malignancy with a considerably low α/β ratio. It has been hypothesized that prostate cancer is such a malignancy, but long-term results from studies testing this theory have been mixed (35,36). Disadvantages of HDR compared to LDR include the requirement for catheters to stay implanted in the patient's perineum for the course of the therapy, and the need for multiple surgical procedures to place the catheters if the treatments are separated in time by more than a few days.

Isotope

Contrary to LDR brachytherapy, HDR brachytherapy uses one radioactive source to treat several patients. As previously mentioned, the most commonly used isotope is iridium-192. It has significantly higher energy emission in comparison to the sources used for LDR brachytherapy with an average photon energy of 0.38 MeV and a half-life of 73.8 days. This allows for a greater dose to be delivered to the tissues surrounding the source over a shorter period of time. Treatments administered with ^{192}Ir are therefore administered over several minutes as a single source is propelled by a computer-controlled stepper motor unit through the catheters that are placed in the OR. Given its relatively short half-life, care must also be taken to appropriately account for the decay of the isotope prior to the delivery of each fraction.

Surgical Technique

Similar to LDR brachytherapy, HDR brachytherapy also involves the placement of catheters in and around the prostate gland in the OR with the patient in the dorsal lithotomy position. After the patient is properly positioned, TRUS is used along with a template to aid in the placement of at least 14 catheters similar to placement described earlier for LDR brachytherapy. Typically, the patient will be transferred after catheter placement, and the template will have a locking mechanism to reduce displacement of the catheters during transfers. Fiducials can also be placed intraoperatively at the base and apex of the prostate gland not only for treatment planning but to also assess for changes in anatomy if multiple fractions are planned. No preplanning is required for HDR as this process takes place after catheter placement. No sources need be ordered for a particular patient as the HDR unit houses the source on site for use with multiple patients.

Treatment Planning

HDR brachytherapy planning uses a three-dimensional image data set to define a target treatment volume and avoidance structures similar to the intraoperative LDR approach described earlier. These images can be obtained intraoperatively by TRUS similar to LDR treatment planning or the patient can be transferred to a CT scanner after catheter placement and a CT data set used for treatment planning. The advantage of planning a treatment via ultrasound is this allows for the treatment to be administered without transferring the patient. However, in this case, the OR must be properly equipped with appropriate radiation shielding and have access to the HDR unit. Alternatively, the advantage of planning based on a postoperative CT scan is reduction in the post-acoustic shadowing caused by the catheters on ultrasound and improved visualization of the organs at risk with CT. Once the images are transferred to the treatment planning software, the physician contours the region to be treated, known as the clinical treatment planning volume (CTV), and the structures that are to be avoided, known as the organs at risk (OAR) including bladder, rectum, and urethra. The CTV should encompass the entire prostate and any extraprostatic extension of disease. In most practices, the CTV is equivalent to the planning treatment volume (PTV), although an additional margin for motion may be added to the CTV to form the PTV. The catheters are also identified on the image data set and registered to identify the available dwell positions along each catheter.

Computerized treatment planning algorithms use geometric or inverse planning to optimize the dose to the PTV while minimizing dose to the OARs. Differences in the dose distribution are created by varying the dwell positions used and the time the iridium source will stop at each position. The algorithm produces isodose volumes that represent the dose that will be delivered on the three-dimensional image set. The physician then has the opportunity to adjust the dose distributions either through manual optimization or by repeating the algorithm with different parameters. Generally adequate coverage of the PTV constitutes 90% to 95% of the PTV receiving at least 100% of the prescription dose. The maximum dose to the urethra, bladder, and rectum should also be calculated and recorded. Additional normal tissue parameters that should also be documented include the V100 of the urethra and the V75, D2cc, and D5cc of the rectum. Specific recommendations of the dose tolerance of each of these structures are dependent on the prescription dose and fractionation used, which vary widely (Table 34.4).

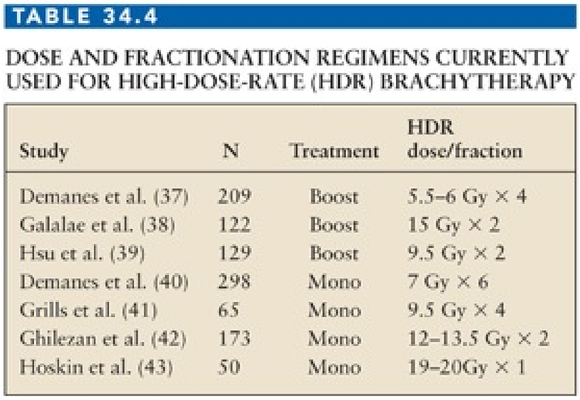

TABLE 34.4

DOSE AND FRACTIONATION REGIMENS CURRENTLY USED FOR HIGH-DOSE-RATE (HDR) BRACHYTHERAPY

Study	N	Treatment	HDR dose/fraction
Demanes et al. (37)	209	Boost	5.5–6 Gy × 4
Galalae et al. (38)	122	Boost	15 Gy × 2
Hsu et al. (39)	129	Boost	9.5 Gy × 2
Demanes et al. (40)	298	Mono	7 Gy × 6
Grills et al. (41)	65	Mono	9.5 Gy × 4
Ghilezan et al. (42)	173	Mono	12–13.5 Gy × 2
Hoskin et al. (43)	50	Mono	19–20Gy × 1

If multiple fractions are planned for the same implant, repeat imaging should be obtained to confirm the catheters have not migrated from their initial placement. The length of the catheters can also be measured as a guide for displacement in addition to changes in the location of the fiducial markers that were placed intraoperatively. Patient comfort must also be addressed between fractions with either an epidural or intravenous pain medication. If the patient will return to the OR for an additional insertion, care should be taken to provide a uniform dose distribution. This can be accomplished by replicating the patient's position from his previous implant and using a similar catheter distribution. Repeat imaging should also be performed for each insertion so the physician may contour the CTV and OARs on the new image data set. The previous plan can be superimposed on this data set and adjusted as needed or a new plan can be created.

Initially, prostate HDR brachytherapy was developed as a boost to EBRT but several institutions have implemented the technique as monotherapy. Dose and fractionation schemes are highly variable between institutions as demonstrated in Table 34.4 with a trend toward extreme hypofractionation, one to two fractions, to eliminate the need for multiple implants or epidural pain management. Generally two to four fractions are used when administered as a boost to EBRT with a range of 4 to 15 Gy per fraction. When used as monotherapy, a larger variability is noted, where one to seven fractions are administered at 6 to 20 Gy per fraction.

Posttreatment Care

At the completion of the HDR treatment, the catheters are removed and perineal pressure applied. Bladder irrigation is also commonly used to flush out any blood clots before the urinary catheter is removed. Antibiotics are commonly prescribed if the patient's treatment required hospitalization and may be continued after discharge at the discretion of the treating physician.

OUTCOMES

Complications

Immediate symptoms following brachytherapy are related to needle placement and include edema, bleeding, pain, and infection. The risk of infection can be minimized with the use of intraoperative antibiotics and a short course of postoperative antibiotics. Intraprostatic edema and bleeding in LDR brachytherapy may lead to urinary retention in approximately 5% to 15% of patients (4) and 1% to 12% for HDR brachytherapy (5,44). Large prostate volume and an elevated pretreatment IPSS predict an increased risk of urinary retention, and some studies have shown that a short course of androgen deprivation may reduce this risk particularly for LDR implants (18).

Urinary irritation may develop within 1 to 2 months after ^{125}I implantation and within 1 to 2 weeks with ^{103}Pd, ^{131}Cs or ^{125}Ir. These symptoms can be monitored and prospectively recorded through utilization of IPSS evaluation at each subsequent follow-up. The majority of men undergoing prostate brachytherapy will experience urinary symptoms such as increased frequency, dysuria, nocturia, and weakened stream, which can be treated symptomatically with alpha blockers and antimuscarinics. Most men will return to their baseline function at 1 to 2 years. Proctitis may also occur in approximately 15% of men and manifest as mild hematochezia typically 1 to 2 years after treatment. These symptoms can often be managed conservatively by avoiding constipation with stool softeners and in severe cases with argon-plasma coagulation.

Late complications associated with prostate brachytherapy include erectile dysfunction, a low risk of incontinence, and the remote possibilities of severe rectal injury or secondary malignancies of the pelvis. Rectal injuries such as a rectal-urethral fistula occur in less than 1% of cases (16). The risk of developing incontinence after LDR brachytherapy is limited except for men who have undergone a previous TURP or require a TURP for obstruction after brachytherapy (20). Currently, there is no evidence to suggest that patients who undergo HDR brachytherapy are at a similar risk if they had a previous TURP. Erectile function will likely decrease in 20% to 30% of men 2 to 3 years after brachytherapy, although the majority of these patients have improvement in their erectile function with pharmacologic agents. Finally, EBRT has been associated with an absolute 1% increase in secondary malignancies of the rectum or bladder as compared to patients undergoing prostatectomy alone (45). Theoretically, prostate brachytherapy would carry a similar risk, and at least one retrospective review has suggested that brachytherapy may be associated with a small increased risk of developing a bladder cancer after prostate brachytherapy (46).

Results

Defining and subsequently reporting prostate cancer outcomes has been the subject of much debate. Unlike with prostatectomy, PSA levels decrease but often do not become undetectable following radiation therapy. Therefore, the American Society for Therapeutic Radiology and Oncology Consensus Panel issued a consensus statement in 1997 defining biochemical failure following radiation therapy for prostate cancer as three consecutive increases in PSA value. The date of failure was defined as the midpoint between the postirradiation nadir PSA and the first of the three consecutive rises (47). These recommendations were found to be unwieldy and were subsequently revised in 2006 based on a consensus meeting in Phoenix, Arizona, to the current definition of a PSA relapse after radiotherapy (EBRT or brachytherapy): a PSA rise of 2 ng per mL or more above the nadir PSA with no backdating (48). This is referred to as the Phoenix criterion for PSA relapse.

Prostate cancer outcomes have been actively studied following brachytherapy, and long-term outcomes have now been published confirming the utility of this procedure as a boost to EBRT for all risk groups or as monotherapy for the low to intermediate risk groups. Table 34.5 summarizes nine series reporting long-term outcomes following brachytherapy as the sole intervention for localized prostate cancer. Freedom from PSA failure at 10 years is approximately 90% and compares favorably with outcomes obtained from other therapeutic options such as EBRT and prostatectomy. Table 34.6 summarizes six series that combined brachytherapy and EBRT. Long-term outcomes reveal that freedom from PSA failure at a minimum of 5 years is greater than 75% for intermediate-risk patients and greater than 60% for high-risk patients.

CHAPTER 35 IMAGING, INNOVATION, AND NOVEL THERAPIES

ANDREW D. HARDIE, G. JOEL DECASTRO, AND SANDIP M. PRASAD

Historically, the use of imaging technologies to guide urologic therapies has been limited to ultrasound and fluoroscopy. With declining costs and increasing availability and quality of cross-sectional imaging, especially magnetic resonance imaging (MRI), the use and indications of these imaging technologies is ever-expanding. We will review the role of MRI in the diagnosis, evaluation, and management of prostate cancer.

MAGNETIC RESONANCE IMAGING OF PROSTATE CANCER

Unlike many other common oncologic diseases, the ability to evaluate prostate cancer by imaging had been limited until the development of modern MRI technology. Prostate MRI is increasingly performed clinically as a means of locally staging prostate cancer, and MRI has demonstrated a good performance which has steadily improved over time (1). However, the advent of newer advanced MRI technology and a new “multiparametric” approach to image interpretation has revolutionized the field. Although many of the technical requirements of MRI for imaging of prostate cancer are beyond the scope of this discussion, significant improvements in MRI field homogeneity, gradient strength, and to some degree the increased availability of high field strength 3 Tesla (3T) MRI have been critical to these improvements. These and many other technical advances have allowed for the development of multiple high-quality image sequences which evaluate different aspects of the prostate gland: (a) high-resolution T2-weighted (T2W), (b) diffusion-weighted (DW), and (c) dynamic contrast-enhanced (DCE) imaging. The combined interpretation of these three primary MRI sequences, termed *multiparametric imaging*, allows experienced radiologists to maintain a very high performance for identification of prostate cancers that are likely to be clinically significant.

Multiparametric Magnetic Resonance Imaging: T2-Weighted Magnetic Resonance Imaging

Spin-echo-based T2W MRI sequences form the basis of high-resolution prostate imaging. These images (in which water has high signal) allow excellent visualization of the margins and internal anatomy of the prostate gland as well as the seminal vesicles, lymph nodes, and bladder (2–4). The anatomic detail depicted on T2W sequences forms the foundation of the multiparametric approach to interpretation of prostate MRI (5,6). Examples of the typical prostate anatomy on the T2W sequence are depicted in Figure 35.1. However, T2W MRI has been shown to have poor specificity for prostate cancer when interpreted alone (7,8). Among the reasons for the poor performance is the similarity of the appearance of prostate cancer to commonly seen changes of prostatitis as well as that of benign prostatic hyperplasia (BPH) (6,7). Figures 35.2 and 35.3 depict typical findings at prostate MRI in clinical practice. Recently, there has been near universal adoption of an interpretation approach based on a combination of T2W and two other MRI sequences (DW and DCE) which is termed *multiparametric* (8). In fact, a standardized reporting language based on specific criteria from these three sequences has been proposed (9).

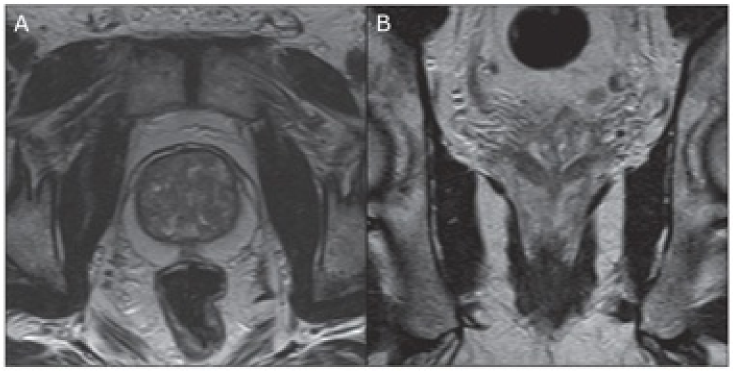

FIGURE 35.1 Axial T2W images demonstrating a normal appearance of the prostate (**A**) with diffuse high signal in the peripheral zone and mild BPH in the central gland. Coronal T2W image demonstrating a normal appearance of the seminal vesicles (**B**).

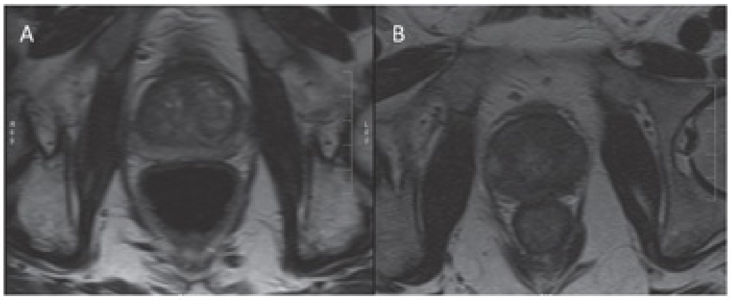

FIGURE 35.2 Axial T2W images demonstrating diffuse low level decreased signal in the bilateral peripheral zones (**A**) typical of benign prostatitis. Compare to a case with nearly diffuse dense low signal in the bilateral peripheral zone (**B**) typical of prostate cancer.

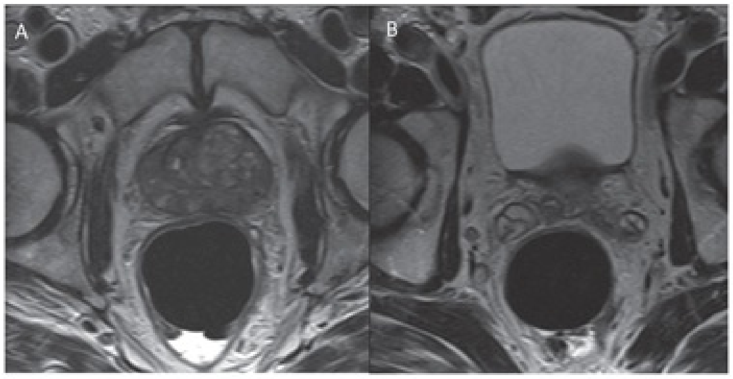

FIGURE 35.3 Axial T2W image demonstrating multiple dense areas of decreased signal in the bilateral peripheral zones (**A**) typical of multifocal prostate cancer. Axial T2W image demonstrating invasion of the seminal vesicles by tumor (**B**).

Multiparametric Magnetic Resonance Imaging: Diffusion-Weighted Magnetic Resonance Imaging

DW MRI is a technique that allows visualization of the random movement of water molecules (Brownian motion). This allows for a differentiation of tissues that have different levels of cellularity, based on the level of restriction of the natural random motion of water (10). Simple fluids, which have no restriction of this motion, are readily differentiated from the minimally cellular normal peripheral zone of the prostate and from highly cellular prostate cancer (11). An example case of prostate cancer with abnormal signal on DW-MR is depicted in Figure 35.4. Experience in the interpretation of DW-MR is necessary as the differentiation of prostatitis and BPH from cancer can still be problematic, as with the other sequences when read independently (8,9).

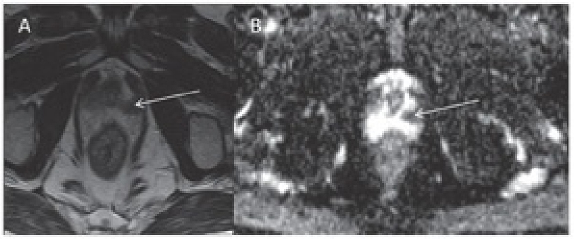

FIGURE 35.4 Axial T2W (A) and DW (B) sequences demonstrating a focus of tumor (*arrow*) in the left apical peripheral zone.

Multiparametric Magnetic Resonance Imaging: Dynamic Contrast-Enhanced Magnetic Resonance Imaging

The third essential sequence for high-quality prostate MRI, DCE MRI, assesses the vascularity of tissues in the prostate. In brief, intravenous gadolinium-based contrast agents are administered rapidly through automated bolus injectors and carefully timed MRI sequences are performed. Prostate cancer should be visible as tissue that has a rapid, early enhancement and rapid clearance (washout). Normal prostate tissue more often has a slower peak to the contrast enhancement curve and a more delayed clearance, although BPH can overlap in appearance (9,12). This method can be the most difficult technically and also takes experience in interpretation. Postprocessing technology exists in order to simplify the interpretation, although the addition of another layer of image processing can be yet another source of error; therefore, knowledge of processing artifacts is essential (12). DCE MRI images from the same patient as in Figure 35.4A are included in Figure 35.5.

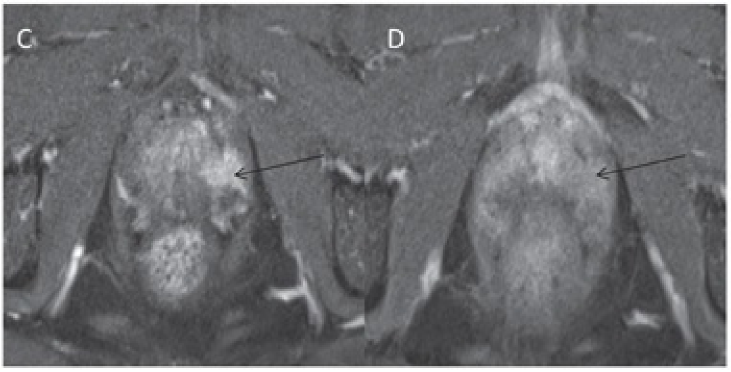

FIGURE 35.5 Axial early phase DCE (C) and late phase DCE (D) images demonstrating a focus of tumor (*arrow*) in the left apical peripheral zone with brisk enhancement and delayed contrast washout.

Performance of Magnetic Resonance Imaging for Prostate Cancer

Although the overall performance of multiparametric MRI for identifying prostate cancer is good, there can still be significant discrepancies between MRI interpretation and prostate biopsy results (8,9,13). A major point to consider is that until recently, most available research evaluating the correlation between MRI and prostate biopsy depended on the assumption that the areas identified on MRI could be well-correlated by transrectal biopsy or prostatectomy specimens. Many experienced researchers would likely acknowledge the major limitations of this approach. Recently, there is a growing body of research which uses more direct means of correlation including MRI-guided biopsy and real-time image fusion between MRI and transrectal ultrasound-guided biopsy (13–15). These methods have increased the ability to evaluate the performance of MRI, given the increased confidence of correlation between MRI and biopsy. However, MRI will not identify all or even nearly all prostate cancer. Clinically, the significance of such a reduced sensitivity for cancer has at least two potential outcomes. First, many of the cancers undetected by MRI are low-grade, clinically insignificant cancers (16). However, failure to identify cancers that would be deemed to be of low clinical significance by MRI may potentially represent a desirable outcome. However, clinically significant cancers can also be undetectable at MRI, leading to potentially deleterious patient outcomes. Therefore, despite the strong ability of MRI to identify cancer, the optimal clinical role of MRI in its diagnosis has not been established to date (17).

Prostate Magnetic Resonance Imaging in Clinical Practice

It is important to note that there is not a high clinical need for prostate MRI to identify all prostate cancer foci. In fact, the diagnosis of prostate cancer is often not difficult to obtain, given the high incidence of the disease and the high sensitivity of routine prostate biopsy for cancer. Although the exact role of prostate MRI has yet to be universally established, there has been a rapid expansion of the use of this technology based on published reports and anecdotal accounts. In the following sections, potential clinical roles for prostate MRI will be explored. Specifically, postulated clinical information which prostate MRI can supply in several common clinical scenarios will be reviewed.

Magnetic Resonance Imaging in Patients with a Biopsy Diagnosis of Low-Risk Prostate Cancer

The options for patients with a biopsy result consistent with low-risk prostate cancer include surgical or radiation treatment (often without concomitant hormonal therapy) as well as nontreatment approaches such as active surveillance. However, there is a potential risk of undertreatment or inappropriate inclusion into active surveillance monitoring due to undersampling of cancer with subsequent understaging. There is a growing body of literature demonstrating the ability of MRI to identify patients with higher risk cancers that were not initially sampled by biopsy (18,19). Figure 35.6 depicts an MRI of a patient with an initial biopsy of low-risk prostate cancer that was subsequently confirmed to have high-risk cancer following MRI and rebiopsy. Areas of the prostate gland prone to undersampling include the anterior and periurethral central gland (transitional zone) as well as portions of the peripheral zone located far laterally and apically. Therefore, an MRI performed following a low-risk cancer biopsy result may demonstrate areas worthy of rebiopsy. The fact that MRI demonstrates a relatively poor sensitivity for low-risk prostate cancer but a higher sensitivity for intermediate and high-risk cancers results in a potentially advantageous situation whereby many areas that undergo rebiopsy could upgrade the clinical risk of a patient’s prostate cancer. Conversely, if no areas of additional suspicion are identified on MRI, rebiopsy is unlikely to yield a higher risk cancer.

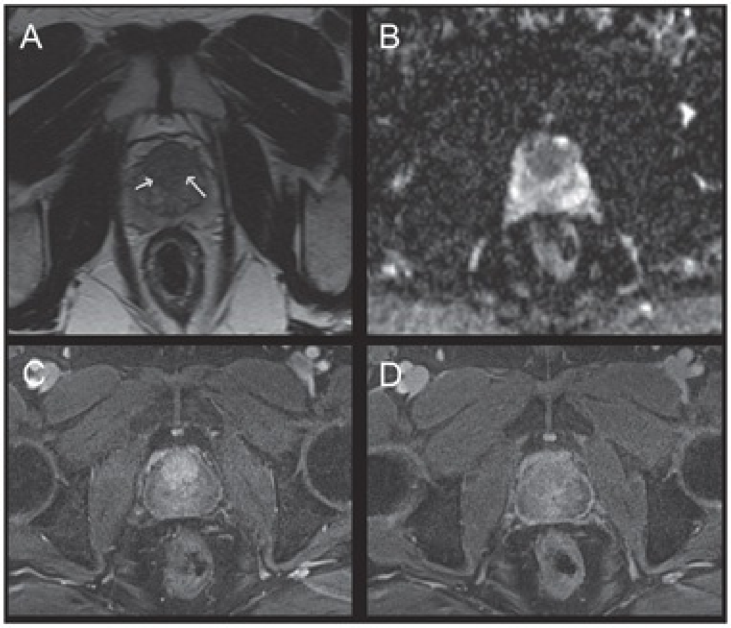

FIGURE 35.6 Axial T2W (A), DW (B), early phase DCE (C), and late phase DCE (D) image sequences demonstrating a large focus of tumor (*arrow*) in the far anterior central gland.

Magnetic Resonance Imaging in the Setting of Negative Biopsy

A significant portion of patients presenting for prostate biopsy will obtain a negative result. However, MRI can be employed in this scenario to evaluate selected patients with persistent clinical suspicion of cancer. As previously discussed, the value of MRI in this setting is that most clinically significant cancers will be visible on MRI, and biopsy can be directed at these areas. Conversely, a negative MRI result can serve as additional reassurance that the patient indeed is unlikely to harbor a clinically significant prostate cancer. Figure 35.7 depicts a patient with multiple sets of negative biopsies by standard 12-core method. A suspicious focus on MRI was found to represent Gleason 3+4 cancer.

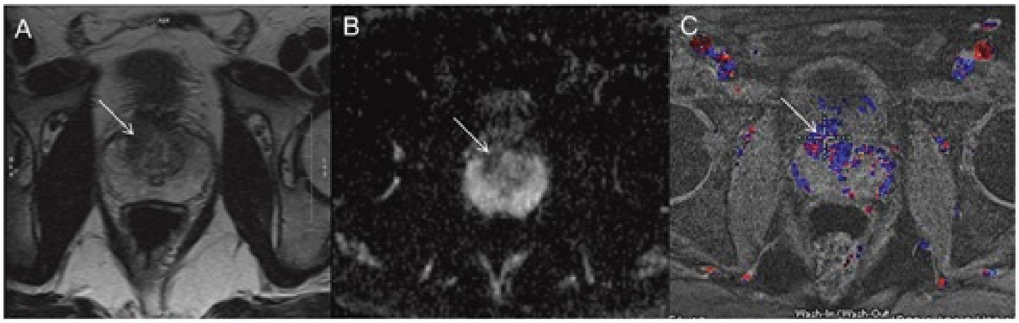

FIGURE 35.7 Axial T2W (A), DW (B), and post-processed color-coded DCE (C) image sequences demonstrating a focus of tumor (*arrow*) in the right central gland.

For many patients who undergo prostate MRI following negative 12-core biopsy, no suspicious foci will be identified on MRI. For these patients, the likelihood of a clinically significant cancer is likely low, although it has not been entirely eliminated. There is currently limited but ever expanding data available which attempts to address the question, “How long is a negative MRI good for?” Although this question cannot be answered with any degree of certainty yet, foci of prostate cancer may become detectable by MRI on follow-up MRI between 6 and 24 months (20,21). Figure 35.8 illustrates this finding.

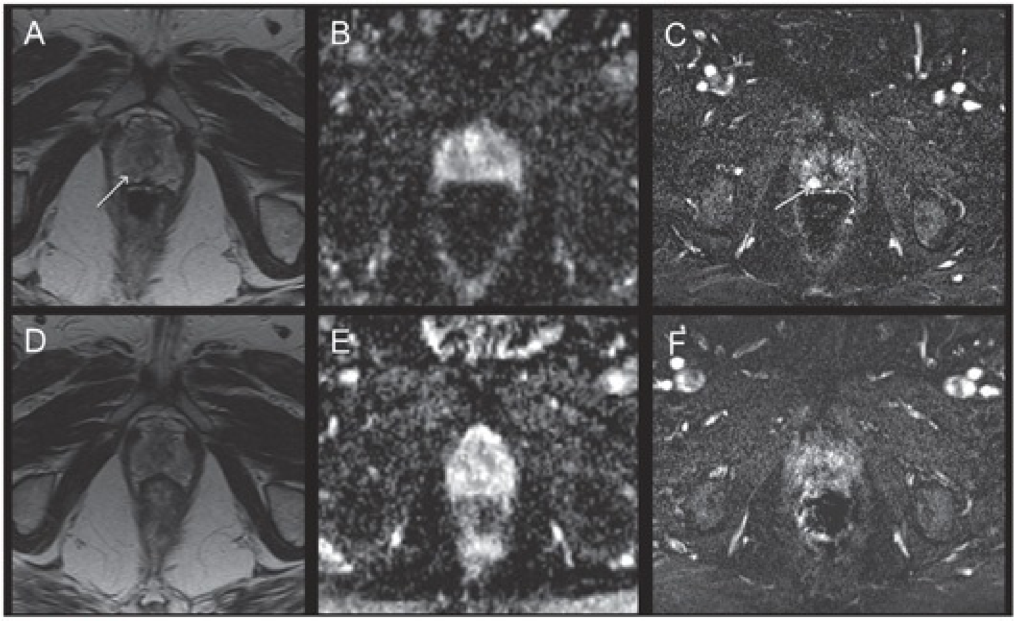

FIGURE 35.8 Axial T2W (A), DW (B), and early phase DCE (C) in a patient with a newly visible focus of tumor (*arrow*). Axial T2W (D), DW (E), early phase DCE (F) of the same patient from an MRI 2 years prior.

Use of Magnetic Resonance Imaging in Guidance for Biopsy of Suspected Prostate Cancer

As previously discussed, MRI has the ability to identify prostate cancer, particularly higher risk cancer, but suspicious MRI foci must be localized for biopsy. Although direct methods exist for biopsy of lesions on the MRI scanner, these approaches have been slow to penetrate clinical practice. Not only does direct MRI-guided biopsy require specialized equipment and subspecialty training not widely available, but the process can be time-consuming for MRI units which often have high diagnostic imaging utilization. Often, suspicious foci identified on MRI are referred back for transrectal ultrasound (TRUS) biopsy. One approach the TRUS operator can take is to attempt to visually identify the focus on ultrasound following review of the MRI. Given that many lesions identified on MRI can be identified on TRUS once the MRI images are reviewed, this approach can be successful and may improve overall accuracy of prostate grading (22). Recently, technology has become available, which can fuse the images from the MRI in real time with the TRUS during the biopsy procedure. This approach may ensure the most accurate correlation possible between lesions on MRI and biopsy results (22–24). Image guidance and image fusion technology will likely continue to improve.

Role of Magnetic Resonance Imaging Following Prior Therapies

Since the inclusion of gadolinium-based contrast-enhanced protocols, MRI has the ability to assess patients following prior therapeutic treatments for prostate cancer. The clinical scenario becoming most common for use of MRI is in the patient with evidence of biochemical failure following whole-gland prostate radiation (including both external beam and brachytherapy techniques). Although difficult, if not impossible, to discern on traditional T1- and T2-weighted sequences, recurrent/residual prostate tumor demonstrates enhancement following gadolinium contrast. Experience is necessary in interpretation of these images, given that some level of contrast enhancement of the gland can exist following radiation therapy and may be difficult to differentiate from diffuse tumor. However, asymmetric foci of enhancement in the gland can often be identified in addition to enhancing tumor outside the gland including in the seminal vesicles (25). Once identified, these foci can be readily localized for biopsy and potentially be used to identify appropriate candidates for salvage cryotherapy (26). Conversely, cases suggestive for spread of tumor beyond the prostate (including lymphadenopathy) may be less likely to benefit from cryotherapy (Figs. 35.9 and

35.10). MRI can also be performed after clinical failure of initial cryotherapy to assess for residual disease (Fig. 35.11).

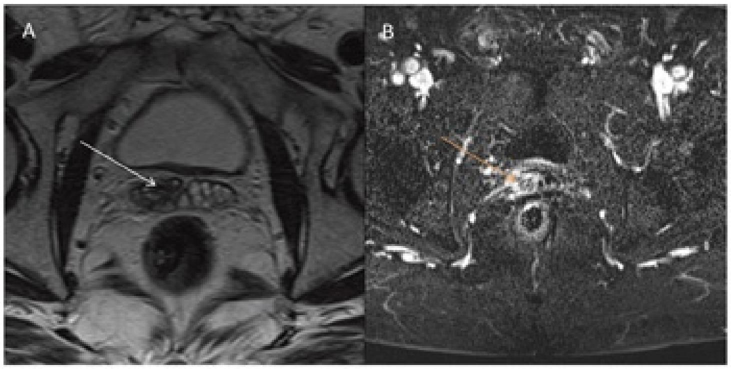

FIGURE 35.9 Axial T2W (**A**) and early phase DCE (**B**) images of a patient with tumor (*arrow*) in the right seminal vesicle after clinically ineffective salvage cryotherapy.

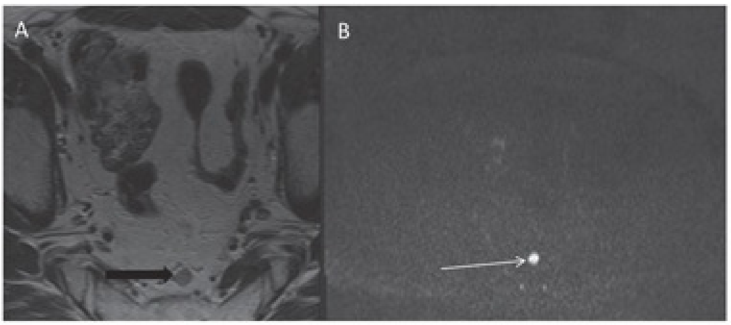

FIGURE 35.10 Axial T2W (**A**) and DW (**B**) images demonstrating a malignant perirectal lymph node (*arrow*) in a patient with a rising PSA following whole gland external beam radiotherapy.

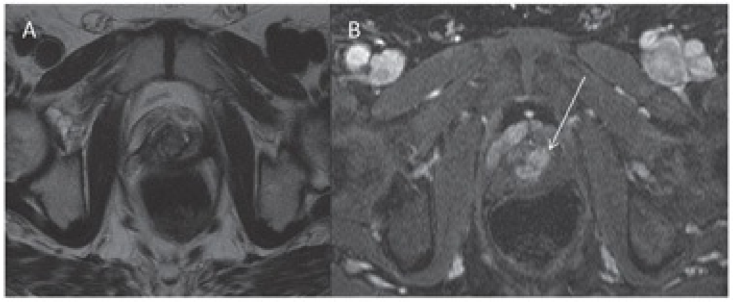

FIGURE 35.11 Axial T2W (**A**) and early phase DCE (**B**) images from a patient with persistent PSA elevation following salvage cryotherapy. Note the difficulty in visualizing the focus of tumor on T2W but ease of visibility on the contrast enhanced image (*arrow*). Also note the nontumor enhancement in the periurethral prostate (a typical finding following cryotherapy).

In conclusion, the field of MRI will likely continue to rapidly advance. High-quality research studies are still needed to better elucidate whether these techniques truly impact the clinical outcomes for patients. However, based on the clear improvement in the ability to identify foci of prostate tumor that may have been undiagnosed in the past, the likelihood is that prostate MRI will become an essential tool in the accurate risk assessment and staging of prostate cancer and may streamline treatment algorithms. The ability to accurately identify prostate cancer also opens up numerous possibilities for novel approaches to prostate cancer treatment that were not possible before.

FOCAL THERAPY FOR PROSTATE CANCER

One of the main motivating factors for the development of focal therapies is the notion that prostate cancer is overtreated. Since the introduction of prostate-specific antigen (PSA), the incidence of prostate cancer has increased dramatically, accompanied by a downward stage and grade migration of new cases (27,28). This has resulted in the diagnostic dilemma of whether traditional curative treatments that target the whole gland are necessary for what are predominantly low-risk cancers. Although such treatments—including radical prostatectomy and radiation—are effective, they are associated with significant side effects. On the other hand, although active surveillance for low-risk disease is well-established, safe, and effective—with cancer-free survival rates at 10 years exceeding

80% (29)—it is burdensome both physically and emotionally.

One of the main purported advantages of focal therapy is that injury to the organ is limited to areas harboring cancer, thereby sparing presumably noncancerous tissue and gland from side effects of that treatment. By treating localized tumors, and sparing the rest of the prostate along with the urethral sphincter and neurovascular bundles, the common side effects of whole gland therapies are minimized.

Cryotherapy

Of the multiple focal therapies available at present, cryotherapy is the most well-studied. In 2008 (and updated in 2009), the American Urological Association published their Best Practices guidelines, describing primary cryotherapy as an "option in selected patients" (30). Selection criteria included both disease-specific and patient-specific factors: Low and intermediate risk patients are most suitable (although high-risk patients are not excluded) as are patients who cannot (or do not wish to) undergo radical prostatectomy.

Cryobiology involves several mechanisms. Direct cellular injury results from ice crystal formation in the extracellular fluid, with subsequent movement of water from within the cell to the extracellular matrix, leaving the cell hyperosmolar. As the cell shrinks, the intracellular matrix, including its protein components, is disrupted. Eventually, ice crystals form within the cell and rupture the membrane. In addition, direct vascular injury and platelet-induced thrombosis compromise blood flow, resulting in ischemic damage. Additional proposed mechanisms of cell death include apoptosis, or programmed cell death, resulting from activation of various pathways and immune-mediated mechanisms (31,32).

Cryotherapy was first used in the 1960s: Cooling was achieved via liquid nitrogen-infused probes, and access to the prostate was done transurethrally or through an open perineal incision (33,34). At that time, no mechanism was used to protect adjacent structures, resulting in frequent injury to the rectum and external urethral sphincter (35). The technology gained greater acceptance in the 1990s when the introduction of transperineal probes and urethral warmers led to fewer complications (36,37). In addition, the replacement of liquid nitrogen with pressurized argon gas allowed for rapid freezing/warming in real time. The use of thermocoupling devices allowed for monitoring the temperature of the ice ball as well as of adjacent structures and for termination of the freezing cycle when the desired temperature (usually −40°C) was achieved.

In 2002, Onik and colleagues (38,39) first reported on the use of cryotherapy for prostate cancer in a group of 48 patients with clinically unilobar disease. At 2 years, 95% of patients had no biochemical recurrence (following ASTRO criteria), with no significant change in urinary symptoms and preservation of potency in 90% of patients who were potent preoperatively. More recently, Bahn and colleagues (40) reported on 70 patients with unilateral, low-intermediate risk disease. With a median follow-up of 3.7 years, matched pair analysis with patients undergoing radical prostatectomy showed similar "salvage-free" survival rates. Cohen et al. (41) has reported on the series with the longest median follow (12.6 years). In a total group of 370 patients, the 10-year negative biopsy rate was 77%, and biochemical recurrence-free survival ranged from 46% to 81% depending on initial risk stratification.

High-Intensity Frequency Ultrasound

High-intensity frequency ultrasound (HIFU) is a relatively novel technology that uses sound waves directed at tissue located at a specific distance from the emitting probe (42). Ablation occurs through heating of the targeted tissue as it absorbs energy from the sound waves and through cavitation, which describes the induction of oscillating microbubbles of water that result in dispersion of energy (43).

Ahmed and colleagues (44) were the first to conduct a trial using HIFU. The results of their phase I/II study in 2011 showed that 89% of 20 men attained the trifecta of being pad-free, potent, and with no histologic evidence of disease at 12 months (44). In a more recent report of 56 men with low-, intermediate-, and high-risk pathology found within an MRI-detected "index" lesion, short-term results were promising. Over 80% had no residual or recurrent disease on biopsy, and baseline urinary and sexual function was preserved in 92% and 77%, respectively (45).

Pros and Cons of Focal Therapy

Although focal ablative therapies are attractive due to their minimal invasiveness and potential reduction in side effects, they face several obstacles in gaining full acceptance as primary treatment. Although both cryotherapy and HIFU appear to be promising technologies, with good short- and intermediate-term disease-free survival rates along with reduced side effects, they have limitations. First and foremost, although the technology appears to be safe and efficacious, there is a dearth of long-term quality data on a large cohort of patients. Regarding patient selection, it is unclear who is best suited for these therapies. Nguyen and colleagues (46) have suggested that focal cryotherapy may be an alternative for patients considering active surveillance—that is, those with low-risk disease. In this context, focal therapy is seen as a compromise between active surveillance, which leaves the cancer untreated, and traditional curative techniques, which are associated with potential side effects (46,47).

One of the main concerns regarding focal therapy is that prostate cancer has long been considered to be *multi*focal. Indeed, in radical prostatectomy series, multifocality has been found in 67% to 87% of specimens (48). Therefore, ablating one or even several lesions detected on imaging may miss other tumor sites. A counter argument is that despite the multifocal nature of the disease, there is often an "index" lesion that harbors the most malignant potential (49). Therefore, treating this lesion may be sufficient, especially for lower grade and more indolent disease. Detection of the malignant lesion has also posed a challenge in the past. Although ultrasonography is notoriously inaccurate, improvements in MRI have led to positive predictive values of suspicious lesions (based on biopsy results) of more than 98% (50,51). However, the actual delivery of the ablative energy may be challenging in the case of anterior lesions, both for needle-based targeting using cryoablation and for HIFU.

Finally, a major deficiency in focal therapy is the fact that there is no true consensus on how to monitor patients after treatment for disease recurrence. To date, researchers have adopted similar criteria as for postradiation patients (e.g., ASTRO), but this has not been effectively validated.

Although obstacles do exist to the widespread acceptance of focal therapies, the push for treatments with fewer side effects but acceptable oncologic control will continue. If additional longer term data confirms the safety and efficacy of these technologies, they may replace traditional whole gland therapies for a subset of patients.

ADVANCED ROBOTIC SURGERY

With the rapid adoption of robot-assisted laparoscopic surgery within a decade of its introduction worldwide, there is significant interest in the development of alternative robotic platforms for urologic surgery. We review several advanced mechanisms for delivery of robotic surgery in urology.

Flexible Robot-Assisted Ureteroscopy

The initial use of flexible robotic-assisted techniques was in interventional cardiology, where the robot was used to facilitate transseptal puncture and endocardial catheter navigation (52). Like the heart, subtle manipulation of flexible instruments in the kidney is affected by breathing movements and lack of stability. Robotics has been proposed as a possible adjunct to traditional ureteroscopy, with the added benefit of removing the surgeon from the radiation source (53).

Hanson Medical System (Mountain View, California) devised the Sensei robotic system for ureteroscopy. The Sensei robotic system is similar to the da Vinci system used for surgical robotics as it is a master–slave system but has four unique components: (a) a surgeon console with an LCD screen and master input device (MID) (Fig. 35.12), (b) a remote table-mounted catheter manipulator (Fig. 35.13), (c) a steerable catheter system, and (d) an electronic rack. At the console, three LCD monitors display endoscopic, fluoroscopic, and other procedure-specific imaging and information. The MID is a joystick that the surgeon manipulates, and these movements are translated to the catheter tip. An outer catheter sheath (14Fr/12Fr) is first manually positioned, followed by an inner catheter guide (12Fr/10Fr) through which the steerable catheter is inserted. The workstation's remote positioning has the secondary advantage of decreasing radiation exposure to the operating surgeon.

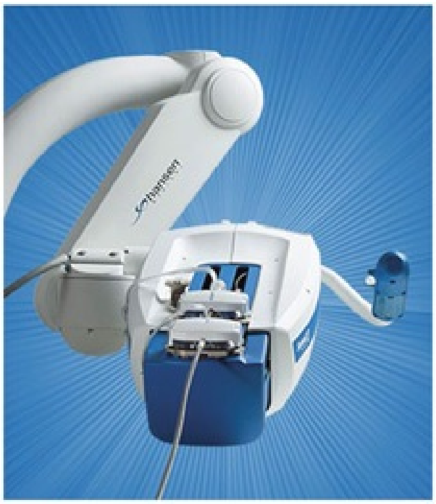

FIGURE 35.13 Table-mounted robotic manipulator. (Courtesy of Hansen Medical Inc.)

The feasibility of robotic ureterorenoscopy was demonstrated in both the porcine model (54) and in patients (55). Initial animal experience demonstrated remarkable tip stability as well as ease of manipulation with successful manipulation remotely into 83 of 85 calyces (98%). The human experience was similarly promising, with 18 patients with renal calculi ranging in size from 5 to 15 mm (mean stone size 12 mm) undergoing flexible robotic ureteroscopy. The flexible robotic catheter system was manually introduced into the collecting system over a guidewire under fluoroscopic control, but all subsequent intrarenal maneuvers, including stone relocation and fragmentation, were done exclusively from the robotic console. There were no conversions or intraoperative complications and the mean robotic time was 41 minutes with mean operative time totaling 91 minutes. Based on computerized tomogram/excretory urogram at 3 months, the complete stone clearance rate was 89%, and all patients had stable renal function and unobstructed drainage.

Natural Orifice Transluminal Endoscopic Surgery and Miniature Robots

Given the urologists’ familiarity with both endoscopic/endoluminal surgery and laparoscopic/extraluminal techniques, natural orifice transluminal endoscopic surgery (NOTES) has been of interest since the earliest published reports of this technique in 2004 (56). NOTES involves traversing intact hollow viscera (stomach, vagina, colon, bladder) to access intra-abdominal targets for ablative, extirpative, and reconstructive surgery. The proper instrumentation and entrance/exit strategies for NOTES vary by provider, and the early experience with this approach underscored the importance of improved instrumentation beyond traditional laparoscopy due to the complex movements required with NOTES.

Multiple approaches have been identified to address this concern. The da Vinci robotic platform has been used to perform a variety of transvaginal, transcolonic, and transgastric urologic procedures in animal models, including nephrectomy, pyeloplasty, and partial nephrectomy (57,58). Typically, a multichannel transumbilical port was used with an additional working arm placed transvaginally. The common complaint of external clashing of robotic arms limiting the range of motion has pushed surgeons to consider novel surgical tools, including flexible laparoscopic instruments. The first NOTES transvaginal nephrectomy was described by Haber and colleagues (58) in 2008 using a 5-mm umbilical port and a transvaginal GelPort containing two 5-mm trocars and one 12-mm trocar. They noted the necessity of flexible laparoscopy as well as long, articulating instruments to perform this procedure.

Another approach is to use task-specific miniature robots deployed in vivo inside the peritoneum, which without the typical constraints of an externally actuated flexible endoscopic device. Current miniature robotic prototypes are either fixed-base or mobile robots (59). Fixed-base robots are deployed and positioned and cannot self-navigate from their initial position. A pan-and-tilt camera, fashioned with LEDs for illumination, a 15-mm diameter conical design, spring-loaded tripod “legs,” and two independent motors controlling camera movement (pan 360 degrees, tilt 45 degrees). This camera was deployed through an abdominal incision and used in conjunction with standard laparoscopic equipment to facilitate porcine cholecystectomy (60). A second-generation tilting camera has been used in conjunction with a standard laparoscope for canine prostatectomy (59). This initial prototype is a “wired” camera for power input, and wireless prototypes are on the horizon (61,62).

In animal studies, a mobile camera has been used to provide sole visualization for abdominal exploration and cholecystectomy (63). In this case, the camera port was therefore unnecessary and the cholecystectomy was performed with two trocars. In another study, the mobile robotic platform has demonstrated the successful biopsy of three samples of hepatic tissue (64). For NOTES applications, successful remote-controlled exploration through a gastrotomy has been performed in the porcine model (65). This was monitored by the endoscopic rather than the robotic camera, but it successfully demonstrated proof of concept. The robot was then retracted into the gastric cavity, and the transgastric incision was closed using two endoclips and one endoloop. Also in pigs, the feasibility of using multiple miniature robots for improving spatial orientation and providing task assistance has been demonstrated. Three miniature in vivo robots, shown in Figure 35.14, including a peritoneum-mounted imaging robot, a lighting robot, and a retraction robot, were used in conjunction with a standard upper endoscope to demonstrate various capabilities for NOTES procedures.

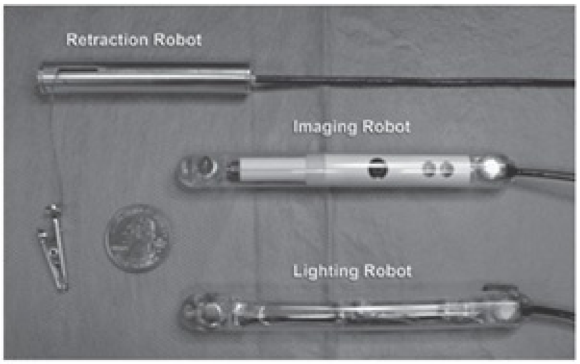

FIGURE 35.14 Miniature in vivo robots. (Photo courtesy of Dr. Dmitry Oleynikov, University of Nebraska Medical Center, Omaha, NE.)

As task-specific robotic systems progress in development, flexible robotics, NOTES surgery, and in vivo miniature robots are likely to transform our concept of minimally invasive surgery in the coming decades as endourology, laparoscopy, and robotic surgery has in the prior ones.

SECTION IV■ URETHRA

Section Editor: ERIC S. ROVNER

CHAPTER 36■ANATOMY OF THE URETHRA

LAWRENCE M. DAGROSA AND E. ANN GORMLEY

FEMALE URETHRA

Gross/Microscopic

The female urethra extends 3 to 5 cm from the bladder neck to the external urethral meatus. This fibromuscular tube from the lumen outward is composed of a mucosal lining, a submucosal layer, and a muscular layer. The proximal urethra is lined with transitional cell mucosa and is continuous with the bladder urothelium. Distally, the mucosa transitions to nonkeratinized stratified squamous epithelium (Fig. 36.1). The submucosa consists of abundant longitudinal and circular elastic fibers and contains a prominent venous system. The engorgement of this venous plexus decreases the luminal diameter of the urethra creating a hermetic seal, which has been reported to account for up to 33% of urethral closing pressure (1,2). Historically, it has been described that these veins are hormone-sensitive and their relative volume has been shown to decrease with age, likely adding to the age-related decrease in urethral closing pressure seen in the postmenopausal population (3). Colleselli and others (4) have shown that in the proximal third and most of the middle third of the urethra, there are three smooth muscle layers, including outer and inner longitudinal layers and a middle transverse or circular layer. These muscles are continuous with the bladder neck proximally and terminate distally in the subcutaneous tissue surrounding the external urethral meatus, intermingling with the striated muscle fibers of the rhabdosphincter. In fetal specimens, the smooth muscle layer is more defined distally, whereas this layer is thin or absent in the distal urethra of the adult (4). The density of urethral circular smooth muscle decreases with age, which may also contribute to the decrease in urethral closure pressure and incontinence associated with increasing age (5).

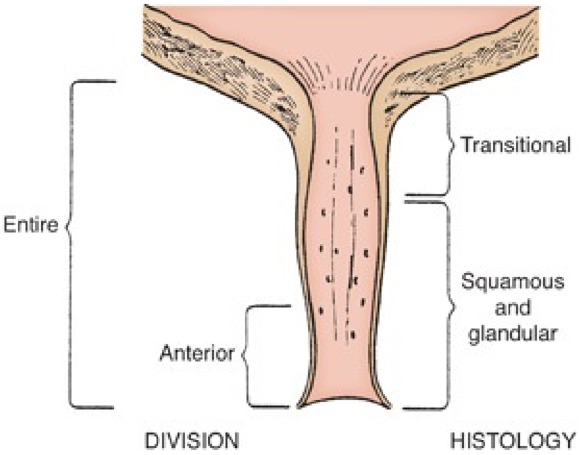

FIGURE 36.1 The female urethra.

In the distal two-thirds of the urethra, a layer of striated muscle, the rhabdosphincter, surrounds the smooth muscle layer, on the dorsal and lateral aspects making an omegalike-shaped sphincter (4). The rhabdosphincter is composed of delicate type I (slow-twitch) fibers and consists of three distinct muscles. Proximally, the muscle forms a ring (sphincter urethrae) that encircles the urethra. Distally, the muscle (compressor urethrae) fans out laterally along the curve of the inferior border of the pubic rami to compress the urethra against the anterior vaginal wall. At the vestibule, the muscle completely surrounds the urethra and vagina to form a urethrovaginal sphincter (Fig. 36.2) (6). The three muscles work together to provide constant urethral tone (Fig. 36.3) (7). Normally, the striated sphincter plays a minimal role in resisting abdominal pressure. However, preservation of the rhabdosphincter is necessary for continence after creation of a female neobladder (4).

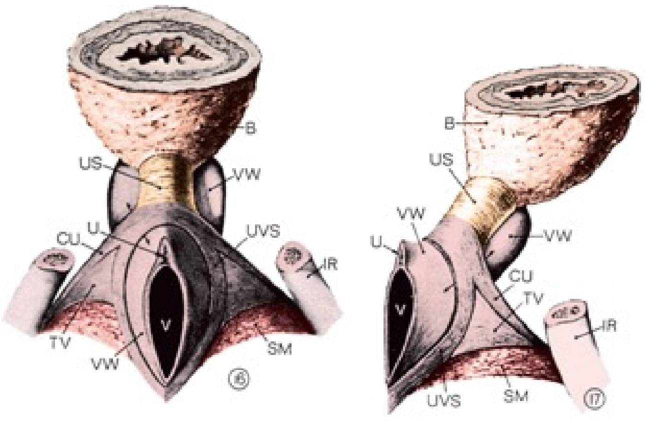

FIGURE 36.2 Striated urogenital sphincter muscle seen from below after removal of the perineal membrane and pubic bones. *US*, urethral sphincter; *UVS*, urethrovaginal sphincter; *CU*, compressor urethrae; *B*, bladder; *IR*, ischiopubic ramus; *TV*, transverse vaginae muscle; *SM*, smooth muscle; *U*, urethra; *V*, vagina; *VW*, vaginal wall. (Reprinted with permission from Oelrich TM. The striated urogenital sphincter muscle in the female. *Anat Rec* 1983;205:223. Copyright © 1983 Wiley-Liss, Inc, a Wiley Company.)

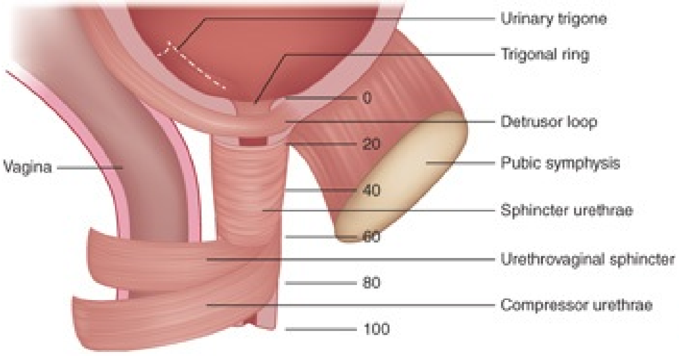

FIGURE 36.3 Location of various structures along the urethra. Note the three parts of the rhabdosphincter.

There are numerous small periurethral mucous glands that run along the length of the urethra and open into small recesses in the mucosa. Paired periurethral (Skene) glands drain on either side of the midline just posterolateral to the urethral meatus.

Vascular Anatomy

The arterial supply to the female urethra is from the urethral artery, a branch of the internal pudendal artery, which in turn is a branch of the internal iliac artery (8). The venous drainage is via the pelvic venous plexus.

Innervation

The smooth muscle of the urethra is innervated by parasympathetic nerves. The predominant sympathetic receptors are alpha-adrenergic (9). These receptors are responsible for urethral smooth muscle contraction and possibly engorgement of the submucosal vasculature to create a watertight seal of the urethral mucosa (10). The striated muscle fibers of the rhabdosphincter receive innervation from the pudendal and pelvic somatic nerves (11). Both somatic and autonomic nerves to the urethra travel on the lateral walls of the vagina near the urethra. Various authors have advised against dissection in this area during transvaginal surgery to prevent development of stress urinary incontinence due to intrinsic sphincter dysfunction (12).

Lymphatics

The lymphatic drainage of the proximal urethra is to the deep pelvic lymph nodes. The drainage of the distal portion of the urethra is to the inguinal nodes.

Contiguous Structures

A “hammock” of vaginal tissue supports the urethra (13). Although the exact nomenclature is contested in the literature, the urethral supports, also termed “pubourethral ligaments,” include fascial and muscular attachments to the arcus tendineus fasciae pelvis and levator ani muscles. These supports are only present in the distal third of the urethra. It has been postulated that they “fix” the urethra to the pubic bone; however, there is conflicting anatomic data that suggests the bladder, urethra, and the anterior vaginal wall are freely mobile (14). The pubovesical muscle is a separate structure that is an extension of the smooth muscle of the bladder, which extends from the detrusor muscle to the arcus tendineus fasciae pelvis and pubic bone (Fig. 36.4) (15).

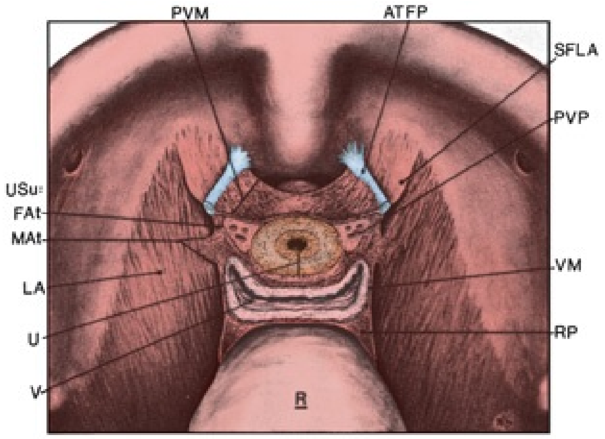

FIGURE 36.4 Cross section of the urethra (*U*), vagina (*V*), arcus tendineus fasciae pelvis (*ATFP*), and superior fascia of levator ani (*SFLA*) just below the vesical neck (drawn from cadaver dissection). Pubovesical muscles (*PVMs*) lie anterior to urethra and anterior and superior to paraurethral vascular plexus (*PVP*). The urethral supports (*USu*) (the pubourethral ligaments) attach the vagina and vaginal surface of the urethra to the levator ani muscles (*MAt*, muscular attachment) and to the superior fascia of the levator ani (*FAt*, fascial attachment). *LA*, levator ani; *R*, rectum; *RP*, rectal pillar; *VM*, vaginal wall muscularis. (Reprinted with permission from DeLancey JOL. The pubovesical ligament, a separate structure from the urethral supports. *Neurol Urodynam* 1989;8:53. Copyright © 1989 Wiley-Liss, Inc, a Wiley Company.)

The urethra is intimately related to the anterior surface of the vagina for the distal two-thirds of its course (16). The periurethral fascia is located immediately beneath the vaginal wall and is seen as the glistening white layer that surrounds the urethra when an incision is made in the anterior wall of the vagina. The fascia extends from the meatus to the bladder neck and laterally to where it fuses with the endopelvic fascia at the pubic bone (Fig. 36.5).

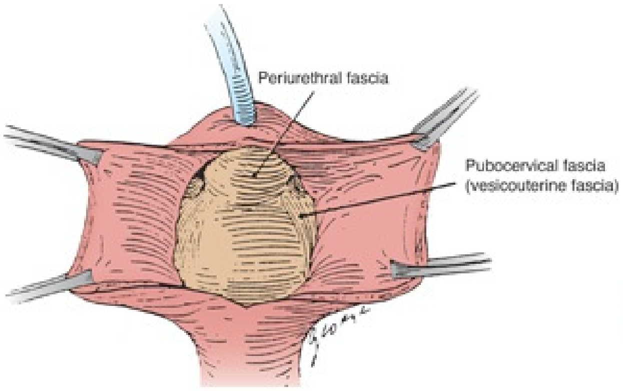

FIGURE 36.5 View of the anterior vaginal fascial support, which is found beneath the vaginal wall (shown retracted). The periurethral fascia, which forms the vaginal layer of the urethropelvic ligaments, is continuous with the pubocervical fascia proximally.

MALE URETHRA

Gross/Microscopic

The posterior urethra extends from the bladder neck, through the prostate, to the urogenital diaphragm. It is divided into the prostatic urethra and the membranous urethra, which traverses the urogenital diaphragm just prior to entering the corpora spongiosa. The anterior urethra runs from the urogenital diaphragm to the tip of the glans penis and may be further divided into the bulbous urethra, extending from the root of the penis to the convergence of the corpora cavernosa, and the pendulous or penile urethra that traverses the pendulous portion of the penis. There is a dilation of the urethra in the area of the glans penis called the fossa navicularis (Fig. 36.6).

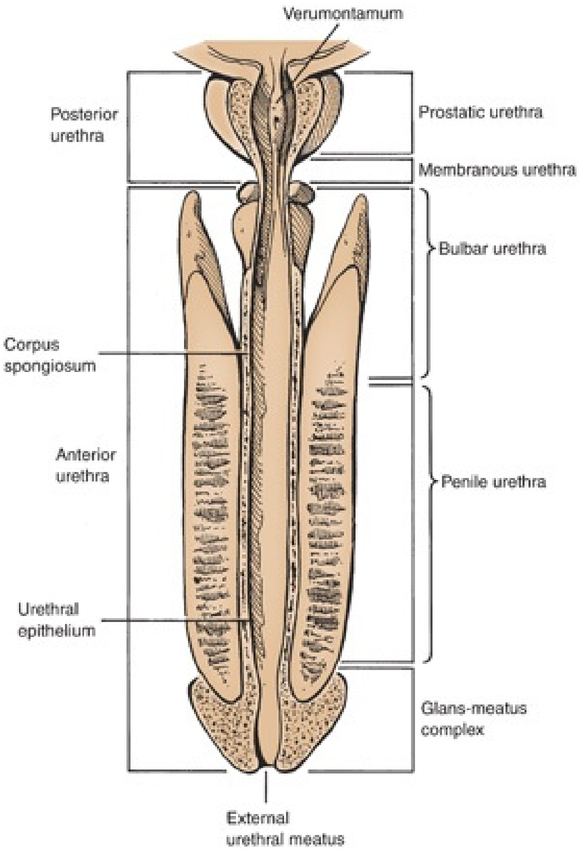

FIGURE 36.6 The male urethra and its divisions with associated histology.

A number of ducts empty into the lumen of the urethra. The orifices of the paired bulbourethral (Cowper) glands are found on the floor of the pendulous urethra, 2 to 3 cm distal to the membranous urethra. On the roof of the pendulous urethra, there are openings for the glands of Littre, or the submucosal urethral glands, and small recesses termed *urethral lacunae*. The lacuna magna is a larger lacuna in the midportion of the anterior aspect of the fossa navicularis.

The urethral epithelium varies along the length of the urethra. In the prostatic urethra, the cells are transitional, whereas in the membranous urethra, they are stratified columnar. The epithelium of the penile urethra is composed of pseudostratified and columnar cells. In the fossa navicularis, the epithelium is composed of stratified squamous cells.

Vascular Anatomy

Paired bulbourethral arteries, which arise as the first of three penile branches of the internal pudendal artery, supply the urethra. The venous drainage is via the emissary veins, which drain to the circumflex branches of the deep dorsal vein of the penis.

Innervation

The urethral mucosa is innervated via the urethrobulbar nerve. It is a branch of the nerve to the bulbocavernosus, which is a branch of the perineal nerve derived from the pudendal nerve. A branch of the bulbocavernosus nerve at the 3 and 9 o'clock positions penetrate the striated urethral sphincter (17). The pudendal nerve, consisting of fibers from the second, third, and fourth sacral spinal nerves, is thus both motor to the urethral sphincter and sensory to the urethra and glans penis.

Lymphatics

The lymphatic drainage of the anterior urethra is into the superficial and deep inguinal nodes and ultimately to the external iliac nodes. The lymphatics of the posterior (the bulbous, membranous, and prostatic) urethra can take three routes: to the external iliac nodes, to the obturator and internal iliac nodes, or to the presacral nodes.

Contiguous Structures

The membranous urethra is covered by the fibers of the striated urethral sphincter (rhabdosphincter). Brooks et al. (18) used computer-generated, three-dimensional reconstruction of the male pelvis from the visible human data set to show that the striated urethral sphincter is circular with abundant posterior tissue, making it more singet ring–shaped. Anteriorly and laterally, the rhabdosphincter is separated from the membranous urethra by a thin sheath of connective tissue (19). Anteriorly, the sphincter is approximately twice as long as it is posteriorly. An intrinsic smooth muscle lies between the urethral mucosa and the striated urethral sphincter. This muscle begins above the striated sphincter and then gradually thins distal to the striated sphincter (18).

The remainder of the anterior urethra lies within the corpus spongiosum, lying in the ventral groove of the corpora cavernosa of the penis. The Cowper glands (bulbourethral glands) lie within the urogenital diaphragm posterior and lateral to the membranous urethra.

CHAPTER 37 FEMALE URETHRAL RECONSTRUCTION FOR FISTULA AND FEMALE URETHRAL DIVERTICULUM

AHMED M. EL-ZAWAHRY AND ERIC S. ROVNER

Female urethral problems can be debilitating and disturbing to the quality of life in women secondary to problems affecting voiding or devastating incontinence. Reconstruction of the female urethra is technically demanding. Understanding the surgical principals is critical to optimize outcomes. The goal of surgery is to reconstruct the urethra and to obtain a functional urethra that enables the patient to void volitionally and be socially continent. Urethra fistula and urethral diverticula, although both relatively uncommon, are probably the two most common conditions of the female urethra requiring major reconstruction.

RECONSTRUCTION OF THE FEMALE URETHRA FOR FISTULA

In the developing world, the major causes of the development of urethral fistula are related to obstetric trauma secondary to prolonged labor. This is responsible for the development of about 90% of urinary fistula in women (1). In contrary, in the developed world, urethral damage is most commonly iatrogenic. This can occur secondary to (a) transvaginal surgery such as transvaginal urethral diverticulectomy, bladder neck suspension, anterior colporrhaphy (2), or vaginal hysterectomy (Table 37.1); (b) complications caused by erosion of synthetic materials placed during pelvic reconstructive surgery or midurethral sling procedures (2); (c) obstetric complications from instrumentation during vaginal delivery, such as cerclage sutures (2); (d) prolonged indwelling urethral catheter in neurogenic disorders; (e) locally invasive malignancies and long-term effects of radiation (3); and (f) pelvic trauma resulting in laceration of the urethra (4).

Diagnosis

In patients with urethrovaginal fistula, presentation depends on the location of the fistula. Distal urethrovaginal fistula may be asymptomatic, or the patient may present with vaginal voiding or splitting and spraying of urinary stream. Urethrovaginal fistula proximal to the sphincter can present with urinary incontinence.

A thorough history and physical examination are critical for evaluating a patient with suspected urethral fistula. The causes of the urethral problems need to be identified because it may impact the choice of surgery. Proper pelvic examination using suitable light and a speculum is important to identify the site of injuries or fistula, size, proximity to the bladder neck and urethral sphincter, and ureters. Any concomitant and adjacent injuries should be identified. The vaginal walls should be properly inspected for urine leak, and the quality of adjacent local tissue and the vaginal wall that could be used for reconstruction should be assessed.

Cystoscopy should be considered to help identify the location of the fistula relative to the bladder neck and sphincter and the extent of the pathology. If there is difficulty in identifying the fistula, vital dye such as indigo carmine diluted in saline could be used during cystoscopy or infused through a partially inflated Foley catheter in order to localize the fistula. Cystoscopy may also help to rule out the presence of any other concomitant pathology.

Radiographic imaging may be helpful to assess the integrity of the rest of the urinary tract. Abdominal and pelvic computerized tomography with intravenous contrast can help to identify concomitant injuries. Cystogram and voiding cystourethrogram (VCUG) may be helpful if bladder injury is suspected or to further identify the location of the fistula or the length of associated urethral stricture. Retrograde pyelography or other upper tract imaging can be performed when ureteral injury is suspected (2,5).

Videourodynamic (VUD) examination should be considered in patients with coexisting lower urinary tract symptoms or symptoms suggestive of bladder neck injury. VUD helps to diagnose problems with bladder function such as the presence detrusor overactivity, abnormal bladder compliance, bladder capacity, bladder outlet obstruction, ureteral reflux, and urethral stricture and can identify concurrent vesical fistulas or diverticula.

Indications for Surgery

Surgical repair of the injured urethra should be considered in any symptomatic patient able and willing to undergo surgery. Other considerations during planning for surgical correction of the damaged urethra include (a) an autologous fascial pubovaginal sling may be considered during urethral reconstruction to help with incontinence; (b) a vascularized flap may be used in patients with history of radiation or extensive scarring to help with the poor quality of tissue and assist with healing; and (c) in patients with a small bladder capacity or low compliance, other procedures can be considered such as augmentation cystoplasty to improve vesical compliance and/or capacity.

The timing of surgery to repair fistula is variable. Historically, it was recommended to delay repair in iatrogenic fistula for 3 to 6 months to allow inflammation and edema of the local tissues to subside. This was felt to improve the quality of the tissue and render the tissue more pliable for repair. However, often this delay is not necessary, especially if physical examination reveals healthy pliable local tissues with minimal edema and inflammation. In such cases, surgical repair can be planned without the need to waiting. For obstetric fistula, where the injury is likely to be ischemic in origin, it is still preferable to wait 2 to 6 months to allow for demarcation of devitalized tissue to maximize likelihood of the success of the repair.

Alternative Therapy

Alternatives to urethral reconstruction for fistula include observation for asymptomatic individuals, or indwelling catheterization and supravesical urinary diversion for symptomatic patients. Chronic indwelling catheterization is an option especially if patients are unable or unwilling to undergo surgery. However, long-term indwelling catheterization is associated with complications such as infections, stones, detrusor dysfunction, possible urethral erosions, ostitis pubis, urothelial metaplasia, and a risk of development of squamous cell cancer. In some patients with radiation-induced urethral damage, a urinary diversion should be discussed because it may be the best long-term option.

Surgical Technique

Certain well-accepted general principles should be followed during reconstructive surgery of the urethra (Table 37.2). Rotational vaginal wall flaps are often adequate for repair. In addition, in some cases, alternative well-vascularized pedicle flaps assist with healing and prevent recurrent fistula formation especially with extensive scarring or history of radiation therapy. The available sites for flap harvest include the labia majora (6), the rectus abdominis muscle (7), gracilis myocutaneous (8), or perineal artery axial fasciocutaneous (Singapore) flaps (9).

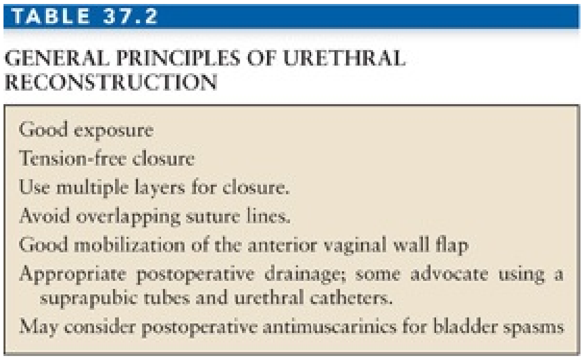

TABLE 37.2

GENERAL PRINCIPLES OF URETHRAL RECONSTRUCTION

Good exposure
Tension-free closure
Use multiple layers for closure.
Avoid overlapping suture lines.
Good mobilization of the anterior vaginal wall flap
Appropriate postoperative drainage; some advocate using a suprapubic tubes and urethral catheters.
May consider postoperative antimuscarinics for bladder spasms

For reconstruction, the patient is placed in the dorsal lithotomy position and then cystourethroscopy is performed to identify the location and extent of the damage. If the fistula is high and close to the trigone, then the ureteral orifices are visualized and the ureters may be catheterized to help with identification during surgery. If a suprapubic tube placement is planned, then the site is marked and a suprapubic cystostomy tube is placed under direct visualization unless concurrent abdominal incision is anticipated in which case the suprapubic tube is placed as part of the abdominal procedure.

The choice of surgery is variable and depends on (a) the location and size of the defect and (b) the availability of local tissue for flaps (10).

1. Small urethral defects: A tension-free *primary closure* (Fig. 37.1) is often adequate for small urethral defects. A 14Fr or 16Fr urethral catheter is placed, and the balloon is inflated. The vaginal wall around the fistula is marked and then hydrodissected using sterile saline. The vaginal wall around the fistula is dissected to mobilize a vaginal flap to help with closure (alternatively an inverted U-shaped incision is used). Then the periurethral fascia is dissected and mobilized to expose the urethra. The urethra is closed primarily with interrupted 4-0 or 5-0 absorbable sutures. It is often not necessary to excise the epithelium of the fistulous wall because such tissue can often be mobilized and used as a first layer of closure. This avoids increasing the size of the fistula. The periurethral fascia is then closed over the repair in a perpendicular direction to minimize overlapping of the suture lines. The vaginal wall is then advanced beyond the fistula repair and secured with absorbable sutures ensuring a lack of overlapping suture lines.

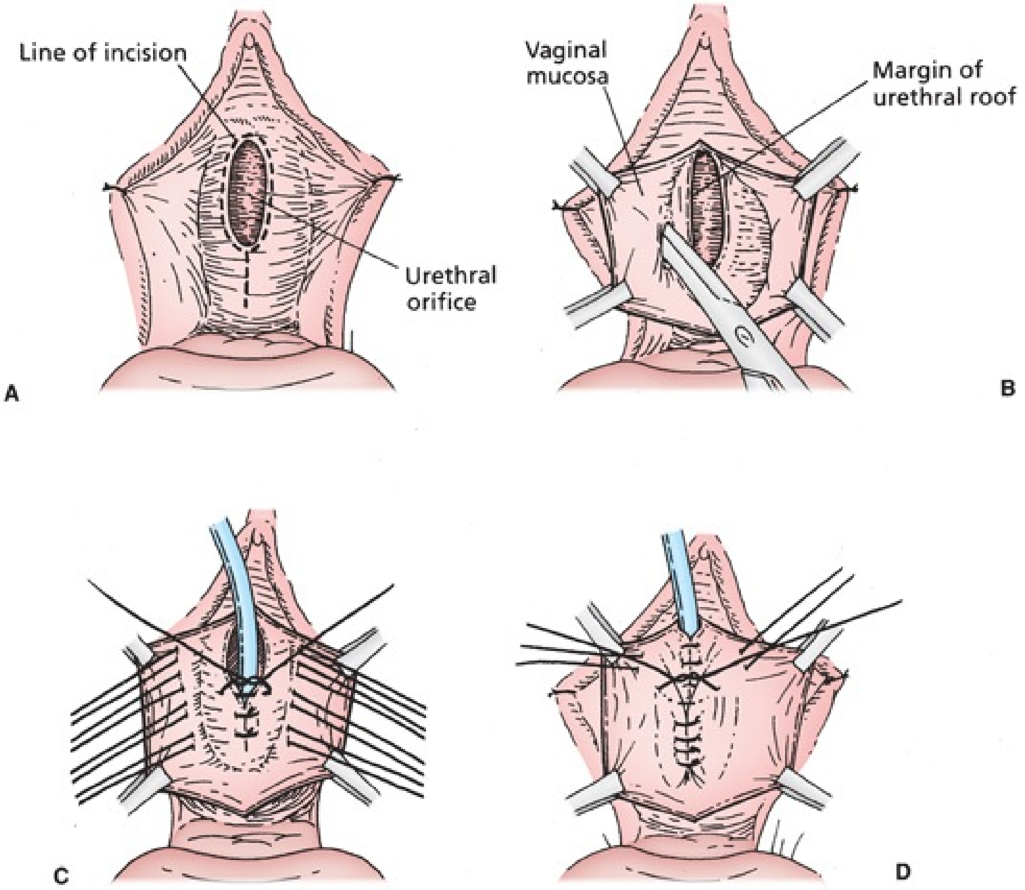

FIGURE 37.1 Primary closure. **A:** The fistula is circumscribed. **B:** Hydrodissection and then the lateral vaginal wall flaps are developed, and the lateral urethral walls are mobilized and freed. **C:** The urethra is closed primarily with interrupted tension-free watertight 4-0 or 5-0 absorbable sutures around a 14Fr catheter. **D:** The vaginal wall is closed primarily if possible or through mobilizing a U-shaped flap trying to avoid overlapping suture lines. (Modified from Mattingly RF, Thompson JD, eds. *Telinde's Operative Gynecology*, 6th ed. Philadelphia: JB Lippincott Co, 1985:662.)

2. Obliterated distal urethral tissue: A U-shaped *advancement anterior vaginal flap* (Fig. 37.2) is used if the distal urethral is obliterated and no sufficient urethral tissue exists for primary closure. Bilateral parallel incisions are made on the vaginal wall distal to the proximal urethra to the site of the urethral meatus. A flap is dissected of the anterior vaginal wall, advanced, and rotated 180 degrees and is sutured to the incisions on the distal vaginal wall to form the posterior and lateral walls of the neourethra. The urethra is closed over a 14Fr urethral catheter using 4-0 or 5-0 absorbable sutures. The vaginal wall is then advanced and closed primarily.

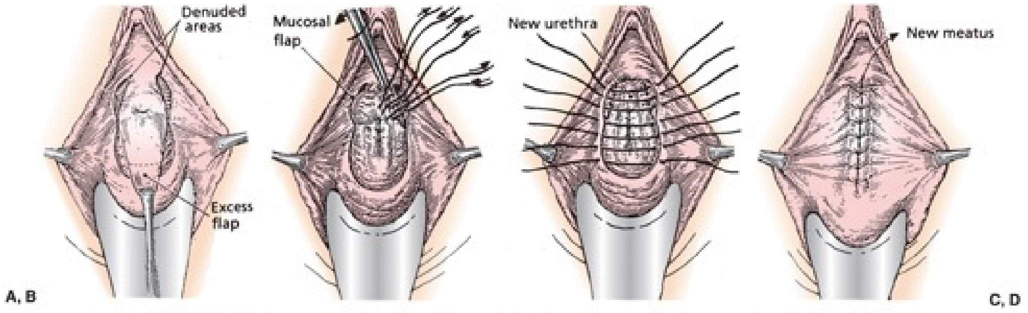

FIGURE 37.2 Advancement flap. **A:** A U-shaped incision is made with the arms of the U extending caudally as far as the planned urethral meatus. **B:** The flap is elevated and rotated 180 degrees. **C:** The flap is sutured to the edges of the parallel distal incisions over the catheter to form the new urethra. **D:** The vaginal wall is closed either primarily or with a U-shaped flap, depending on the availability of local tissue. (Modified from Mattingly RF, Thompson JD, eds. *Telinde's Operative Gynecology*, 6th ed. Philadelphia: JB Lippincott Co, 1985:660–661.)

3. Extensive loss of urethral tissue: A vaginal wall flap can be employed, as a *tube flap* (Fig. 37.3), as another available option in the setting of extensive loss of urethral tissue. A wide rectangular area (about 2.5 cm × 3.5 cm) is marked on the vaginal wall at the location of the distal urethra. Incisions

are made and then the rectangular vaginal wall flap is mobilized and fashioned into a tube over a 14Fr urethral catheter using 4-0 or 5-0 absorbable sutures. The tube is then connected to the proximal urethra and to the site of urethral meatus using 3-0 absorbable sutures. In this situation, a pubovaginal sling is often used to achieve continence. A rotational flap of the vaginal wall is then mobilized to close the gap of the vaginal wall.

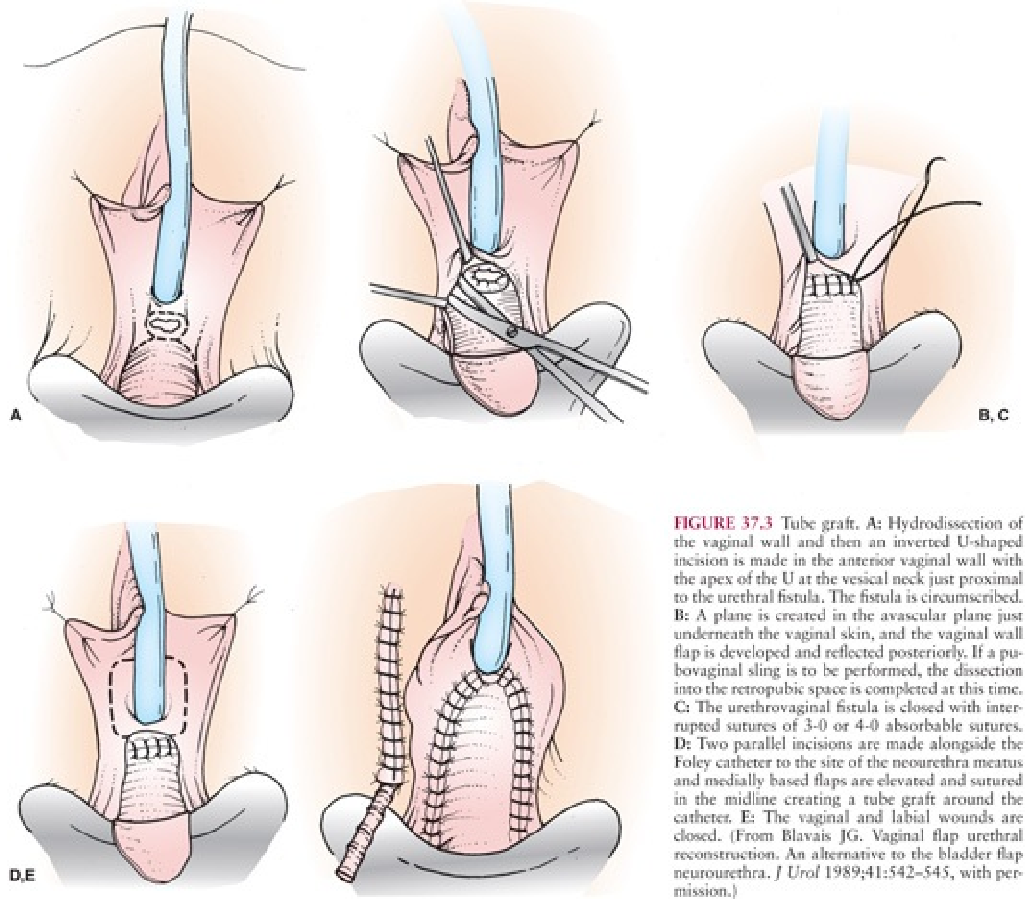

FIGURE 37.3 Tube graft. A: Hydrodissection of the vaginal wall and then an inverted U-shaped incision is made in the anterior vaginal wall with the apex of the U at the vesical neck just proximal to the urethral fistula. The fistula is circumscribed. B: A plane is created in the avascular plane just underneath the vaginal skin, and the vaginal wall flap is developed and reflected posteriorly. If a pubovaginal sling is to be performed, the dissection into the retropubic space is completed at this time. C: The urethrovaginal fistula is closed with interrupted sutures of 3-0 or 4-0 absorbable sutures. D: Two parallel incisions are made alongside the Foley catheter to the site of the neourethra meatus and medially based flaps are elevated and sutured in the midline creating a tube graft around the catheter. E: The vaginal and labial wounds are closed. (From Blavais JG. Vaginal flap urethral reconstruction. An alternative to the bladder flap neurourethra. *J Urol* 1989;41:542–545, with permission.)

4. Extensive urethral damage and insufficient vaginal wall: A *labia minora pedicle flap* (Fig. 37.4) is best suited for patients with this problem. A rectangular flap 3 cm × 3.5 cm is marked on the labium and then it is incised close to the site of the urethral reconstruction and mobilized. A tunnel is created under the vaginal wall and the labium flap is then mobilized with its vascular pedicle and underlying fat and is passed beneath the vaginal wall to the site of the urethra. The flap is then fashioned around a 14Fr catheter in a tension-free manner so that the mucosal surface is facing inward to form the lumen of the future urethra. The vaginal wall is then closed. A Penrose drain is placed in the labial harvest site for 24 hours and the labial skin is closed with 3-0 absorbable sutures. The Foley catheter is left to gravity for 10 to 14 days.

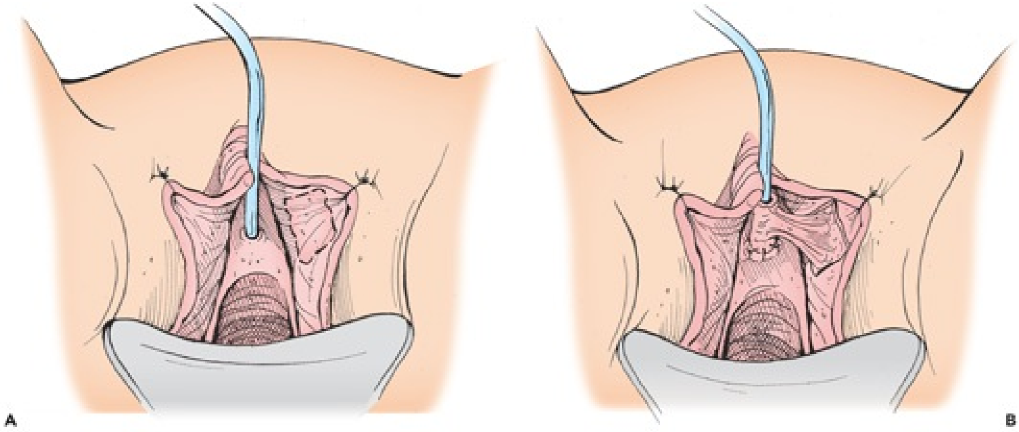

FIGURE 37.4 Labia minora pedicle graft. **A:** A rectangular incision 3.5 cm × 2.5 cm in the labia minora after hydrodissection is made and then the labial tissue and underlying fat is mobilized on the vascular pedicle. **B:** The flap is passed through a tunnel created under the wall of the labial skin to the site of the neourethra and sutured into position with the mucosal surface of the labia becoming the lumen of the neourethra.

5. Extensive urethral damage and extensive vaginal wall scarring: An anterior bladder flap can be used as an alternative to a vaginal wall flap in case of extensive vaginal scarring and vaginal wall loss secondary to a large urethrovaginal fistula that precludes using vaginal flaps. However, in this case, a concomitant anti-incontinence procedure should be strongly considered (6) (Fig. 37.5).

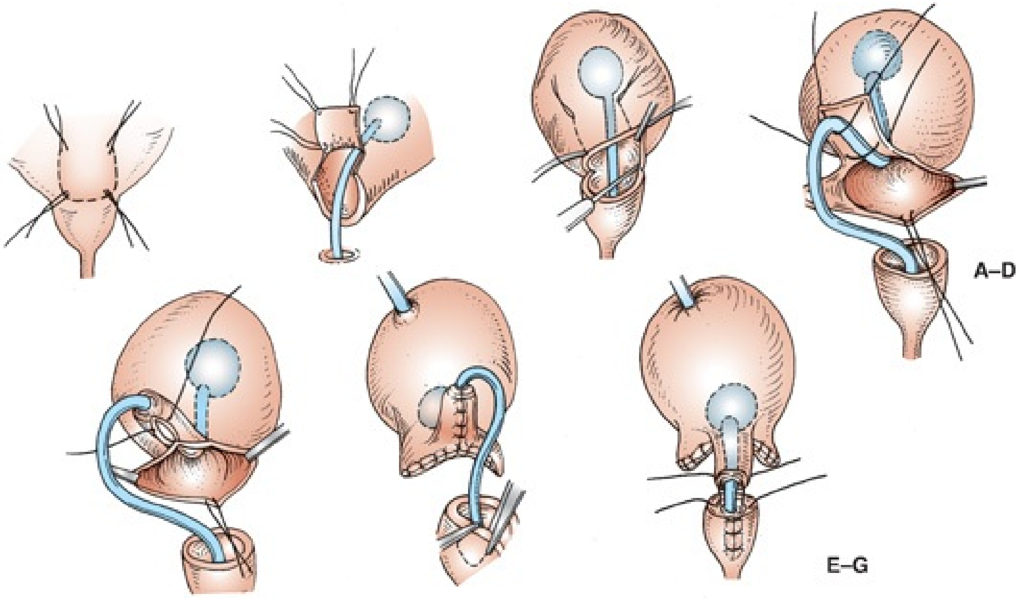

FIGURE 37.5 Bladder flap reconstruction. Tanagho anterior bladder flap reconstruction can be used in lieu of vaginal flap reconstruction. **A–D:** The bladder flap is marked on the anterior bladder wall with stay sutures. A full thickness of the bladder wall is cut and formed into a tube around a 16Fr urethral catheter. **E–G:** The bladder wall is sutured around the catheter using 3-0 or 4-0 absorbable sutures. The neourethra is then fixed to site of the urethral meatus. (Reprinted with permission from Tanagho EA. Bladder neck reconstruction for total urinary incontinence: 10 years of experience. *J Urol* 1981;125:321. Copyright © 1981 American Urological Association, Inc. Published by Elsevier Inc. All rights reserved.)

The edges of the fistula are freed by sharp dissection from the pubic rami. Next, the bladder is freed anteriorly and inferiorly from its attachments. A 4 cm × 2.5 cm rectangular flap is mobilized from the anterior bladder wall and fashioned into a tube around a 14Fr catheter using 4-0 or 5-0 absorbable sutures. The distal end of the tube is then fixed to the site of the new urethral opening in the original site. The neourethra is then fixed to the subcutaneous tissue or the periosteum of the pubic bone. A Martius flap can be performed to separate the overlapping suture lines (6).

An anti-incontinence procedure is advisable as a part of the reconstruction of the urethra to minimize the risk of postoperative incontinence. An autologous pubovaginal sling is the procedure of choice because the use of synthetic materials is not recommended due to the risk of erosion of the synthetic graft (11). It is important to avoid placing the pubovaginal sling until the urethra is completely reconstructed (Fig. 37.6). After placement of the autologous pubovaginal sling, a vascular pedicle graft (Martius flap) is often positioned between the pubovaginal sling and reconstructed urethra (Fig. 37.7). The vaginal wall is then closed, and at the conclusion of the operation, the long ends of the sling are tied together in the midline over the rectus fascia without tension.

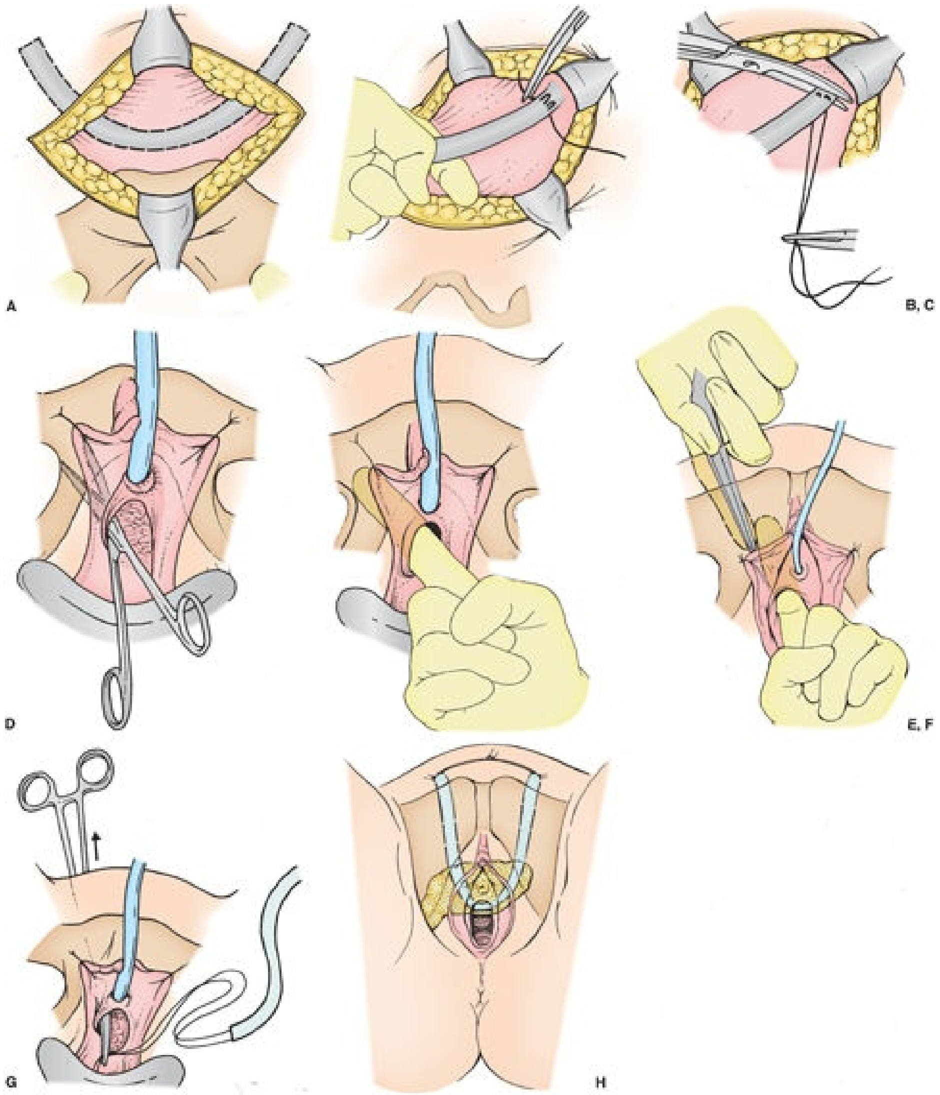

FIGURE 37.6 Pubovaginal sling. **A:** A lower abdominal Pfannenstiel incision is made at the skin crease, and dissection is carried out to the level of the rectus fascia. A 2 to 3 cm wide and 8 cm to 10 cm in length graft is outlined with the incision kept parallel to the direction of the fascial fibers. **B:** A 2-0 nonabsorbable running horizontal mattress suture is placed across the most lateral portion of the graft, and the ends are left long. **C:** Each end of the fascial graft is transected approximately 1 cm lateral to the mattress suture. **D:** Transvaginally, dissection is begun with Metzenbaum scissors in the avascular plane just beneath the vaginal skin. **E:** The endopelvic fascia is perforated with Mayo scissors with the tips of the scissors directed toward the patient's ipsilateral shoulder and ensure the tip of the scissors are marching on the posterior aspect of the pubic bone until the retropubic space is entered. **F:** A Pereyra-Raz ligature carrier or a long tonsil clamp is passed from the abdominal to the vaginal wound lateral to the urethra while protecting the urethra with a finger to bring one end of the graft to the abdominal incision. **G:** The fascial graft is passed around the urethra and brought to the abdominal wound. **H:** The long ends of the sling are tied together in the midline under no tension. The labial fat pad, if used, is positioned between the sling and the vesical neck. (A–G from Blavais JG. Pubovaginal sling procedure. In: Whitehead ED, ed. *Current Operative Urology*. Philadelphia: JB Lippincott Co, 1990:93–101, with permission.)

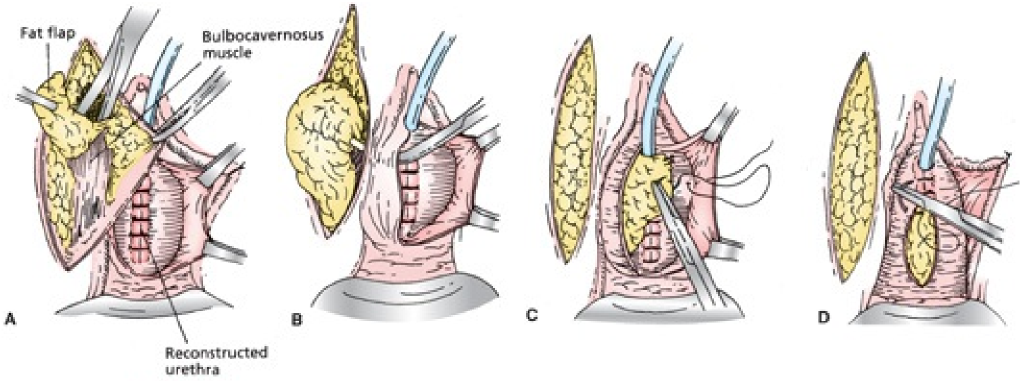

FIGURE 37.7 Vascular pedicle graft (Martius flap). **A:** Incisions in skin crease of the labia majora to expose the underlying fat pad, the blood supply to the superior margin is controlled with suture ligation and then the flap is mobilized posteriorly. **B:** The flap is tunneled under the skin to the vaginal incision. **C:** The flap is fixed over the reconstruction site at two sites with 3-0 or 2-0 absorbable sutures. **D:** The vaginal wall is closed over the reconstruction, and the flap and the donor site is inspected for any bleeding and then closed. If a pubovaginal sling is performed, it is placed beneath the vaginal wall prior to the closure. (Modified from Mattingly RF, Thompson JD, eds. *Telinde's Operative Gynecology*, 6th ed. Philadelphia: JB Lippincott Co, 1985:663.)

A VCUG is obtained through the suprapubic catheter about 2 weeks after the procedure. If the patient successfully voids with no extravasation, the suprapubic catheter can be removed.

Outcomes

Results

Reconstruction of female urethra has been reported to be successful in 67% to 100% of cases. Improved outcomes are noted using vascular pedicle flaps especially in patients with history of fistulae secondary to radiation therapy and in patients with extensive scarring (12,13). Continence can be achieved in 55% to 93% of patients after reconstruction with proper surgical techniques. Continence outcomes are improved with using an anti-incontinence pubovaginal sling procedure. Urethral obstruction can also occur after reconstruction in 2% to 41% which may require additional procedures. Overall functional success of urethral reconstruction is reported to be up to 90% (10). Table 37.3 summarizes results of urethral reconstruction (14).

[b] Buccal grafts used for repair.

Complications

Postoperative complications can be minimized by careful adherence to the general principles of reconstruction; however, in complex reconstructive cases, such problems are not rare.

Complications may include bleeding which can be avoided by careful and meticulous dissection in the proper surgical planes. Cautery to control bleeding should be used with caution as this may jeopardize blood supply and lead to flap necrosis.

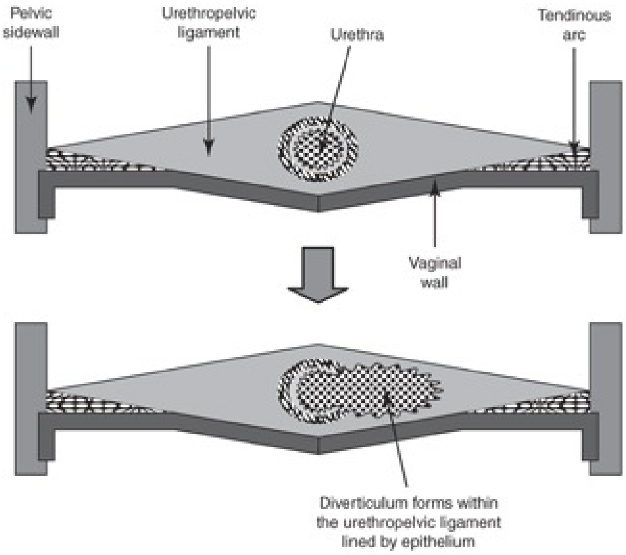
Urethrovaginal fistula may result and may require additional procedures. Meticulous attention to surgical technique, good hemostasis, avoidance of infection, preservation of a well-vascularized anterior vaginal wall flap, and a multilayered closure with avoidance of overlapping suture lines should minimize the risk of urethrovaginal fistula formation.

Urinary obstruction may develop secondary to scarring or from the pubovaginal sling. Such an occurrence may require additional procedures such as urethral dilation, urethral reconstruction, or sling incision with or without urethrolysis.

Urinary incontinence from sphincteric deficiency may develop in 50% to 90% of patients not undergoing concomitant sling. Blavias and Heritz (13) reported successful reoperation in such patients who suffered from sphincteric incontinence. Recurrent stricture was reported by Blavias et al. (14) in 2 of 17 patients (11%) who underwent urethral reconstruction for female urethral stricture. Meatal stenosis has also been reported (15).

RECONSTRUCTION OF THE FEMALE URETHRA FOR URETHRAL DIVERTICULUM

Urethral diverticula (UD) in women represent a challenge in both diagnosis and reconstruction for the surgeon. The actual prevalence of UD is not known, but it is reported to occur in 1% to 6% of adult women (16,17). UD is an epithelialized cavity dissecting its way within the fascia of the urethropelvic ligament (Fig. 37.8) (18). This cavity forms an isolated cyst-like appendage, usually with a single connection to the urethral lumen, termed the *neck* or *ostium*. Complicated UD may extend partially around the urethra to form a “saddlebag” UD, or more uncommonly anterior to the urethra (19), or circumferentially around the urethra (20).



Pelvic sidewall
Urethropelvic ligament
Urethra
Tendinous arc
Vaginal wall
Diverticulum forms within the urethropelvic ligament lined by epithelium

FIGURE 37.8 Diverticulum forms within the urethropelvic ligament.

It is generally believed that an adult UD is formed secondary to infection and obstruction of the periurethral glands. These glands are tubuloalveolar glands and are anatomically located in the distal one-third of the urethra ventral and lateral to the urethral lumen. It is postulated that infection of these glands leads to abscess formation and eventual rupture of the abscess back into the urethral lumen, resulting in an epithelialized cavity in communication with the urethra.

Often, although not invariably highly symptomatic due to the location, the most common coexisting condition is probably urinary incontinence, especially stress urinary incontinence (SUI), which may coexist in up to 50% of individuals (16). Malignant and benign tumors in UD are quite rare. The most common malignant pathology in UD is adenocarcinoma, followed by transitional cell and squamous cell carcinomas. Calculi within UD may be diagnosed in 4% to 10% of cases and are most likely due to urinary stasis and/or infection.

Diagnosis

The diagnosis of UD can be made with a combination of a thorough history, physical examination, and selected imaging. The symptoms of UD are classically described as the “three Ds”: dysuria, dyspareunia, and dribbling (postvoid). However, common presenting symptoms vary and include storage and voiding symptoms, pain, and urinary tract infection (UTI), which is reported in almost one-third of patients (21). Other symptoms include a vaginal mass, hematuria, vaginal discharge, obstructive voiding symptoms, and even urinary retention. Up to 20% of patients may be completely asymptomatic and are thus diagnosed incidentally on imaging or physical examination. Symptomatic patients may often be overlooked and treated for years for a number of unrelated conditions, such as interstitial cystitis, recurrent cystitis, vulvodynia, endometriosis, and vulvovestibulitis, before the diagnosis of UD is made.

Physical examination should include a careful inspection of the anterior vaginal wall. Masses or areas of tenderness should be noted and further examined. Suspected UD should be carefully differentiated from vaginal prolapse, including cystourethrocele, vaginal wall cyst, or Skene gland abscess. Most UDs are located ventrally over the middle and proximal portions of the urethra corresponding to the area of the anterior vaginal wall 1 to 3 cm inside the introitus. During physical examination, a tender cystic mass is felt on the anterior vaginal wall and may be gently “stripped” or “milked” distally in an attempt to express purulent material or urine from within the urethral lumen out through the urethral meatus, which strongly suggests the diagnosis of UD.

Endoscopic examination of the bladder and urethra is performed in an attempt to visualize the UD ostium (communication to the urethra) as well as to evaluate for other causes of the patient’s presenting symptoms. A flexible cystoscope or a specially designed rigid female cystoscope with a short beak to maintain the discharge of the irrigation solution immediately adjacent to the lens is most useful in visualizing the lumen of the relatively short female urethra. During cystoscopy, simultaneous gentle compression of the bladder neck and the diverticular sac with an assistant’s finger can express luminal discharge of purulent material during urethroscopy localizing the ostium.

High-quality preoperative imaging is important in the diagnosis of UD as well as in planning operative therapy. This will help to provide an accurate reflection of the relevant anatomy of the UD and its anatomic relationships. No single study can be considered the gold standard for the evaluation of UD. Furthermore, the availability and quality of individual radiologic techniques is quite variable across centers. Currently available techniques for the evaluation of UD include double-balloon positive-pressure urethrography (PPU), VCUG, ultrasound (US), and magnetic resonance imaging (MRI) with or without an endoluminal coil (eMRI). eMRI (22) has several distinct advantages over VCUG; however, these studies are often complementary. We currently use MRI in the evaluation of all patients with known or suspected UD because the complexity of these lesions is more readily appreciated using this technique (Fig. 37.9). Urodynamic studies, especially VUDs, are used in patients with urinary incontinence or significant voiding dysfunction in order to characterize these symptoms, especially if surgery is planned. This may also help in counseling the patient about the value of a synchronous anti-incontinence procedure. These studies are also useful in evaluating the anatomy of the UD, assessing the competence of the bladder neck, assessing bladder function, and confirming the diagnosis of SUI.

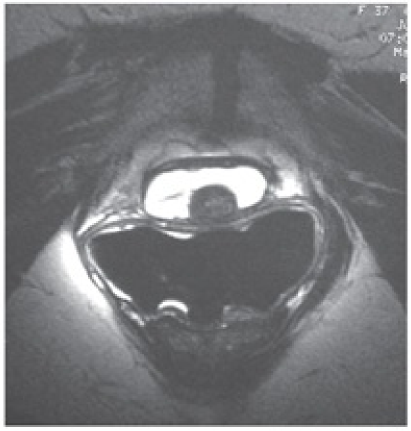


FIGURE 37.9 Axial T2-weighted MRI of an unusual anterior urethral diverticulum.

Indications for Surgery

Symptomatic patients should be offered surgical excision and reconstruction. Those with concomitant SUI can be considered for a simultaneous anti-incontinence procedure at the time of UD excision.

Asymptomatic patients and those who are unwilling or medically unable to undergo surgical excision should be informed that the natural history of untreated UD is unknown. In such cases, patients should be counseled that certain carcinomas or other complications such as stones or urinary incontinence may arise and that close follow-up is warranted.

Alternative Therapy

For patients electing nonoperative management, a conservative approach can be offered with daily low-dose antibacterial prophylaxis for infection and digital stripping of the anterior vaginal wall following micturition to prevent postvoid dribbling and reduce the risk of UTI due to stasis in the UD.

Most commonly, UD are treated with a complete excision and urethral reconstruction (16). However, a variety of other surgical interventions for UD have been reported. Approaches have included transurethral and open marsupialization, endoscopic unroofing, fulguration, incision and obliteration, and coagulation (16). One noteworthy alternative to excision and reconstruction is transvaginal marsupialization as described by Spence and Duckett (23). This approach may reduce operative time, blood loss, and recurrence rate but is probably only applicable to UD in very selected cases involving the distal one-third of the urethra due to the risk of sphincteric injury and resulting de novo SUI in those UD located more proximally. This procedure involves incision of the urethra at the floor from the level of the diverticular ostium to the urethral meatus. This will result in urinary spraying and vaginal voiding.

In rare cases, when the UD is highly symptomatic, acutely infected, and unresponsive to antibiotic therapy, or in cases when a complete elective excision should be postponed, such as during pregnancy, a transvaginal incision (diverticulotomy) can be performed directly into the UD cavity. This will create a temporary urethrovaginal fistula from the UD ostium through the UD cavity into the vagina, thus decompressing the diverticulum. The UD and fistula are subsequently repaired at the time of planned elective excision and reconstruction.

Surgical Technique

Excision and reconstruction is probably the most common surgical approach to UD in the modern era. The principles of the urethral diverticulectomy operation have been well described (Table 37.4). There are only a few minor differences between surgical approaches, including the type of vaginal incision (inverted “U” versus inverted “T”), whether it is necessary to remove the entire mucosalized portion of the UD, and finally, the optimal type of postoperative catheter drainage (urethra only versus urethra and suprapubic).

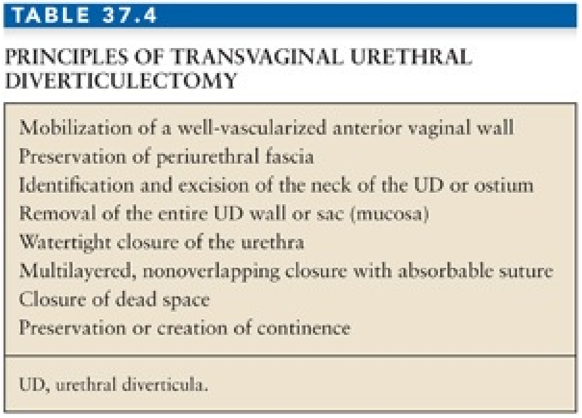

TABLE 37.4

PRINCIPLES OF TRANSVAGINAL URETHRAL DIVERTICULECTOMY

Mobilization of a well-vascularized anterior vaginal wall
Preservation of periurethral fascia
Identification and excision of the neck of the UD or ostium
Removal of the entire UD wall or sac (mucosa)
Watertight closure of the urethra
Multilayered, nonoverlapping closure with absorbable suture
Closure of dead space
Preservation or creation of continence

UD, urethral diverticula.

Preoperative preparation includes (a) antibiotic administration in patients with recurrent or persistent UTIs to control infection, (b) stripping of the anterior vaginal wall to prevent urinary stasis and recurrent UTIs, and (c) application of topical estrogen creams for several weeks prior to surgery in postmenopausal patients with atrophic vaginitis to optimize the quality of vaginal tissue and promote healing.

The patient is placed in a high lithotomy position with all pressure points well padded. We have found that the use of padded adjustable stirrups for the lower extremities greatly enhances operative access to the female perineum. A standard vaginal antiseptic preparation is applied. The use of a headlight as well as operative magnification (1.5× to 2.0×) assists with the dissection and precise reconstruction. A Foley catheter (16Fr) is placed in the urethra. A suprapubic tube may be used for an additional postoperative urinary drainage if desired. An appropriate preoperative antibiotic is given.

A weighted vaginal speculum and Scott retractor with hooks offer enhanced exposure. An inverted U is marked out along the anterior vaginal wall proximal from the urethral meatus with the limbs extending to the bladder neck or beyond (Fig. 37.10). The inverted U incision provides excellent exposure laterally at the level of the midvagina and can be extended proximally as needed for lesions that extend beyond the bladder neck. Hydrodissection with normal saline can be used along the lines of the incision beneath the vaginal wall to facilitate dissection. A posterolateral episiotomy may be of help in some patients with a narrow introitus, especially in nulliparous women.

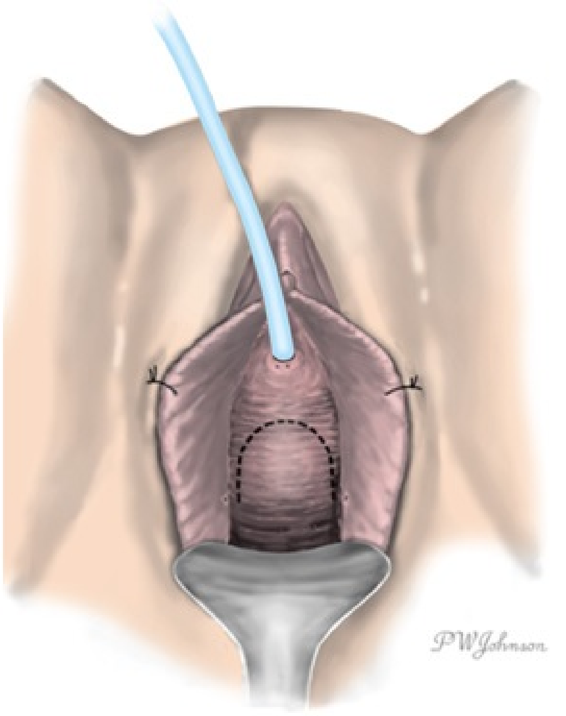

FIGURE 37.10 Incision along the anterior vaginal wall, with the base of the U at the level of the distal urethra, provides an excellent lateral exposure at the midvagina for transvaginal urethral diverticulectomy. All rights reserved.)

An anterior vaginal wall flap is created by careful dissection in the potential space between the vaginal wall and the periurethral fascia. The use of sufficient countertraction during this portion of the procedure is important in maintaining the proper plane of dissection and aid in the dissection process.

During the dissection, it is important to (a) preserve the periurethral fascia, (b) maintain an adequate blood supply to the anterior vaginal wall flap, and (c) avoid inadvertent and premature entry into the UD. The periurethral fascia forms a distinct layer that is usually interposed between the vaginal wall and the UD; however, in some lesions, it may be deficient (24). Preservation and later reconstruction of the periurethral fascia is of paramount importance in order to prevent UD recurrence, close dead space, and overlap the suture lines in order to avoid urethrovaginal fistula formation postoperatively. Pseudodiverticula have been described where this layer of tissue is considerably attenuated or even absent (24). In these patients, an interpositional flap, or graft such as a pubovaginal sling, may be used for reconstruction.

Following the completed takedown of the anterior vaginal wall flap, the periurethral fascia is incised sharply transversely (Fig. 37.11). Proximal and distal layers of periurethral fascia are carefully developed by both sharp and blunt dissection, avoiding entrance into the UD. The UD is then sharply dissected back to its origin on the urethra at the ostium within the leaves of the periurethral fascia (Fig. 37.12). In many cases, with extensive adhesions, it may be necessary to open and enter the UD to facilitate dissection from the surrounding tissues. The ostium or connection to the urethra is identified and the walls of the UD are completely excised. Every effort should be made to remove the entire mucosalized surface of the UD in order to prevent recurrence. All abnormal tissues in the area of the ostium should be removed if possible to ensure that no mucosal elements of the UD wall remain that could result in postoperative urine leakage and recurrence. Following complete excision of the UD, the urethral catheter is often seen through a defect in the urethra (Fig. 37.13). The urethra can be reconstructed over a Foley catheter as small as 14Fr without long-term risk of urethral stricture and should be closed in a watertight fashion with 4-0 synthetic absorbable sutures (Fig. 37.14). The closure should be tension-free and should include the full thickness of the urethral wall. In patients with circumferential UD, Rovner and Wein (20) described transecting the urethra and then reanastomosis to be able to access the anterior portion of the UD to ensure adequate removal of the diverticular sac. After urethral closure, the periurethral fascial flaps are reapproximated with 3-0 synthetic absorbable sutures in a perpendicular orientation to the urethral closure line in order to minimize overlap and hence the risk of postoperative urethrovaginal fistula formation (Fig. 37.15). Care is taken to secure the periurethral fascial flaps in such a way as to close all dead space.

All rights reserved.)

If desired, a fibrofatty labial (Martius) flap can be harvested at this point and placed over the periurethral fascia as an additional layer of closure. Indications for such a flap are not universally agreed on. However, it can be considered in (a) patients with poor-quality tissues or attenuated periurethral fascia or (b) in patients whom significant inflammation is encountered intraoperatively. A well-vascularized adjuvant flap such as a Martius flap may potentially reduce the risk of wound breakdown and subsequent complications such as urethrovaginal fistula.

The anterior vaginal wall flap is then repositioned and reapproximated with absorbable 2-0 sutures (Fig. 37.16). This completes a three-layer closure (four layers if a Martius flap is used). An antibiotic impregnated vaginal pack is placed postoperatively.

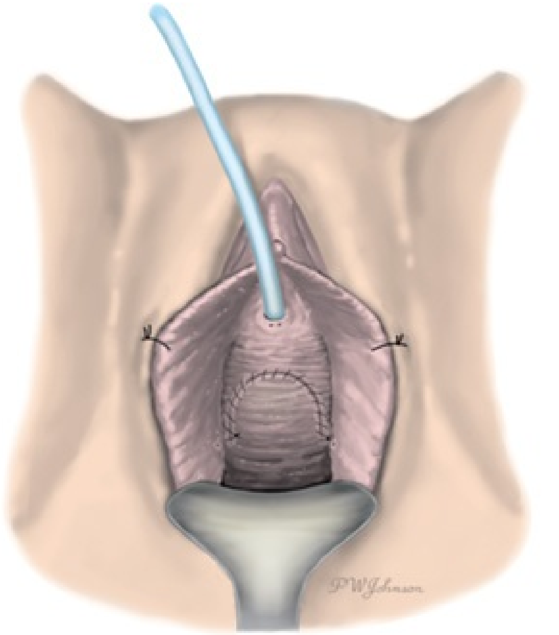

FIGURE 37.16 Closure of the vaginal wall with reapproximation of the anterior vaginal wall flap. This completes a three-layer closure including closure of the urethra, periurethral fascia, and vaginal wall. (Reprinted with permission from Rovner ES. Urethral diverticula. In: Raz S, Rodriguez L, eds. *Female Urology*, 3rd ed. Philadelphia: Elsevier, 2008:825–844. Copyright © 2008 Elsevier Inc. All rights reserved.)

The vaginal packing is removed within 6 to 24 hours, and the patient is discharged home with closed urinary drainage. Antispasmodics are used liberally to reduce bladder spasms. A pericatheter VCUG is obtained at 14 to 21 days postoperatively. If there is no extravasation, the catheters are removed. If extravasation is seen, then repeat pericatheter VCUGs are performed weekly until resolution is noted. In the vast majority of cases, extravasation will resolve in several weeks with this type of conservative management.

Complications

Postoperative complications can be avoided by careful adherence to the principles of transvaginal urethral diverticulectomy. Nevertheless, complications may arise. Large diverticula (>4 cm) or those associated with a lateral or horseshoe configuration may be associated with a greater likelihood of postoperative complications (25). Complications include recurrent diverticulum (1% to 29%), stress incontinence (1.7% to 16.0%), urethral stricture (0% to 5%), and recurrent UTIs (0% to 31%) (16).

Intraoperative bleeding can be avoided by maintaining the proper plane of dissection during takedown of the anterior vaginal wall flap. If bleeding is encountered, cautery or suture ligature can be used. Excessive use of cautery should be avoided because this can lead to flap necrosis and fistula formation.

Urethrovaginal fistula is a disabling but fortunately rare complication that may result from diverticulectomy. A fistula can be located either distal or proximal to the sphincteric mechanism. A distally located fistula is usually not associated with symptoms other than perhaps a split urinary stream and/or vaginal voiding. As such a distal urethrovaginal fistula may not require repair, although some patients may request repair. Conversely, a proximal fistula located at the bladder neck or within the proximal half of the urethra in patients with an incompetent bladder neck will likely result in considerable symptomatic urinary leakage. These patients should undergo repair with or without the use of an adjuvant tissue flap such as a Martius flap to provide a well-vascularized additional tissue layer. Meticulous attention to surgical technique, good hemostasis, avoidance of infection, preservation of the periurethral fascia, a well-vascularized anterior vaginal wall flap and a multilayered closure with nonoverlapping suture lines should minimize the potential for postoperative urethrovaginal fistula formation.

Coexisting SUI can be treated at the time of urethral diverticulectomy as noted previously. Synthetic materials should not be used in this setting (11). However, de novo SUI may occur following urethral diverticulectomy. The proximity of most UDs to the sphincter mechanism puts the patient at risk for this complication even with meticulous attention to surgical technique.

Persistence or recurrence of symptoms following diverticulectomy may occur in some patients. This may be caused by a new medical problem (e.g., UTI), a new UD, or alternatively, recurrence of the original lesion. Recurrence of a UD may be due to incomplete excision of the UD, inadequate closure of the urethra or residual dead space, or other technical factors. Ljungqvist et al. (26) found recurrence in 11 out of 68 of their patients over 26-year follow-up with a 92% overall satisfaction. Repeat urethral diverticulectomy surgery can be challenging due to altered anatomy, scarring, and the difficulty of identifying the proper anatomic planes.

Outcomes

The significance of appropriate preoperative patient counseling regarding surgery and postoperative expectations of cure cannot be overemphasized. Individuals with UD have a myriad of symptoms, including pain, UTIs, and urinary dysfunction. Although these are often related to the presence of the UD, sometimes they do not resolve even with a technically successful surgery. Nevertheless, surgical outcome for the UD has generally been good. Outcome can be evaluated by resolution of the patient's symptoms or recurrence of the diverticulum. Successful excision of UD has been reported in 85% of patients (21).

ACKNOWLEDGMENT

The authors acknowledge that they are indebted to Drs. Blaivas and Purohit for providing substantial material for construction of this chapter derived from the prior edition of this book.

CHAPTER 38 ■ SURGICAL MANAGEMENT OF THE INCOMPETENT BLADDER OUTLET IN THE PATIENT WITH A NEUROGENIC BLADDER

TERESA L. DANFORTH AND DAVID A. GINSBERG

The two primary goals of treatment of patients with neurogenic bladder (NGB) include protection of the upper urinary tracts by maintaining low storage pressures and allowing the patient to sustain optimal urinary control. Incontinence may be due to bladder dysfunction (i.e., detrusor overactivity) and/or bladder outlet dysfunction. The bladder outlet in patients with NGB may behave in one of three ways: normal functioning outlet, obstructed outlet (often caused by detrusor external sphincter dyssynergia [DESD] leading to incomplete bladder emptying or urinary retention), or an incompetent bladder outlet leading to incontinence.

DESD is usually seen in patients with suprasacral spinal cord injury and is defined as involuntary contraction of the striated sphincter at the time of a detrusor contraction. This may result in obstruction from the contracted external sphincter as well as activation of the sacral arc reflex leading to a poorly sustained bladder contraction and incomplete bladder emptying. If male patients are unable or unwilling to perform intermittent catheterization (IC), standard treatment is usually reflex voiding to an external catheter which is often combined with either pharmacologic (alpha-blocker, baclofen, onabotulinumtoxinA) or surgical external sphincterotomy to maintain satisfactory bladder emptying. Patients with DESD and recurrent autonomic dysreflexia are also considered candidates for sphincterotomy to ameliorate their symptoms. Repeat sphincterotomy is commonly necessary in this population, and growth of the prostate may require subsequent bladder neck incision or resection to relieve obstruction at the bladder neck. Patients who can no longer use condom catheters secondary to body habitus may require management with an indwelling catheter.

The incompetent bladder outlet has multiple etiologies, all resulting in incontinence at baseline. Patients with sacral spinal cord injury, spina bifida, or history of radical pelvic surgery may have an incompetent bladder outlet secondary to dysfunction of the striated and/or smooth sphincters. Iatrogenic destruction of the outlet may be caused by prior transurethral resection of the prostate or chronic indwelling catheter (Fig. 38.1).

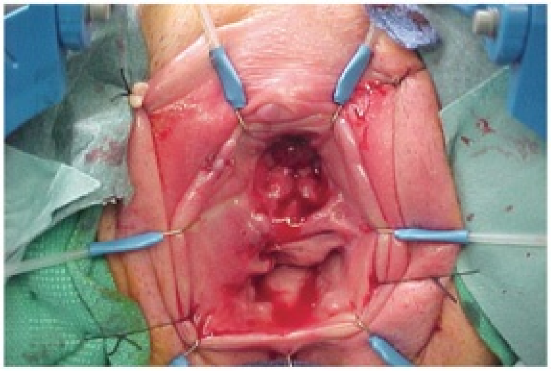

FIGURE 38.1 Urethral erosion. A patulous urethra caused by a chronic indwelling catheter in a female with multiple sclerosis.

Female patients with NGB present unique challenges because women have more difficulty with IC due to inaccessible anatomy. Sphincterotomy is not an option for females with DESD because there is not an adequate external collection device currently available. Females may also have baseline stress urinary incontinence of nonneurogenic etiology in addition to their NGB voiding dysfunction. Incontinence may be exacerbated by detrusor overactivity as commonly seen in patients with multiple sclerosis.

This chapter will discuss the surgical options for treatment of the patient with NGB and an incompetent bladder neck, focusing on technique of bladder neck closure (BNC).

SURGICAL OPTIONS

Management of the incompetent bladder neck varies depending on the degree of incontinence and the health of the existing urethra. Options include injectables, transvaginal slings, puboprostatic slings, artificial urinary sphincter (AUS), and BNC, transvaginal or abdominal, with or without bladder reconstruction.

Patients with mild incontinence may benefit from injectable therapy (1–3). The few studies in the neurogenic patient population report that often multiple injections are needed with an improvement rate of up to 67% but low cure rates. None of these studies evaluate long-term efficacy. Theoretically, this would not be an optimal therapy for a patient population requiring regular IC. Long-term results in nonneurogenic patients show relatively poor durability.

Slings have been used in the management of incontinence for both neurogenic and nonneurogenic patients. Female patients with adequate urethral length may be candidates for either a mesh midurethral sling or an autologous fascial sling at the bladder neck. Male patients may benefit from a mesh sling placed in the perineum or a puboprostatic fascial sling. Little data is available on the use of male slings in patients with NGB. Groen et al. (4) recently evaluated 20 male patients who underwent the AdVance male sling and found a 65% improvement and/or cure rate. The advantage to using mesh slings in both sexes includes shorter operative time and less morbidity. However, if the sling's purpose is to obstruct the outlet in patients who catheterize, many prefer to use fascia because it allows the surgeon to put more tension on the urethra without the risk of mesh erosion (5).

AUSs are commonly used in male patients with NGB (less commonly in females), both in those who reflex void as well as those who do IC. Patients must have adequate hand function to use the pump located in the scrotum. AUS revision rates at 5 years are approximately 20% to 25% due to mechanical failure, infection, and urethral erosion (6). Most studies regarding AUS procedures in NGB patients have been in children, with higher revision rates, upward of 36%, likely secondary to the younger ages at which the prosthesis is placed as well as increased complexity of the case (7). Herndon et al. (8) report cuff erosion rates of 16% in the NGB population, not surprisingly higher than nonneurogenic patients because many NGB patients perform regular IC.

BNC is a relatively uncommon procedure, usually reserved as a last resort. In the female patient, BNC may be performed transvaginally or abdominally.

INDICATIONS FOR BLADDER NECK CLOSURE

Females

Female patients with NGB and incontinence managed with an indwelling urethral catheter frequently suffer from leakage around the catheter, leading to upsizing of the catheter and increases in balloon volume, eventually causing a patulous urethra. Patients with sufficient urethral length may benefit from a fascial sling. Watanabe et al. (9) report that for adequate urethral compression, a patient must have an intact bladder neck and 1 cm of proximal urethral tissue. Unfortunately, this is not usually the case in many females with this issue who may have erosion up to the level of the pubic symphysis. The erosion seen in these patients may be severe enough that the bony undersurface of the pubic symphysis can be directly palpated per the urethra and one or even two fingers can be placed directly into the bladder. Other indications may include failed urethrovaginal fistula repair or severe intrinsic sphincter deficiency that has not responded adequately to prior treatments.

As opposed to the abdominal approach, transvaginal BNC is preferred in patients who have not undergone prior pelvic radiation and will be managed long term with a suprapubic tube (SPT). Prior pelvic radiation may significantly devascularize the vaginal tissue and increase risk of fistulas. If one is planning concomitant lower urinary tract reconstruction, for example, in order to create a continent catheterizable stoma, the abdominal approach is preferred.

Males

Male patients who have failed prior treatments for incontinence or those who develop urethrocutaneous fistulas are candidates for BNC. The typical scenario that leads to BNC in men is the male patient with severe pressure ulcer disease which has involved the urethra, resulting in a large urethral defect within the pressure ulcer that is unable to be repaired. Patients who are not candidates for AUS secondary to hand function or those with severe urethral stricture disease not amenable to repair are also good candidates. BNC concomitantly with salvage prostatectomy and bladder reconstruction after radiation for prostate cancer or for complications secondary to cryotherapy has been described (10,11).

PREOPERATIVE WORKUP

The preoperative evaluation and patient selection are of vital importance to the success of BNC. History of prior pelvic, urethral, and flap surgeries and history of radiation to the pelvis should be elicited. Assessment of the patient's medical comorbidities will help determine how extensive a procedure to pursue. Physical exam should assess a patient's ability to be positioned appropriately in the operating room, as patients with severe contractures may make vaginal access impossible. One should also assess the skin integrity of the perineum.

If the patient has limited hand function, it is important to assess the ability to catheterize if the patient desires a continent cutaneous diversion. If unsure, referral to occupational therapy will help determine if the patient will be able to perform IC. If a patient does not want to IC, decision of an incontinent stoma (conduit versus BNC and ileovesicostomy) versus SPT will often be determined by the patient's comorbidities and preference regarding bladder management.

Patients with chronic indwelling catheters or who are wheelchair-bound are often debilitated and malnourished. It is important to assess preoperative nutrition status because poor nutritional status is associated with poor wound healing, increased rate of infection, higher pulmonary complication rates, prolonged hospitalization, and higher mortality (12).

The bladder should be evaluated with cystoscopy, especially in patients with chronic indwelling catheters, to rule out any malignancy. If considering a continent diversion, it is important to evaluate bladder filling pressures with urodynamics. This often requires placement of a catheter balloon at the bladder neck to prevent leakage at the incompetent outlet, thus allowing the bladder to fill. Fluoroscopy will allow for assessment for any bladder diverticula or vesicoureteral reflux. Patients with elevated storage pressures may require an augmentation cystoplasty along with construction of the continent urinary stoma.

In patients with urethrocutaneous fistulas, it is often helpful to evaluate the urethra with a retrograde urethrogram with or without voiding cystourethrogram to document the extent and location of the fistula.

It is imperative to counsel the patient and the caregiver preoperatively about the options and risks of surgery. A transvaginal approach is certainly less morbid; however, it is associated with higher postoperative fistula rates than the abdominal approach (13–18). The potential need for subsequent procedures must be discussed to set appropriate expectations. Surgeon experience also must be taken into account because inexperienced pelvic surgeons might find the transvaginal approach technically challenging.

SURGICAL TECHNIQUE

BNC can be performed vaginally in women or transabdominally in both sexes. Regardless of technique, BNC requires adequate mobilization of the bladder neck, multilayer, tension-free closure with nonoverlapping suture lines and consideration of interposition of tissue over the closed bladder. The bladder can be reconstructed to allow for IC or continuous drainage via a stoma or drainage by an SPT. Specifics of lower urinary tract reconstruction will be addressed in other chapters. All patients should have preoperative urine culture to plan appropriate antibiotic coverage to sterilize urine.

Vaginal Approach

The vaginal approach is reserved for women who desire permanent bladder drainage via SPT, thus decreasing morbidity by avoiding an abdominal incision. As discussed previously, the vaginal approach might be difficult for surgeons who lack experience with pelvic surgery. Patients are placed in high dorsal lithotomy position with Trendelenburg, and care taken to pad pressure points to avoid nerve injury. Notably, patients who have been bedbound or are contracted may be difficult to position in lithotomy position, making the vaginal approach more challenging. The patient is prepped vaginally as well as up to the level of the umbilicus for SPT placement. A Lone Star self-retaining retractor is placed as well as a posteriorly weighted vaginal speculum to allow for maximum vaginal exposure. A headlight may be used to allow for better visualization, but it is not always necessary.

If an SPT is not already present, one should be placed before the BNC is performed. The anterior vaginal wall is infiltrated with injectable saline or 60 U per 100 mL solution of vasopressin to aid in the dissection of the vaginal wall from the urethra and bladder. A waterproof marking pen may be used to mark two intended incisions along the anterior vaginal wall: one circumferentially around the urethral meatus and the second as an inverted wide-based anterior vaginal wall flap, beginning from the urethral meatus extending past the bladder neck (Fig. 38.2). The vaginal wall flap allows for better access to the bladder neck dissection, and it will later be advanced over the closed bladder neck. The urethra is sharply dissected laterally over the periurethral fascia to the retropubic space and off of the urethropelvic ligaments, followed by transection of the urethra off of the urethropelvic ligament dorsally to the inferior margin of the pubic symphysis (Fig. 38.3). This allows for complete mobilization of the remaining urethra and bladder neck. The ureteral orifices should be identified so as to avoid injury. One ampule of indigo carmine can be given intravenously to help identify their location. The necrotic urethral tissue is then removed, which may in fact be the entire urethra, thus making bladder neck mobility extremely important. If there is viable urethral tissue, the anterior urethra is divided toward the bladder neck and closed by reapproximating the posterior urethra to the anterior urethra, closing the urethra with two layers of absorbable running suture (Fig. 38.4). The urethra is then rotated in an anterior and cephalad direction and secured to the anterior bladder wall with two layers of absorbable suture (Fig. 38.5). This rotates the suture line anteriorly, toward the retropubic space and underneath the pubic symphysis, minimizing overlying suture lines during closure of the vaginal wall flap. In addition, if possible, the sutures used to close the bladder neck can be secured to the undersurface of the pubic symphysis, further placing the BNC anteriorly, away from the vaginal incision. Mobilization of the closure upward should minimize the risk of postoperative fistula formation.

Flaps or graft placements are generally not necessary in primary repair. In cases where the perivesical tissues may be compromised or in patients with history of prior pelvic radiation, one can consider using a Martius flap for interposition. The fat pad from the labia majora is vascularized by either a branch of the external or internal pudendal artery and tunneled through the vaginal wall and placed over the closed bladder neck (Fig. 38.6).

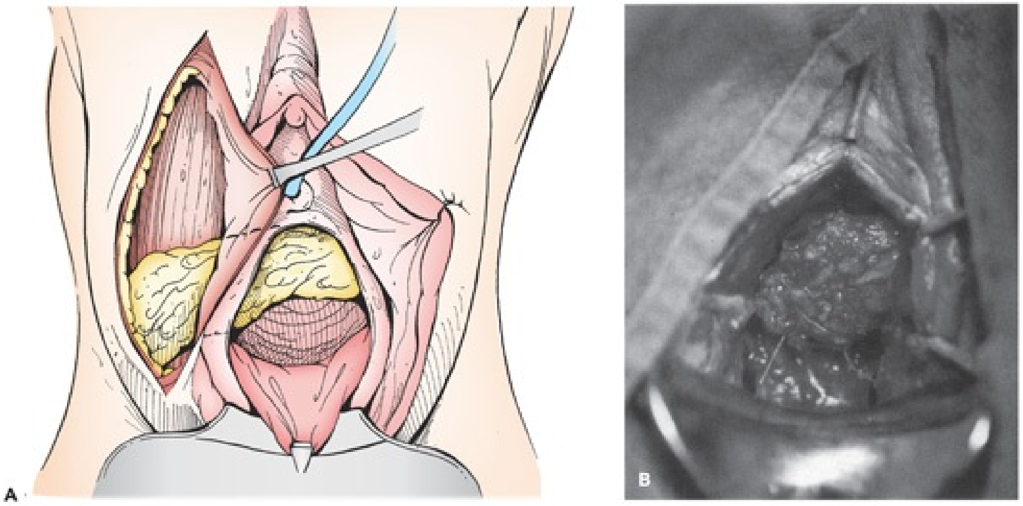

FIGURE 38.6 A: Martius flap tunneled beneath the labia minora. B: Photograph of Martius flap to close over the bladder neck.

The closure is then tested by placing dry sponges in the vagina and filling the bladder with saline colored by indigo carmine to identify any leak. Once confirmed watertight, the vaginal wall flap is closed with absorbable suture and packing is placed (Fig. 38.7). The vagina is packed overnight with antibiotic-soaked gauze.

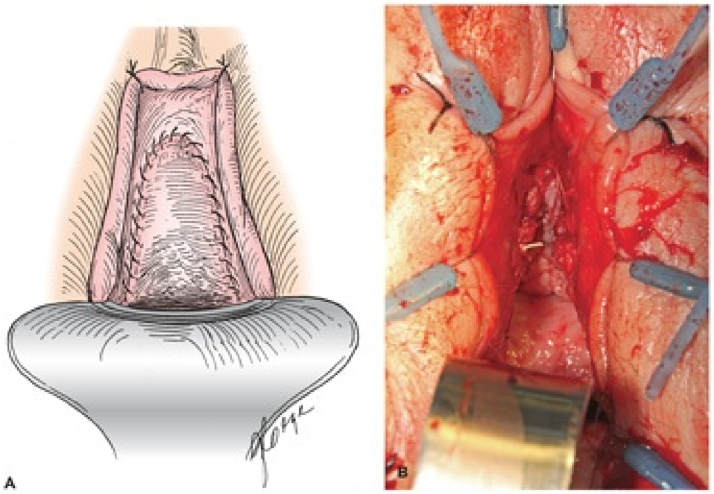

FIGURE 38.7 A: Closure of the vaginal wall flap. B: Photograph of completed vaginal wall closure.

Abdominal Approach (Women)

The abdominal approach in women is considered for patients with a history of prior failed repair, history of pelvic radiation, concomitant bladder reconstruction, or surgeon preference.

The patient is placed in low lithotomy position to allow access to the vagina throughout surgery. For those patients with significant lower extremity contractures, lithotomy position might not be possible. The patient’s entire abdomen is prepped as well as the vagina (if accessible) and an indwelling urethral catheter is placed.

A midline infraumbilical incision is used which may be extended if necessary for access to the peritoneum for bladder reconstruction or harvesting of omentum. A Pfannenstiel incision may be used in patients who plan to manage their bladder with an SPT postoperatively. The rectus muscles are retracted laterally and the space of Retzius is developed using blunt dissection. The peritoneum is retracted superiorly and a self-retaining retractor (either Balfour or Bookwalter) is placed for optimal exposure.

The bladder neck is then identified using the Foley balloon. A figure-of-eight suture is placed at the proximal urethra to ligate the dorsal venous complex. The anterior bladder neck is opened with electrocautery, and the Foley balloon is delivered into the field and secured. Allis clamps or traction sutures are used to secure the bladder neck, with care taken to avoid tearing of the tissue. Once the bladder is opened, the ureteral orifices should be identified and ureteral catheters may be placed (Fig. 38.8). If they are difficult to identify, indigo carmine may be used. The posterior bladder neck is then dissected off of the anterior vagina wall using sharp dissection and electrocautery. The entire bladder neck should be freed to allow for anterior displacement away from the vagina. The unhealthy tissue at the bladder neck is trimmed away and the ureteral catheters are removed. If the patient desires bladder reconstruction, the peritoneum is accessed to harvest bowel. If an SPT is desired, an appropriately sized catheter is brought through the anterior abdominal wall fascia and rectus muscle. The catheter is placed in the dome of the bladder and secured with a purse-string chromic suture. The bladder neck is then closed in two layers with absorbable suture. A watertight BNC is confirmed with irrigation through the SPT.

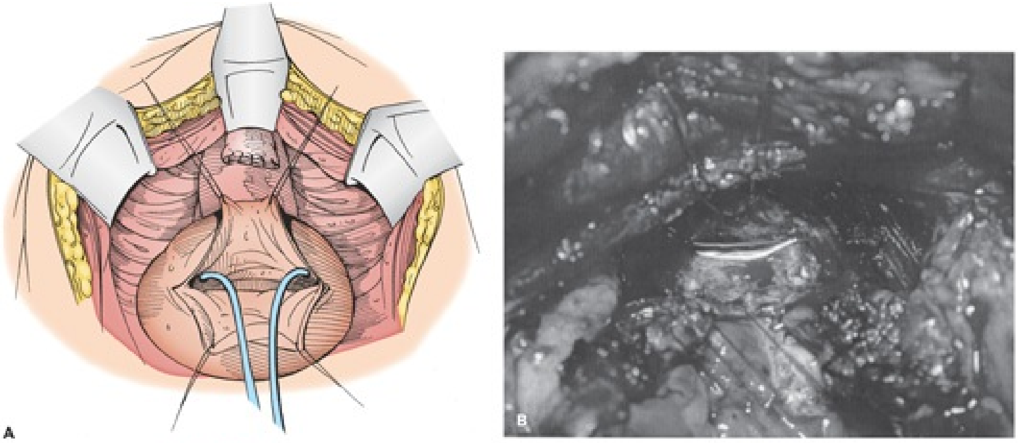

FIGURE 38.8 A: Opened bladder with mobilization of the bladder neck. B: Photograph of divided urethral stump and mobilized open bladder neck.

Peritoneum, omentum, or rectus muscle may be used as an interposition graft to decrease risk of fistula. The omentum can then be brought down and secured in the pelvis between vagina and the closed bladder neck with absorbable suture and peritoneum closed. If the omentum cannot reach the pelvis, it can be mobilized on its pedicle supplied by the left gastroepiploic artery. If omentum is not sufficient, a rectus muscle flap can be harvested with the inferior epigastric vessels as its pedicle. Once collaterals are tied, the flap is rotated downward and secured over the urethral stump. Peritoneum may be used but is not ideal due to its lack of blood supply.

Perineal Approach (Men)

BNC in men is more challenging for multiple reasons, including lack of access to the bladder neck via the perineum due to prostate anatomy and lack of potential interpositional tissue. In the perineal approach, interposition grafts for men would require a gracilis or gluteal flap, carrying higher morbidity and likely expertise of a plastic surgeon. Perineal access to the bladder neck would require a concomitant perineal prostatectomy, which has its own morbidity. Closure of the urethra distal to the prostate is technically easier; however, it has many drawbacks including high rates of fistula formation due to dependent location of closure and prostatic secretions. Distal urethral closure also compromises fertility by causing retrograde ejaculation.

Abdominal Closure (Men)

The biggest advantage to the abdominal approach in men is access to multiple sources for interposition grafts including peritoneum, omentum, and rectus muscle. The most common approach is supraprostatic closure because it is technically easier, preserves ejaculatory function, and allows for better bladder neck mobilization than an infraprostatic approach.

Patients are placed in the supine or low lithotomy position. The abdomen and genitalia are prepped in the field with a Foley catheter placed and accessible on the surgical field. Similar to females, an infraumbilical midline incision is used and can be extended superiorly if desired for bladder reconstruction. The rectus muscle is split in the midline and the space of Retzius is bluntly dissected. For patients undergoing salvage prostatectomy, this portion of the procedure is completed often with a wider excision of the prostate, as there is no urethrovesical anastomosis. This portion of the procedure is detailed in another chapter.

If the prostate is spared, the bladder neck is identified and the superficial dorsal venous complex is ligated with absorbable suture at the prostatovesical junction. Electrocautery is then used to incise the anterior bladder at the level of the prostate. The bladder is entered and Foley catheter is delivered into the field and secured. Again, the ureteral orifices are identified and catheterized. Allis clamps or traction sutures are used to secure the bladder neck. The posterior bladder neck is scored and transected with electrocautery and sharply dissected until the rectovesical space is identified. The posterior bladder neck is then completely mobilized off of Denonvilliers fascia until the bladder neck can be rotated anteriorly away from the urethra. If desired, the bladder can be reconstructed at this time or an SPT is placed in similar fashion to females as described earlier.

If the bladder neck is relatively small, two purse-string sutures may be used to invert the bladder mucosa. More often with larger bladder necks, closure is performed in two layers. Closure is again confirmed by filling the bladder via the SPT. An interposition graft with peritoneum, omentum, or rectus muscle is then placed at the urethral stump to prevent fistulas (Fig. 38.9). A drain is left in the pelvis away from the bladder neck and brought out through a lower abdominal stab incision.

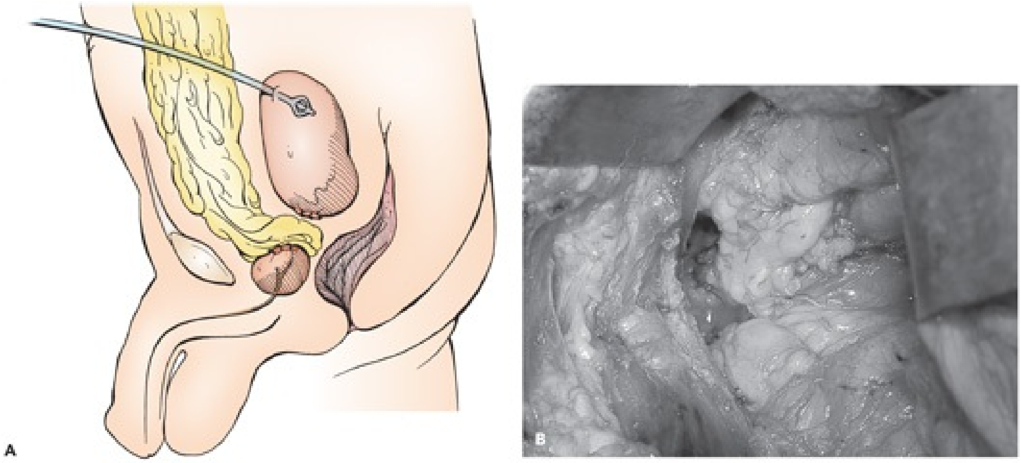

FIGURE 38.9 A: Omental interposition in the man. B: Photograph showing omental wrap over BNC to prevent secondary vesicourethral fistula.

POSTOPERATIVE CARE

Appropriate postoperative management is critical to success of abdominal or transvaginal closure of the bladder neck. Postoperative antibiotics are given for 24 hours. If the patient has bacterial colonization, consider a longer postoperative antibiotic course based on preoperative urine culture. Long-term prophylaxis if often used but not required. The bladder should be continuously draining with regular irrigation via the SPT and securing the SPT to the patient with avoidance of catheter plugging and kinking (13).

Equally important to adequate catheter drainage is management of detrusor overactivity. Although an SPT should allow for continuous bladder drainage, physiologically an open bladder neck may prompt a reflex bladder contraction (19). Higher pressures in the bladder put stress on the suture line, thus potentially increasing the risk of postoperative fistula formation. Administration of anticholinergics will potentially decrease this risk and should be used postoperatively (or continued if patient is already on them) (16). The use of onabotulinumtoxinA at the time of BNC has not yet been studied but presumably would allow for lower bladder pressures and further minimization of postoperative fistula formation.

A cystogram is performed approximately 3 weeks postoperatively to evaluate for fistulas. If the patient underwent bladder reconstruction and has a negative cystogram, the SPT can be removed. Patients with chronic SPT drainage should have their catheter changed every 4 to 6 weeks.

OUTCOMES

Results of series of BNC are difficult to compare because most studies are small and retrospective in nature with variable follow-up (9.6 to 78.6 months) and variable techniques (18,20). Fistula rates for transvaginal BNC range from 0% to 100% (13–15,20–23). Notably, the study with 100% fistula rate looked at only two patients who underwent transvaginal BNC (13). The largest study to look at the transvaginal approach initially included 50 patients, but at an average of 6.5 years follow-up, data was only available for 19 patients. These 19 patients had a fistula rate of 22% after primary repair, which decreased to 8% after revision (22). Overall, fistula rates drop to 0% to 25% after revision (14,20,22). Abdominal BNC fistula rates are notably lower with both primary repair (0% to 18%) and after revision (0% to 6%) (13,14,16–18).

Complications

Fistula formation is the primary complication of BNC and can occur immediately postoperatively or for up to 1 year. Fistulas are diagnosed by cystogram radiographically or by visualization of fluid emanating from the vaginal or perineal closure. Confirmation of a fistula can be done by instillation of indigo carmine mixed with contrast through the SPT to confirm the fistula radiographically and by direct inspection.

Conservative management with continued drainage for several weeks with frequent catheter irrigations and/or placement of bilateral percutaneous nephrostomy tubes may lead to fistula resolution (16). If a patient has a leak on cystogram with bladder filling but is clinically dry with SPT drainage as their primary mode of lower urinary tract management, these patients can usually be managed with regular SPT changes monthly and do not require further intervention unless the fistula progresses and becomes clinically relevant. For a mature fistula tract, repeat surgery may be considered. The choice of transvaginal versus transabdominal versus combined approach is at the discretion of the surgeon. If the repair is not salvageable, more invasive measures for urinary diversion may be considered including cystectomy with continent or incontinent diversion.

Other long-term complications after BNC include bladder stones, leakage from SPT site, SPT dislodgement requiring replacement, fistulas, and decrease in bladder compliance and increased risk of bladder cancer if bladder management is maintained with chronic catheter drainage.

CHAPTER 39 ANTERIOR URETHRAL STRICTURE DISEASE

HUNTER WESSELLS

Urethral strictures have plagued men since antiquity, with descriptions in Indian literature dating as far back as 1000 BC. (1). The presentation of urethral stricture disease differs based on geographical, population, patient, and environmental factors, including prevalence of sexually transmitted infections, occupation of the workforce, and sophistication of health care systems (2). Despite etiologic variation, strategies to care for men with anterior urethral strictures depend less on pathophysiologic mechanism and more on accurate determination of the anatomic characteristics of the stricture including its location, length, luminal diameter, and previous treatment. The concept of a reconstructive ladder, in which progressively more invasive interventions are applied one after the other (3), has been supplanted by an individualized approach in which the best treatment for the stricture is delivered based on anatomic characteristics and probability of recurrence after treatment. Urethral stricture remains the province of surgeons, although innovations in stent technology and regenerative medicine (4,5) may one day allow treatment by minimally invasive proceduralists. Until that time, the care of patients with stricture disease requires a comprehensive and technically complex series of strategies to address the problems of poor tissue vascularization, prior irradiation, and spongiofibrosis; comorbid medical conditions; deficiencies in genital skin; and the unfortunate effects of repeated dilations or urethrotomies applied when success is unlikely (3).

This chapter summarizes the author's approach to the evaluation and treatment of anterior urethral stricture disease, with a focus on management across a spectrum of stricture complexity. The reader is encouraged to review the in-depth treatment of the subject in the International Consultation on Urethral Strictures (6) convened and published under the joint sponsorship of the Societe Internationale d'Urologie and the International Consultation on Urological Disease.

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Anterior urethral strictures are uncommon, accounting for approximately $200 million in direct medical costs per year (2). The average use rate for outpatient visits for stricture disease was approximately 274 visits per 100,000 U.S. population (range 200 to 1,200). Rate of utilization varies by healthcare context, age, ethnicity and other factors: reports among Veterans, Medicare beneficiaries, and the younger commercially insured population differ considerably (2,7,8). Although uncommon, treatment is costly, with strictures being responsible for incremental cost of treatment equaling $6,759 per patient. Additional economic impact of stricture disease derives from the fact that 25% of patients will miss work because of treatment (2).

The etiology of contemporary urethral stricture disease can largely be divided into traumatic, iatrogenic, inflammatory, and idiopathic (9). Pathophysiology will vary by age. Younger men will be more likely to have anterior urethral strictures due to straddle injury or complications from hypospadias surgery, whereas older patients will more likely suffer as a result of prior transurethral instrumentation. Of note, treatment for gonococcal urethritis with penicillin-based antimicrobial agents has effectively eradicated the complex debilitating bulbar urethral strictures previously associated with this disease. However, the emergence of multiply resistant strains of *Neisseria gonorrhoeae* may lead to resurgence in these cases worldwide. Lichen sclerosis (also known as balanitis xerotica obliterans) represents a particularly challenging cause of stricture disease with involvement of genital skin, progression to panurethral disease, and association with comorbidities such as obesity, which complicate treatment and surgery (10).

EVALUATION OF URETHRAL STRICTURE DISEASE

A careful history and physical examination allow the urologist to develop a reasonable understanding of the cause and possible complicating factors of an anterior urethral stricture. Urinary symptoms are the most common cause for presentation, with a reduction in the force of the urinary stream being characteristic. Both obstructive and irritative voiding occurs as a result of stricture disease, and thus questionnaires such as the American Urological Association (AUA) Symptom Index (11), which document these symptoms, have been used in characterizing and quantifying the severity of symptoms. However, these patient-reported outcome measures were not developed to identify the most relevant symptoms in men with stricture disease and do not necessarily address other domains of importance such as penile curvature, ejaculatory dysfunction, urinary incontinence, bother and impact, or responsiveness to treatment. Development of new instruments is an important need for the field (12,13).

Elements of the past history relevant to the cause of stricture and success of urethroplasty include presence of comorbid conditions such as obesity, diabetes mellitus, or severe peripheral vascular disease. A detailed surgical history is essential because of the potential for a stricture to develop as a result of endoscopic surgical manipulation such as transurethral resection of the prostate (14); abdominal perineal resection; and obvious etiologies such as previous urethroplasty, previous hypospadias surgery, or traumatic injuries to the penis or urethra. The personal and social history should be probed for evidence of cigarette smoking, which may significantly impair wound healing (15); long-distance bicycle riding or other sports leading to straddle injury; and risk factors for sexually transmitted infections. A complete review of systems is necessary to identify potentially significant conditions requiring assessment prior to surgery and anesthesia.

The physical examination focuses on the abdominal and genital region. Examination should assess potential bladder distention, presence of previous suprapubic cystostomy, hernia, and other abdominal scars. The phallus should be examined to determine whether the patient has been circumcised, or whether there is sufficient redundant shaft skin to allow creation of a penile skin flap, either circumferentially, based on the distal shaft skin, or longitudinally, based on a ventral skin island. The urethral meatus should be examined for stenosis and the surrounding skin of the glans for signs of lichen sclerosis. A shiny pallor of the glans and/or prepuce is characteristic. The corpus spongiosum should be palpated along its length to identify areas of intense stricture, abscess, or constriction. The scrotum and its contents should be examined. Hair distribution on both the penile shaft and the scrotum should be recorded when skin flaps are considered. Although scrotal skin flaps are no longer commonly used for urethral reconstruction, laser hair removal or other forms of epilation allow scrotal skin to be used in selected circumstances. Perineal and rectal examinations complete the pertinent regions of interest.

Laboratory studies are used selectively to identify associated urologic conditions including urinary tract infection and renal insufficiency. A urinalysis with microscopic evaluation will detect hematuria, pyuria, and bacteriuria. Because urethral strictures frequently cause microscopic hematuria, complete workup is not generally pursued unless persistent. Serum creatinine is not indicated unless signs of poor bladder emptying suggest a risk for renal deterioration.

Noninvasive urodynamic studies are a valuable adjunct to the assessment of urinary symptoms. Uroflowmetry provides a quantitative estimate of the degree of obstruction, which along with postvoid residual urine volume provides a gauge of the severity of urethral narrowing and efficiency of voiding. More formal pressure flow urodynamic studies are only indicated for the evaluation of complex cases. When concomitant prostatic obstruction and urethral narrowing are found, video urodynamics may successfully distinguish the anatomic point of obstruction.

Radiographic Studies

Contrast studies of the urethra are the cornerstone of appropriate and individualized management. The combination of retrograde urethrogram and voiding cystourethrogram allows appropriate delineation of the anterior urethra, accurate assessment of the length of the stricture and narrowing of the urethra, as well as the dynamic understanding of urethral caliber and function above the point of obstruction. Techniques for retrograde and voiding urethrography are beyond the scope of this chapter (16). However, several points require elaboration. A retrograde urethrogram is performed by positioning the patient obliquely at 45 degrees with the bottom leg flexed at the knee and the top leg kept straight. A 12Fr Foley catheter, Brodney clamp, or catheter-tipped syringe is introduced into the fossa navicularis, the penis is placed on gentle traction and 20 mL undiluted water soluble contrast material is injected. Retrograde urethrogram can underestimate the length of bulbar urethral strictures, potentially due to inadequate rotation or stretch of the penis (Fig. 39.1). The penis must be adequately stretched so that the pendulous portion of the penile urethra and the penoscrotal junction are appropriately visualized (Fig. 39.2). Voiding cystourethrography requires that the bladder be filled by retrograde instillation of contrast (Fig. 39.3), which may be challenging if the stricture is very stenotic or the external sphincter is tightly contracted.

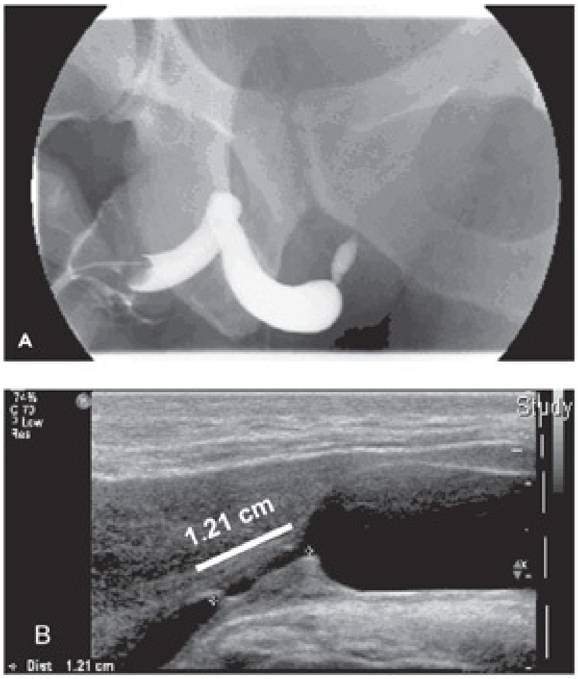

FIGURE 39.1 A: Retrograde urethrogram showing apparently short bulbar stricture. B: Intraoperative sonourethrogram showing corresponding length and narrowness of stricture demonstrating a 1.21-cm long stricture.

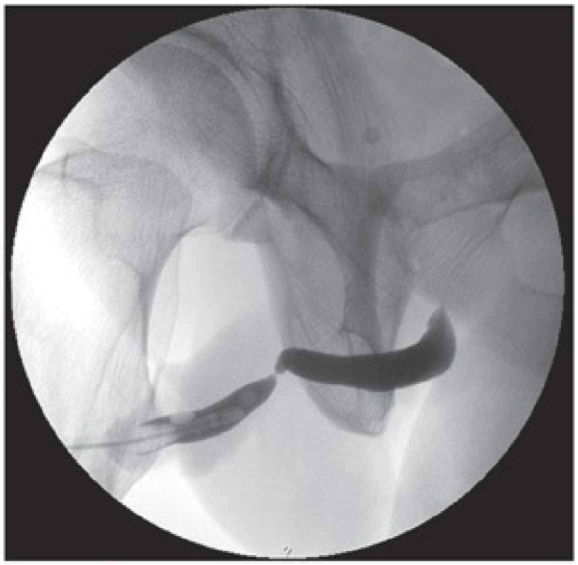

FIGURE 39.2 Retrograde urethrogram showing short stricture of penile urethra well visualized because of adequate rotation and stretch of urethra.

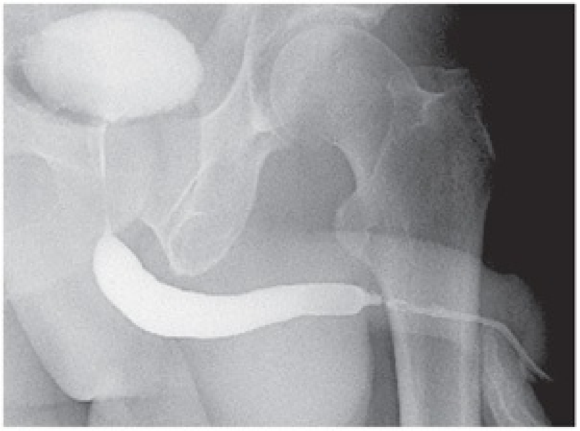

FIGURE 39.3 VCUG showing long penile urethral stricture. Note prostatic urethra narrowed because of concomitant benign prostatic hyperplasia.

Ultrasonography represents an adjunct to fluoroscopic modalities to assess anterior urethral strictures (17). Usually performed intraoperatively, the technique can clarify stricture length when upstream imaging is not possible on voiding cystourethrogram (VCUG), or when rotation of the patient impedes accurate measurement of the length of the stricture (see Fig. 39.1B). Additionally, estimation of the inner diameter of the urethral lumen can aid in deciding whether to perform excision and anastomosis of a portion of a longer stricture as part of augmented anastomotic urethroplasty (*vide infra*).

Endoscopic Studies

Cystoscopic evaluation of urethral stricture disease has a limited role in the diagnostic protocol. It serves an important initial evaluation of men with suspected urethral stricture disease, identifying the distalmost portion of the stricture. However, it cannot determine the length of the stricture nor assess the urethra proximal to the stricture. Further endoscopic evaluation is best reserved for several scenarios. An example is a stricture that cannot be fully visualized due to lack of retrograde filling of the urethra by obliteration or sphincteric spasm during the study. Specialized endoscopes such as a pediatric cystoscope or 8Fr ureteroscope can be used to examine strictures under these circumstances. Another indication is a rare case in which physical examination or other factors raise the suspicion of urethral cancer.

RECONSTRUCTIVE PRINCIPLES

Urethral reconstructive surgeons need to maintain an array of skills to allow transition from simple to more complex reconstructive strategies during the course of a surgical case. An apparently simple stricture will occasionally require more complex care than anticipated prior to surgery. For example, preoperative imaging of a bulbar stricture may underestimate its length, so that an initial anastomotic approach must be supplanted by free graft substitution urethroplasty, based on intraoperative findings, patient anatomy, and other factors. Similarly, a straightforward 3- or 4-cm bulbar urethral stricture, normally treated with ventral or dorsal onlay substitution urethroplasty, may in fact require staged approaches or additional grafts or skin flaps. Thus, it is only appropriate to embark on urethroplasty if one can offer the patient all necessary options and bring all appropriate techniques to the surgical procedure.

The key techniques include endoscopic incision; anastomotic techniques; dorsal and ventral substitution; free graft donor options including full thickness and split thickness skin, oral mucosa, and bladder epithelium; skin flap urethroplasty from penile or scrotal skin; local tissue rearrangement in the form of advancement flaps (YV-plasty, Z-plasty); and flaps for defect coverage such as gracilis muscle or smaller flaps such as dartos and tunica vaginalis.

Internal Urethrotomy

Internal urethrotomy is an important technique for the reconstructive urologist, based on the principle of healing by secondary intention described by Davis for ureteral strictures (18). Sachse (19) applied the concept to urethrotomy, using a cold knife to precisely incise the urethral epithelium under direct vision. Although few strictures are cured with direct vision internal urethrotomy (DVIU), recurrent strictures after urethroplasty can often be effectively treated by DVIU. In cases involving a prior flap or graft, or prior hypospadias surgery, techniques have been modified to create multiple shallower radial incisions (20).

Anastomotic Techniques

Excision and reanastomosis is an essential tool for anterior and posterior urethral reconstruction. Knowledge of the anatomy of the corpus spongiosum (Fig. 39.4) is essential to safely take advantage of the antegrade and retrograde blood supply provided by the bulbourethral and dorsal arteries, respectively (21). The ability to mobilize the urethra, excise portions of it, and reapproximate underlies successful primary anastomosis as well as a variety of augmented approaches (22) in which excision of a portion of the stricture, and reanastomosis, is combined with tissue transfer using a graft or flap (23). In addition to preservation of the longitudinal intrinsic blood supply of the corpus spongiosum, anastomotic urethroplasty requires assessment of the appropriate degree of tension that may be placed on the anastomosis. A rule of thumb in the bulbar urethra is that strictures 1 to 2 cm in length can be bridged with excision and primary anastomosis (EPA). This assumes that the remaining urethra is normal, compliant, and able to undergo elongation to bridge a gap. In cases of proximal bulbar strictures, the uninvolved urethra, if completely normal, may be capable of significant elongation beyond 2 cm (24). The ability to reduce the gap between the ends of the urethra is dictated in part by the location of the gap. In the more proximal bulbar urethra, division of the corporal bodies is a maneuver to reduce the distance between the two ends for tension-free anastomotic urethroplasty. With longer strictures associated with spongiofibrosis of significant portions of the urethra, the behavior of the remaining urethra under stretch may be different. It may not be possible to bridge a 2-cm defect. Thus, augmented anastomotic approaches typically involve excision of shorter portions of the urethra. Likewise, in the penile urethra, the elasticity of the urethra is significantly less, and only short defects can be bridged with EPA.

Free Grafts

Free grafts have been used for reconstruction of complex anterior urethral strictures since the 1960s (25). Full-thickness skin grafts from the prepuce or penile shaft fare well in substitution urethroplasty, although early indications for severe complex strictures exceeded the limits of the technique. The evolution of stricture etiology away from gonococcal infection, with its severe spongiofibrosis, to less complex strictures supports the greater use of free grafts. No prospective study has definitively shown inferiority of full-thickness genital skin to oral mucosa, although a recent meta-analysis found higher odds of recurrence with penile skin (26). Nevertheless, the ease of harvesting, suppleness of the oral tissues, intrinsic acceptance of the moist environment, lesser donor site morbidity, and other factors accelerated the adoption of buccal mucosa as the preferred free graft for substitution urethroplasty. Use of bladder epithelium and full-thickness skin should be considered for specific cases in which pathology of the oral mucosa, paucity of donor sites within the oral cavity, or other factors make oral mucosa unavailable. With any free graft, donor site morbidity and characteristics of the graft must be taken into account in a surgical plan. For example, defatting a full-thickness skin graft is straightforward: Shiny undersurface of the dermis allows for simple and rapid defatting. In contrast, the buccal mucosa harvesting as reported in the literature invites greater variation in technique, for example, relating to the depth of defatting that occurs (27). Such factors may affect outcomes of graft take. Lastly, bladder mucosa has a very thin lamina propria and is extremely pliant, making it unsuitable for meatal reconstruction or staged procedures with exteriorization of the neourethra. Full-thickness skin from the genitalia is relatively thin yet nevertheless does not suffer from substantial contraction. In contrast, split-thickness skin grafts will contract more significantly, limiting their application in all but the most severe and complex reconstructive scenarios.

Skin Flaps

Vascularized skin flaps, once a workhorse of anterior urethroplasty, have become less prevalent due to the increased adoption of buccal mucosa free graft urethroplasty, rise in prevalence of strictures related lichen sclerosis, and lack of sufficient genital skin in many circumcised men. Nevertheless, the island skin-flap approach to urethroplasty remains important, particularly in reoperative cases with extensive spongiofibrosis and poor graft fed characteristics (Fig. 39.5), such as postirradiation, posttraumatic, or postinfectious scenarios (28). Whether a circumferential distal penile flap (e.g., circular fasciocutaneous flap) or a longitudinal ventral flap, the principles are similar. A paddle of skin, which will not contract, is marked out on stretch, so that the exact dimensions of the flap are cut and used during the surgery. Preservation of the pedicle and its blood supply is based on the tunica dartos, either through random vascularity or a specific pedicle. Adequate mobilization of the pedicle is required to transfer the tissue into the appropriate recipient site, whereas preservation of the intrinsic blood supply of the overlying shaft skin prevents necrosis or complications of the donor site. Circular distal flaps (29), whether harvested from the prepuce (uncircumcised) or the distal shaft skin (circumcised), allow up to 15 cm length of skin to be transferred and create a pedicle which can reach all the way into the perineum for the very most proximal bulbar, membranous, and prostatic strictures.

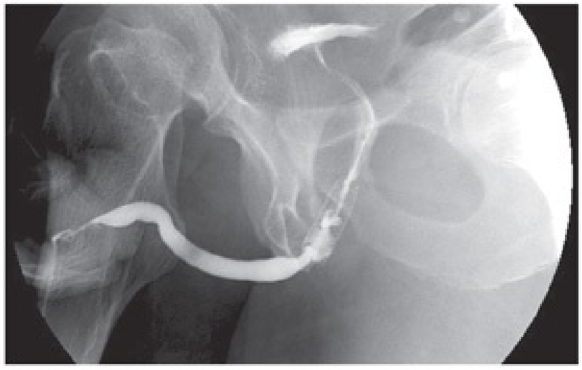

FIGURE 39.5 Retrograde urethrogram showing severe stricture within metallic stent in the proximal bulbar urethra of a previously radiated patient. The stricture was treated with stent removal and skin flap urethroplasty.

Flaps for Coverage

In cases of primary urethroplasty, adjacent tissue such as the tunica dartos or bulbospongiosus muscle can provide for graft vascularization and protection against urethrocutaneous fistulization. However, with reoperative surgery, staged surgery, or other cases in which the graft bed is compromised, the urethra lacks coverage options locally. Due to space constraints on the penile shaft, less bulky coverage flaps such as tunica dartos or tunica vaginalis are required. A potential obstacle to the use of dartos is previous hypospadias surgery. The rearrangement of skin and underlying dartos presents particular technical challenges to mobilization, although these can be successfully navigated (29). For such patients, rearrangement of the tunica vaginalis of the scrotum to bring it up alongside the penile urethra may be the best option (30). In contrast, the perineum can accommodate placement of a gracilis muscle flap in cases of extreme tissue deficit or postradiation cavities.

PREOPERATIVE AND INTRAOPERATIVE DECISION

MAKING

Patient and stricture characteristics dictate the surgical approach necessary to achieve the desired outcome for an individual patient. Except in cases of strictures complicated by urinary retention and/or urethral obliteration, the decision to proceed with urethroplasty versus another approach to a specific urethral stricture is heavily driven by patient expectations and goals. In young men, one may recommend definitive procedures to achieve complete resolution of urinary symptoms, whereas in elderly or debilitated patients, strictures are more likely to be managed in an expectant or “custodial” manner. In all cases, the individual patient goals and circumstances will necessarily be considered.

A brief algorithm for the treatment for urethra strictures is shown in Figure 39.6. For a first-time bulbar stricture less than 1 cm in length, a cost-effectiveness perspective indicates that a single attempt at DVIU is usually recommended prior to urethroplasty (31). The success rates for dilation or internal urethrotomy for short bulbar strictures ranges from 30% to 80% (see summary in Wright et al. [31]) and our approach is, under most circumstances, to proceed with DVIU. Exceptions include individuals in whom a prior straddle injury, and its associated full-thickness spongiosal fibrosis, makes the probability of success with DVIU much lower (Fig. 39.7).

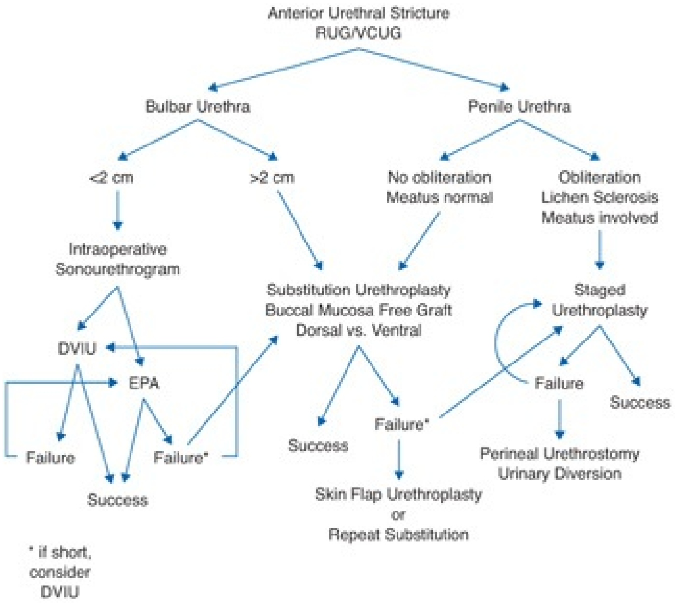

FIGURE 39.6 Algorithm for the management of anterior urethral stricture. *DVIU*, direct vision internal urethrotomy; *EPA*, excision and primary anastomosis; RUG, retrograde urethrogram; *VCUG*, voiding cystourethrogram.

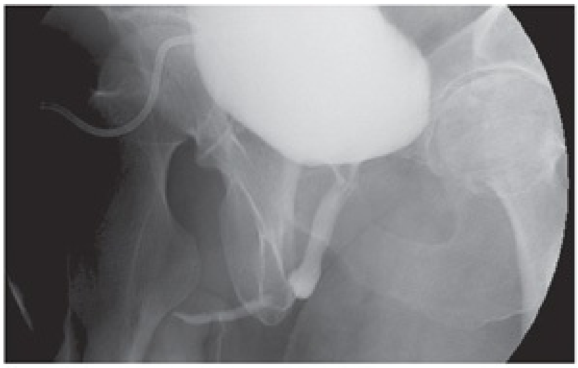

FIGURE 39.7 Short very narrow stricture after straddle injury not suitable for DVIU.

Bulbar urethral strictures between 1 and 2 cm in length are optimally treated with EPA, yielding success rates >95% (31). DVIU for a 2-cm bulbar stricture is very unlikely to yield a successful outcome and theoretically can change the stricture from one amenable to EPA, with overwhelmingly successful outcomes, to a longer stricture requiring substitution. Thus, these individuals should proceed to urethroplasty except under exceptional circumstances. A variety of centers have advocated for alternative surgical approaches to these short strictures, such as “nontransecting bulbar urethroplasty” based on the rationale that the odds of erectile dysfunction after EPA is higher than after substitution urethroplasty (32,33). These reports, however, do not contain sufficient evidence to counterbalance the success of EPA and the generally accepted low rate of erectile dysfunction after urethroplasty, which was 1% in a recent meta-analysis (34).

Strictures greater than 2 cm in length in the bulbar urethra, and any substantial length in the more distal urethra (e.g., Fig. 39.2), require substitution urethroplasty. This generally will be a buccal mucosa free graft using either a ventral or dorsal onlay, although a skin flap (Fig. 39.8) will provide comparable outcomes in the absence of lichen sclerosis or other processes affecting the genital skin (23,35).

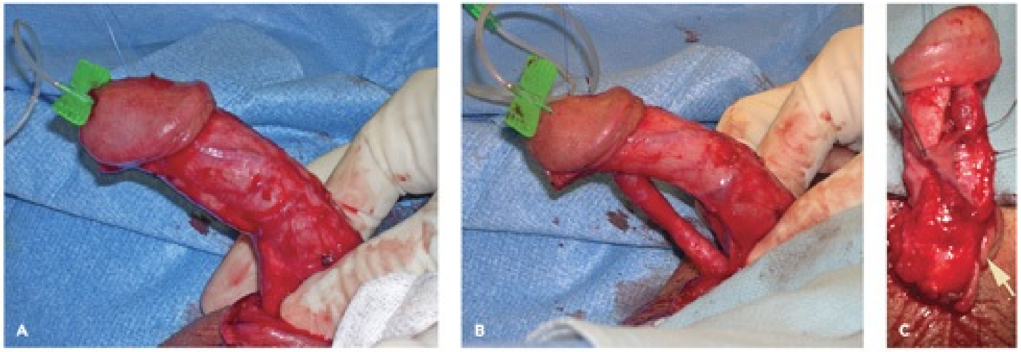

FIGURE 39.8. **A and B:** Penile urethral stricture due to instrumentation (same as Fig. 39.2) causing chordee treated in this case with skin flap urethroplasty (and penile plication for curvature). **C:** *Arrow* shows pedicle of flap rotating around base of penis. Dorsal onlay substitution with free graft could also be considered.

An important exception to these general recommendations is when a segment of a longer urethral stricture is obliterated or nearly completely obliterated (Fig. 39.9). Excision of the most severe portion of the stricture, with ventral or dorsal reanastomosis and free graft reconstruction (augmented anastomotic urethroplasty [22]) offers an effective solution while avoiding excessive urethral removal with its resultant chordee and shortening.

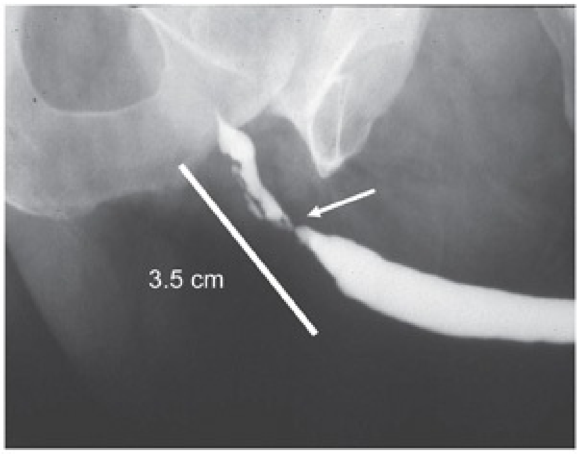

FIGURE 39.9 Dense proximal bulbar stricture with short nearly obliterated segment (*arrow*). The length exceeds that for EPA and thus substitution urethroplasty will be necessary.

Finally, with very long segments of urethral narrowing or obliteration, staged procedures are required. These techniques have been developed in response to the poor outcomes with tubularized free grafts, in which the graft bed fails to vascularize the tubularized tissue transfer (36). In these cases, placement of the free graft directly on a flat vascularized surface, such as the tunica albuginea of the corpora cavernosa, tunica dartos, or tunica vaginalis allows effective, stable bed engraftment and staged tubularization once new collateral vascularity has formed.

GENERAL CONSIDERATIONS IN URETHRAL RECONSTRUCTION

Patient Positioning

The majority of patients undergoing bulbar urethroplasty require placement of the lower extremities in the lithotomy position. Because of the rare but serious risk of neurapraxia and compartmental syndrome (37,38), an experienced member of the surgical team should supervise and approve final lithotomy positioning. Rarely is the exaggerated position required for anterior urethral strictures. Stirrups that provide rotational and longitudinal adjustments in addition to padding are preferred to minimize pressure against the lateral calf in the region of the peroneal nerve and ensure sufficient extension of the knee joint. Factors proposed to influence risk include use of Trendelenburg, knee position, external compression for deep vein thrombosis prophylaxis, method of leg support, duration of surgery, and other measures including age and body mass index (39).

Antibiotic Prophylaxis

The colonization of the urethra by bacteria classifies urethral surgery as clean contaminated and thus at risk for surgical site infection, urinary tract infection, and generalized sepsis. Thus, all instrumentation of strictures, whether endoscopic or open, requires antibiotic prophylaxis. According to AUA Guidelines, DVIU and dilation are appropriately covered by a quinolone antibiotic (40). For open urethroplasty, a first-generation cephalosporin is sufficient. Perioperative antibiotic administration ceases within 24 hours; oral antibiotic administration at time of catheter removal is recommended.

Urethral Sonography

Sonography, as described earlier, may serve as an adjunctive diagnostic test to accurately differentiate between strictures of the bulbar urethra that require DVIU, EPA, or substitution according to the length or diameter of the stricture. After induction of anesthesia, sterile saline is injected at the meatus using a Toomey syringe and concomitant suprapubic pressure is applied to maximize urethral distension. A 7.5- to 12-MHz probe placed on the perineum is then used to image the urethra longitudinally, measuring stricture length and narrowest luminal diameter.

Buccal Mucosal Harvest

We generally harvest a 6 cm × 2 cm segment of oral mucosa from one or both inner cheeks. Briefly, three stay sutures are placed at the lateral aspect of the mouth, and a Jennings mouth gag is used to open the mouth widely. The graft is marked out (Fig. 39.10) taking care to identify and preserve Stensen duct. Bupivacaine with 1:100,000 epinephrine is injected below the submucosa as a form of hydrodissection. The graft edges are then sharply incised with a scalpel and the graft is dissected off of the buccinator muscle with scissors. Bleeding points are cauterized and epinephrine-soaked gauze is packed into the defect. We do not close the defect because evidence suggests less pain and morbidity occurs (41). Graft take depends on imbibition of nutrients for 24 to 48 hours until inosculation occurs. Thus, fat and muscle are removed from the graft as shown in Figure 39.11. When additional oral mucosa is required, harvesting from the undersurface of the tongue (42) is preferred to the lip, the latter being associated with increased morbidity of the donor site in our hands (e.g., deformation of lip).

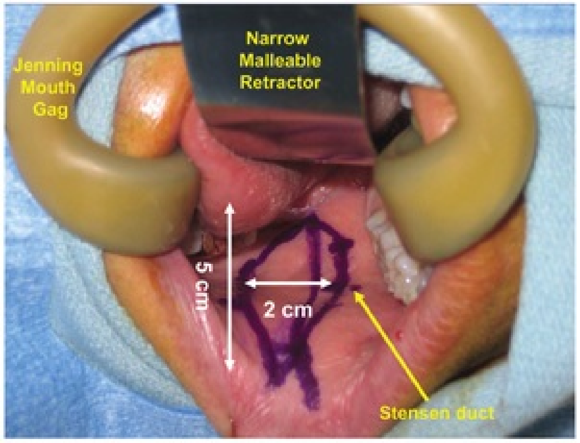

FIGURE 39.10 Buccal mucosa donor site. Note Stensen duct adjacent to second molar tooth (*long arrow*). Width is between 2 and 3 cm depending on type of urethroplasty planned.

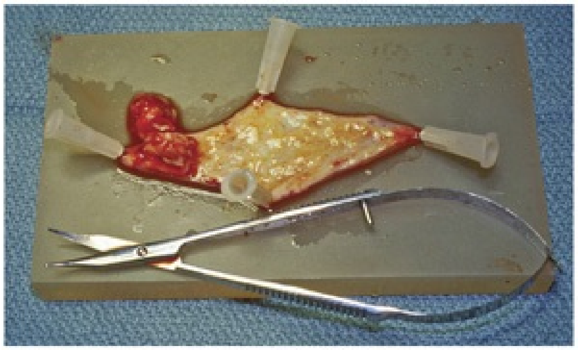

FIGURE 39.11 Defatting a buccal mucosa graft.

Postoperative Care

The vast majority of patients undergoing urethroplasty can be discharged within 24 hours. Routine catheter care and limited physical activity are recommended until the catheter is removed. A VCUG or pericatheter retrograde urethrogram is performed after substitution urethroplasty or if the repair is complex, and if persistent extravasation is noted, the catheter is replaced (VCUG) or kept in place (pericatheter study). Routine imaging is not recommended for DVIU or EPA due to the very low risk of extravasation or complication with early catheter removal (43). A schedule for catheter removal and follow-up care is proposed in Table 39.1. We do not use pharmacologic methods to inhibit erection in the postoperative period but do instruct patients to refrain from sexual activity for 4 to 6 weeks after surgery. Perineal precautions limit pressure on the repair for the first several weeks and prohibit bicycle riding for 3 months.

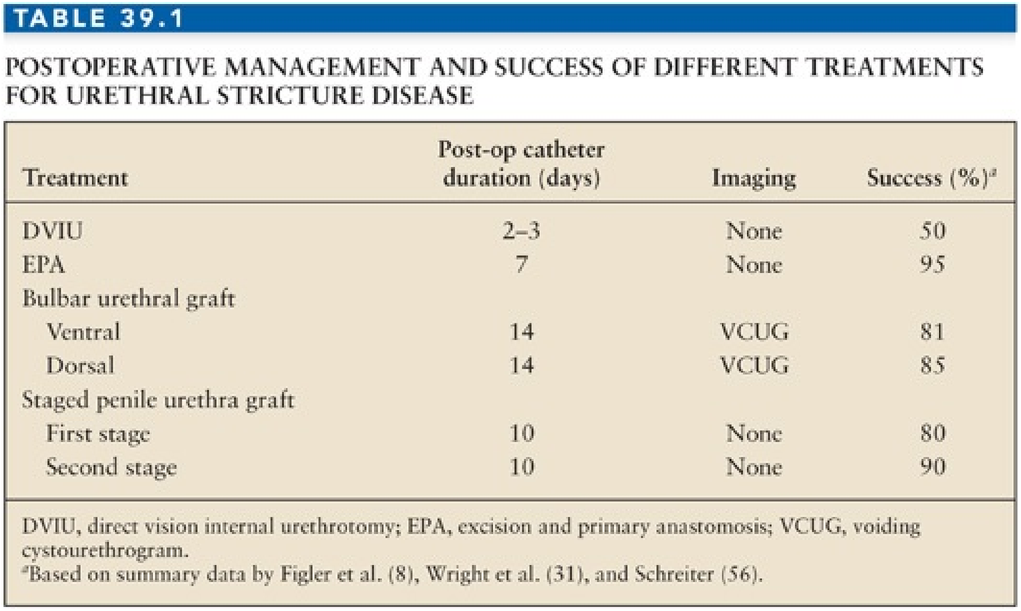

TABLE 39.1

POSTOPERATIVE MANAGEMENT AND SUCCESS OF DIFFERENT TREATMENTS FOR URETHRAL STRICTURE DISEASE

Treatment	Post-op catheter duration (days)	Imaging	Success (%)[a]
DVIU	2–3	None	50
EPA	7	None	95
Bulbar urethral graft			
Ventral	14	VCUG	81
Dorsal	14	VCUG	85
Staged penile urethra graft			
First stage	10	None	80
Second stage	10	None	90

DVIU, direct vision internal urethrotomy; EPA, excision and primary anastomosis; VCUG, voiding cystourethrogram.

[a] Based on summary data by Figler et al. (8), Wright et al. (31), and Schreiter (56).

SURGICAL TECHNIQUES

Direct Vision Internal Urethrotomy

For definitive treatment of a short urethral stricture, incision is made through the full thickness of the stricture into healthy corpus spongiosum to promote healing by secondary intention. The standard approach to DVIU uses the cold knife technique described by Sachse (19). For very tight or long stenoses, wire access can provide guidance for catheter placement. For cases in the penile urethra or where multiple small cuts in a stricture are advisable (see following text), an 8Fr pediatric resectoscope with cold knife urethrotome compares favorably to the diameter of an adult urethrotome sheath (typically 20Fr), mitigating iatrogenic injury. Laser DVIU provides comparable results to cold knife (44) but is not recommended due to the additional cost without benefit (45).

Short-term urethral catheterization is advisable to control venous bleeding, with most studies advising 3 to 10 days of catheterization. We advocate a short period (48 to 72 hours) or until the urine is clear. No benefit has been attributed to longer duration of catheterization. Adjunctive use of intermittent catheterization to enhance the success of DVIU has assessed through small retrospective series and in one negative randomized controlled trial (RCT) (45). Although not shown to reduce stricture recurrence rates, the use of intermittent self catheterization (ISC) is recognized as a means to provide palliative management of a stricture in patients unwilling or unable to undergo urethroplasty (46).

Bulbar Urethra

DVIU for urethral stricture is classically performed at the 12 o’clock position (20). This makes particular sense in the bulbar urethra, to avoid potential injury to the urethral arteries, which are typically located at 3 and 9 o’clock. The incision also avoids the thickest portions of the corpus spongiosum ventrally, thus reducing the likelihood of significant bleeding.

Penile Urethra

Because of the limited spongiosal thickness and higher risk of extravasation, we generally recommend urethral dilation of penile strictures rather than DVIU. Dilation should proceed over a stiff wire to prevent false passage, using either a balloon dilator or other methods of progressive dilation (e.g., Goodwin sounds). Penile urethral strictures after prior hypospadias surgery present a particular challenge because of the absence of spongiosum in many cases. Such tubularized skin urethras are easily disrupted with dilation or DVIU. Reconstruction should be considered for recurrence after such an endoscopic attempt, unless the patient is willing to adopt intermittent self-catheterization as a chronic management strategy.

Post-urethroplasty

After substitution urethroplasty, stricturing typically occurs at the proximal or distal end of the graft. Strictures after EPA will be located at the site of anastomosis. If soft and focal, it has been our preference to make radial incisions that do not extend as deeply into the spongiosum. For such cases, we use a pediatric scope as described previously.

EXCISION AND PRIMARY ANASTOMOSIS

Appropriate stricture length for EPA (Fig. 39.12) can be ascertained with retrograde urethrography and confirmed with ultrasound immediately prior to surgery or by intraoperative measurement. After positioning the patient in the lithotomy position, a midline perineal incision is carried out through skin and Colles fascia. Electrocautery is used to divide fat down to bulbospongiosus muscle, which is split in the midline. After defining the ventral bulb, we identify the location of the stricture by passing a 20Fr catheter to the point of obstruction. We gain circumferential control proximal and distal to the stricture and sharply transect the urethra distal to the stricture. Working proximally, the stricture is excised, exposing healthy proximal spongiosum and a normal urethral lumen. Mobilization of the proximal and distal ends ensures a tension-free anastomosis with adequate vascular inflow. Rarely, previous urethral surgery such as distal hypospadias surgery, or a more proximal anastomotic urethroplasty, may compromise the ability to safely mobilize a segment of the urethra, and indicate the need for a substitution procedure. We spatulate the proximal end dorsally and distal end ventrally for approximately 0.5 cm. The anastomosis is started by securing the back wall in a single layer with five sutures, placing the knots on the inside of the urethra with a 5-0 absorbable monofilament. For the ventral wall closure, we switch to a two-layer closure (47). The first layer consists of a sufficient number of sutures through the mucosa, catching just a bit of the spongiosum. A second layer of sutures closes the tunica of the spongiosum. We close perineum in multiple layers of interrupted 3-0 or 4-0 absorbable sutures. Drains are reserved for persistent diffuse oozing.

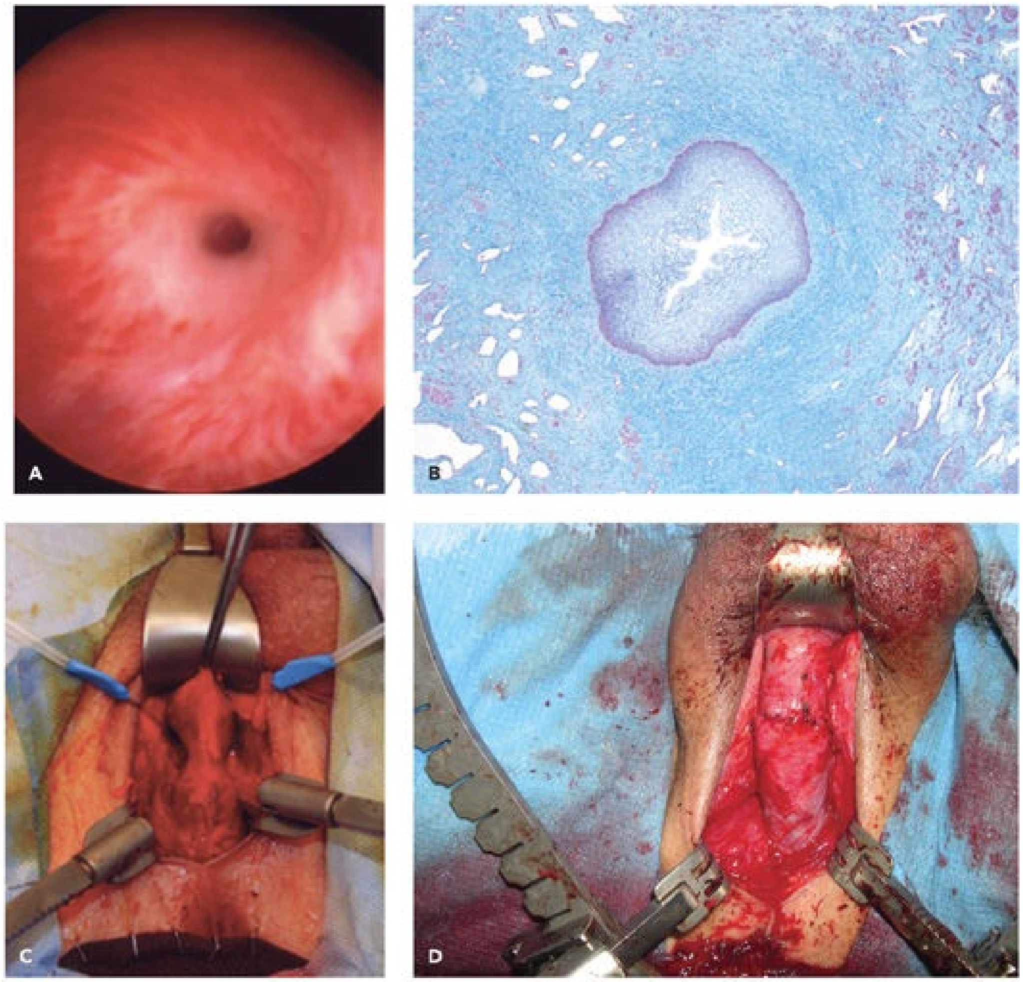

FIGURE 39.12 Short dense stricture treated primarily with EPA. **A:** Endoscopic appearance. **B:** Histologic appearance showing extensive fibrosis (blue color on histology). **C:** Narrowed corpus spongiosum at site of stricture. **D:** Final appearance of corpus spongiosum after anastomosis and closure of tunica.

SUBSTITUTION URETHROPLASTY

A decision must be made regarding the choice of tissue transfer (skin flap versus free graft) and location of onlay, either ventral or dorsal (8,23,35,48). Free graft substitution is favored for most complex bulbar and penile urethral strictures, although selected indications for skin flap urethroplasty remain.

Ventral onlay free graft substitution relies on an adequate ventral corpus spongiosum for its graft bed, which restricts the technique to strictures of the bulbar urethra. In contrast, because dorsally placed grafts rely on the tunica albuginea of the corpora cavernosa for their recipient bed, dorsal onlay can be applied to strictures in the bulbar and penile urethra. One meta-analysis suggested that dorsal onlay provides higher success rates compared to ventral (96% versus 85%), although in our hands, the rates of success were not statistically different (85% versus 81%) (8).

Ventral Onlay Graft

The distal extent of the stricture is identified by gently passing a 20Fr catheter until it meets resistance. Stay sutures of 4-0 are placed through the tunica of the corpus spongiosum parallel to the urethra, at the level of the catheter tip. Using a no. 15 blade, the corpus spongiosum is incised in the ventral midline until the catheter tip and urethral lumen are exposed (Fig. 39.13). The stricture is then incised along its entire length by extending the urethrotomy proximally. Full-thickness stay sutures are placed at close intervals for hemostasis and to aid in later identification of the mucosal edges for anastomosis. Once the entire stricture has been incised, the length and width of the remaining urethral plate are measured. Preservation of the urethral plate allows use of an onlay technique, which has superior outcomes when compared to full circumferential tubularized replacement of the urethra.

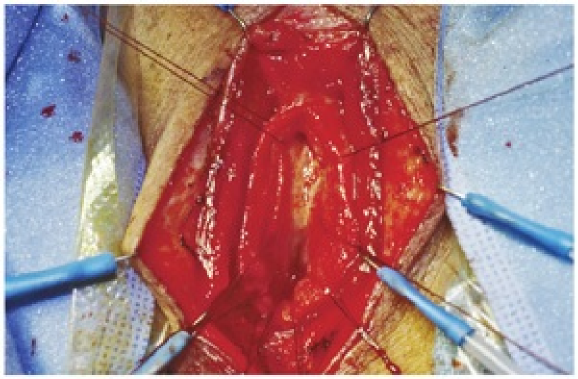

FIGURE 39.13 Ventral urethrotomy in anticipation of ventral onlay substitution urethroplasty.

Proximal and distal calibration of the urethra is critical to identify any residual narrowing. The graft is trimmed to its appropriate size allowing a urethral lumen of 28Fr when possible. Taking into account the modest graft contracture with oral mucosa (15% in one study by Sullivan, 2003 [49]), this usually requires a 2-cm wide graft. One end of the graft is anastomosed to the proximal apex of the urethrotomy with a series of interrupted sutures; 5-0 absorbable monofilament is used to complete a watertight anastomosis along each side of the graft. The proximal lumen is calibrated with bougies to ensure an adequate lumen and a 16Fr urethral catheter is placed prior to closing the distal portion of the urethra. After completion of graft suturing, the corpus spongiosum is closed over the graft with interrupted 4-0 absorbable sutures (Fig. 39.14). If a portion of the stricture is extremely fibrotic or narrow, excision of that portion of the stricture and dorsal reanastomosis should be performed in conjunction with grafting (Figs. 39.15 to 39.18). The bulbospongiosus muscle is reapproximated and Colles fascia and the skin are closed with interrupted absorbable sutures.

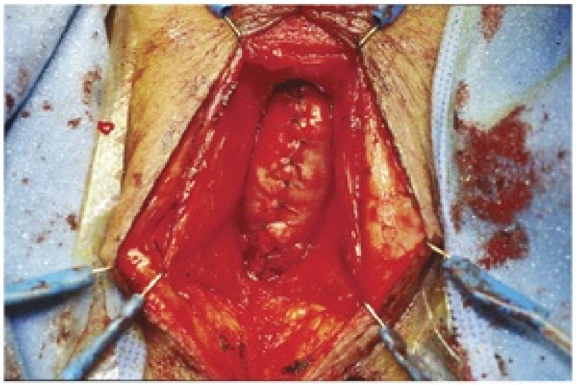

FIGURE 39.14 Completed spongioplasty after ventral onlay free graft.

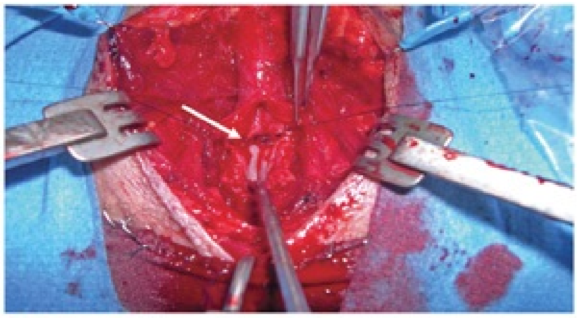

FIGURE 39.17 Reapproximation of dorsal urethral plate (*arrow*) after excision of portion of stricture, the so-called "roof strip anastomosis."

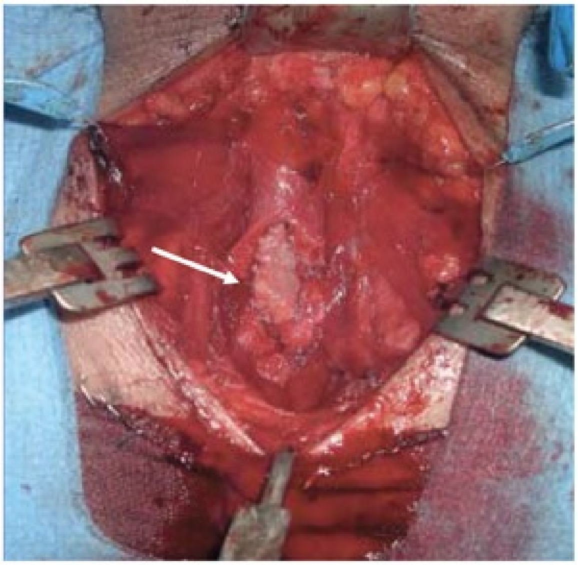

FIGURE 39.18 Ventral placement of buccal mucosa free graft (*arrow*).

Dorsal Onlay Graft

Dorsal graft placement is performed similar to the technique described by Barbagli et al. (50) and Iselin and Webster (51). The urethra is mobilized circumferentially off of the corporal bodies and incised dorsally throughout the length of the stricture into healthy mucosa at each end, which is calibrated to 28Fr. For patients in whom a portion of the stricture is excised (Figs. 39.19 and 39.20), the ventral urethra is reanastomosed with interrupted 5-0 monofilament prior to grafting. Once tailored, the buccal graft is "spread-fixed" to the corpora cavernosa. Approximation of the urethra to the graft along the entire length of the urethrotomy is performed with 5-0 absorbable monofilament sutures.

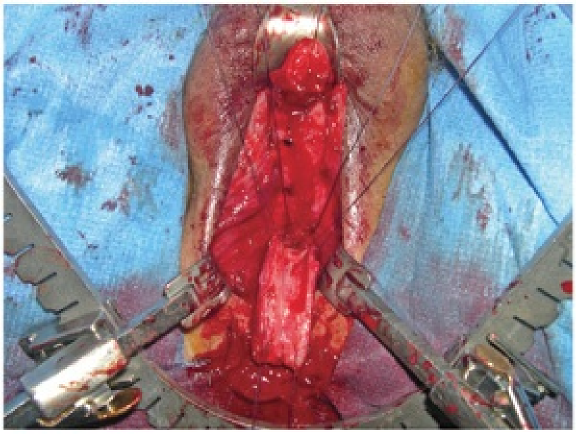

FIGURE 39.19 Augmented anastomotic urethroplasty by dorsal onlay for a long bulbar urethral stricture. The urethra has been transected and the tunica albuginea is exposed. The two ends of the urethra are shown.

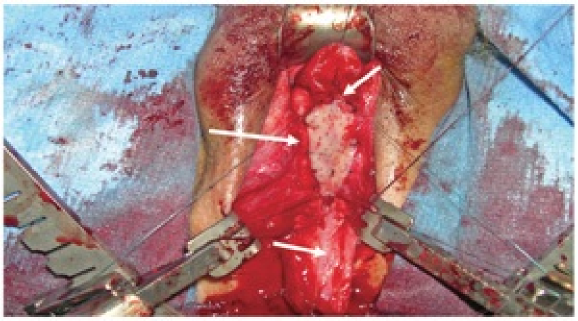

FIGURE 39.20 The buccal mucosa free graft has been spread fixed to the tunica (*long arrow*) and the proximal and distal anastomoses to the urethra have been completed (*short arrows*). Reapproximation of the urethral plate ventrally will be completed next in a so-called "floor strip anastomosis."

A specialized modification of the dorsal onlay addresses very long strictures involving both the bulbar and penile urethra. Pioneered by Kulkarni et al. (52), the entire urethra is approached from a perineal incision, invaginating the penis to expose the distal urethra, and only mobilizing one side of the surrounding muscle and corpus spongiosum. The authors describe techniques that allow placement of the graft into the fossa navicularis and even to the meatus (52).

Penile Skin Flap

Penile shaft skin can be mobilized in a variety of configurations to allow a vascularized tissue transfer into the urethra. Contraindications exist, including lichen sclerosis or premalignant lesions, buried penis configuration, and a lack of hairless skin. Parallel circumferential incisions are marked on the penile shaft. The skin should be stretched flat when marking the incision to avoid a redundant flap. The distal line should be 0.5 cm from the coronal margin. The width of the flap depends on the nature of reconstruction. In general, a flap width of 2 cm is adequate for onlay repairs because the skin will not contract. The flap should be individually tailored to the width of the urethral plate and length of the urethrotomy.

The incisions through the skin are made around the complete circumference of the penis (Fig. 39.21) unless the stricture is short and ventral mobilization alone will suffice. We begin by deepening the distal incision to the level of Buck fascia. Once the dorsal neurovascular bundle is identified, one can be confident that Buck fascia lies below the plane of dissection. Ventrally, the plane of dissection runs right above the corpus spongiosum. Once the deep plane of dissection is completed, one can then develop the superficial plane between the dartos fascia and the skin. Dissection is begun at the proximal skin incision between the skin and the pedicle. A thick fascia pedicle should be created, but care must be taken that visible superficial vessels remain with the skin. This superficial plane of dissection is carried proximally to the base of the penis.

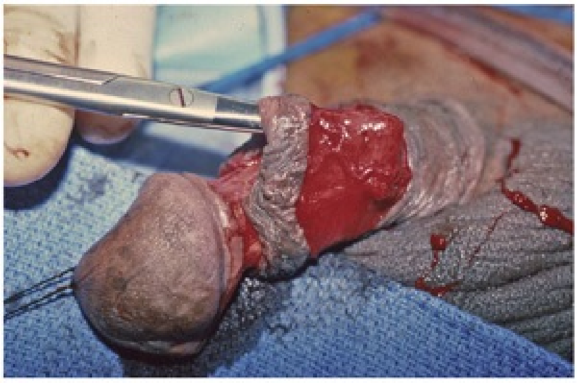

FIGURE 39.21 Circular penile skin flap on a dartos pedicle.

After developing the circular island of skin, midline division of the skin and pedicle allows rotation of the flap around the penile shaft. The skin island can be based on either a dorsal or ventral pedicle and provides up to15 cm of skin (Fig. 39.22).

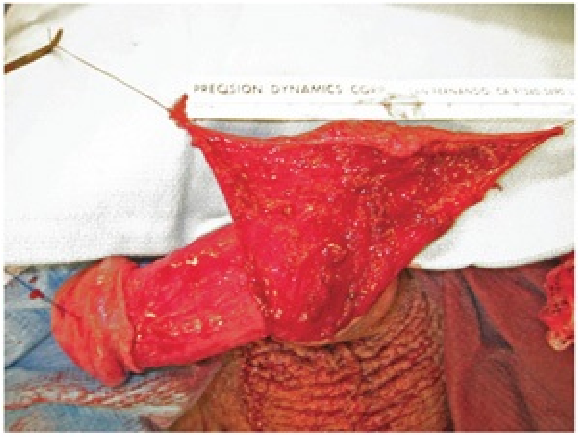

FIGURE 39.22 Circular penile skin flap after division of the skin and pedicle.

STAGED URETHROPLASTY

Strictures causing obliteration or severe fibrotic involvement of the fossa navicularis (Fig. 39.23) or long segments of the penile (or rarely bulbar) urethra may require complete removal, and in these cases, standard anastomotic and substitution procedures are not feasible. Bracka (2000) (53) and Mundy (54) have described a staged approach in such cases. Alternatives include definitive perineal urethrostomy, combined dorsal and ventral grafting, or other individualized strategies. However, for the most severe strictures, the staged approach provides a conservative means to remove severe spongiofibrosis, correct residual chordee, and assure proper graft take and healing prior to tubularization (55).

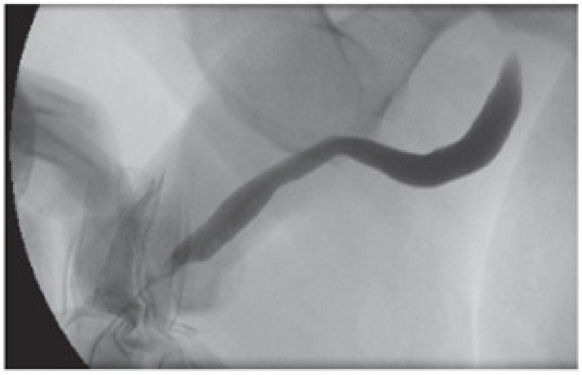

FIGURE 39.23 Retrograde urethrogram showing short severe stricture in distal penile urethra/fossa navicularis.

First Stage

After exposing the distal corpus spongiosum through a midline ventral penile incision, mobilization of the strictured urethra follows. The entire spongiosum is freed off of the underlying corporal bodies. Complete understanding of the stricture extent and severity before committing to a staged substitution is essential. Urethra with little to no luminal diameter is best excised, thus leaving a defect. Buccal mucosa is harvested as described earlier and fenestrated with an 18-gauge needle to prevent seroma formation. The dimensions of the graft are tailored to the length of the defect, allowing a minimum width of 25 to 30 mm. The graft is “spread-fixed” laterally to the tunica albuginea of the underlying corporal bodies (or a reapproximated dartos fascia if available for mobilization and coverage of the corpora) using 5-0 absorbable sutures. Additional sutures approximate the lateral graft to the skin edges in an interrupted fashion, and the graft is quilted to the tunica albuginea as well (Fig. 39.24A). A nonadherent bolster dressing is tied down to the base of the graft (Fig. 39.24B). If a wider residual urethral plate can be preserved, we split and lateralize the corpus spongiosum in a “first-stage Asopa” technique so that less oral mucosa is required (Fig. 39.25).

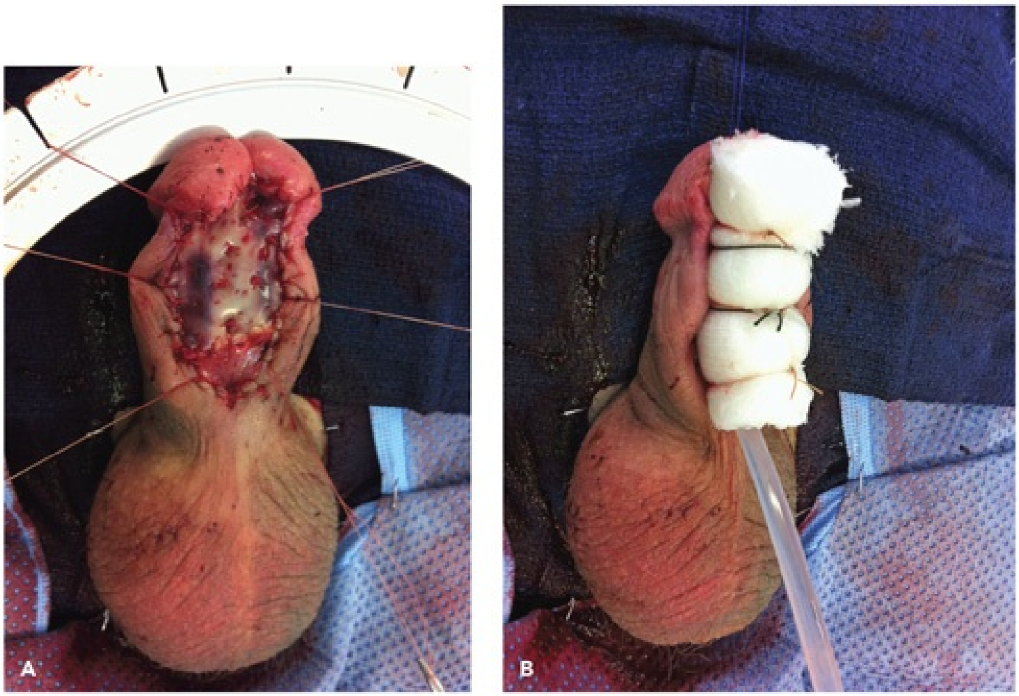

FIGURE 39.24 First-stage urethroplasty. **A:** After excision of entire distal penile urethra and meatus, a buccal graft has been spread fixed in place and anastomosed to the spatulated proximal urethrostomy. **B:** Bolster dressing secured with sutures.

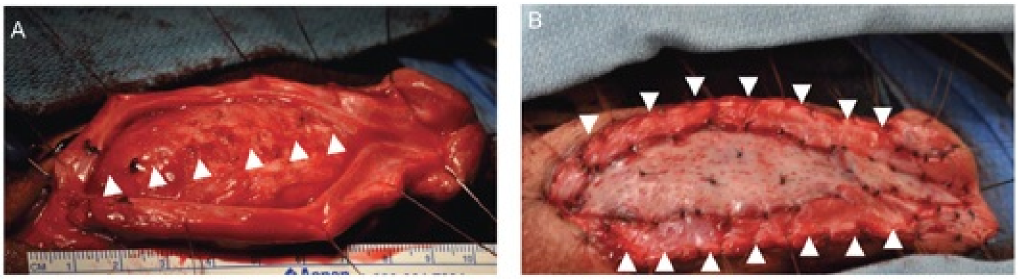

FIGURE 39.25 “Staged Asopa” technique. A long penile urethral stricture after mobilization of the entire corpus spongiosum and ventral urethrotomy. **A:** The urethral plate has been incised ventrally along its length as well as dorsally (*arrowheads* show tunica albuginea visible in defect). **B:** Buccal grafts have been secured in the midline and the urethral plate is fixed laterally (*arrowheads* show lateral margins of urethral plate between graft and skin). Technique described by McClung et al. at 2010 (55) Meeting of the American Urological Association.

Postoperatively, the graft is immobilized for 3 to 5 days, after which time the surgical bolster is removed. During the ensuing week, antibiotic-impregnated fine gauze provides protection and coverage of the grafts, and catheter drainage is continued for a total of 10 to 14 days. Once the urethral catheter is removed, daily application of a barrier emollient (e.g., Eucerin) keeps the skin protected and moisturized until second-stage closure.

Second Stage

The neourethral plate requires 6 to 9 months to gain neovascularization and adequate compliance before tubularization. Once adequate pliability and appearance has been achieved (Fig. 39.26), second-stage closure can be scheduled. Approximately 10% to 20% of cases will require revision for graft contracture, stenosis of the proximal urethrostomy, or other complications (54).

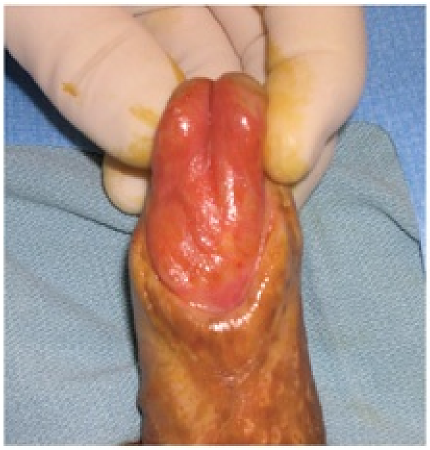

FIGURE 39.26 Appearance of urethra 9 months after first stage urethroplasty.

Adequate width of graft is mapped to tubularize the urethra (Fig. 39.27). The perimeter of the neourethra is incised and sharply elevated off of the tunica albuginea of the underlying corpora cavernosa, preserving any supporting tissue. Once adequate mobilization has been gained, a few holding sutures to reapproximate the edges over a 20Fr catheter confirm adequacy of the diameter (Fig. 39.28). The urethroplasty is closed with running or interrupted 5-0 polyglactin or polyglycolic acid sutures. Coverage with dartos flaps or tunica vaginalis is advisable along the penile urethra and at the subcoronal margin below the glans. The skin is closed in an interrupted fashion with an absorbable suture. The urethral catheter is removed 10 days after surgery. Cosmesis of the meatus may be outstanding if the etiology was iatrogenic or traumatic (Fig. 39.29). With hypospadias and lichen sclerosus, results may be less ideal.

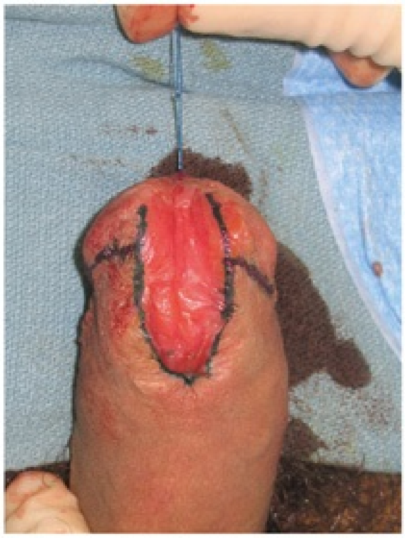

FIGURE 39.27 Second-stage urethroplasty: marked for tubularization.

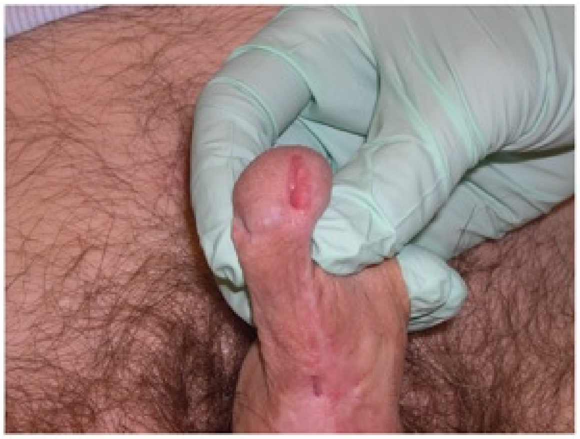

FIGURE 39.29 Second-stage urethroplasty: final cosmetic appearance of glans and meatus.

When the urethral plate does not easily tubularize over a large-bore catheter, adjunctive measures to achieve appropriate closure include incorporation of small skin flaps (Figs. 39.30 and 39.31) or free grafts. Failure to achieve tubularization due to more significant graft loss or fibrosis of adjacent tissues requires revision with placement of additional buccal grafts or meshed split-thickness skin (56,57), delaying closure for another 6 to 9 months.

Outcomes and Follow-up

We define success using a binary outcome based on the ability to pass a flexible 16Fr cystoscope across the reconstructed urethra, although no consensus method has been adopted consistently worldwide (6). Table 39.1 shows rates of stricture recurrence based on the experience of the author, along with our preferred protocol for follow-up by location and type of reconstruction. Surveillance for stricture recurrence varies from center to center; we verify patency at 3 and 12 months. Beyond this time point, recurrence rates decrease and patients are followed symptomatically.

Complications

Complications of urethroplasty relate to positioning, infection, donor site, fistula formation, sexual dysfunction, and stricture recurrence. Minor surgical complications include incisional bleeding, hematuria, and diverticulum formation, occurring in less than 5% of patients after substitution urethroplasty (8). Complications of the lithotomy position include neurapraxia, back pain, and rare compartmental syndrome of the calf. Careful postoperative assessment of the neurovascular integrity of the legs is key to early detection of any problems. Immediate orthopedic consultation is mandatory if compartmental syndrome is suspected.

Oral donor sites may undergo contraction and cause pain or minor difficulties with food or saliva. Fistula formation after staged urethroplasty occurs in 15% of second-stage closures (Fig. 39.32A) but can usually be closed primarily because of the widely patent urethral lumen (Fig. 39.32B). Sexual dysfunction may occur after urethroplasty, and therefore, assessment of baseline function prior to surgery is advisable. Although approximately 40% of men experience a degree of erectile dysfunction after urethroplasty, the majority return to baseline within 1 year (58,59). Orgasmic dysfunction, in particular abnormal ejaculation, is prevalent in men with urethral stricture disease and is likely to improve postoperatively (59).

Perspectives

The essence of reconstructive surgery transcends its technical armamentarium, consisting of a mind-set about how to approach a complex problem, break it down to a series of linked but independent steps, and apply appropriate and increasingly sophisticated techniques to achieve the end goal. The most complex strategies are used only as necessary. A key feature is the stepwise approach, remaining open-minded and flexible and never “burning bridges” until it is clear that lesser techniques are no longer applicable. Examples of this include selection of initial skin incisions that do not limit the subsequent ability to create a skin flap, the choice to transect or incise the urethral plate, considerations about mobilizing dartos or other flaps, and the ultimate decision whether to perform a procedure in one or a series of stages. Successful urethral reconstruction also requires the ability to recognize when one has done enough for a given surgery. A panurethral stricture may be approached in one stage all at once; but different local tissue characteristics, severity of the stricture, body habitus, and need for excision of portions of the strictures may dictate that the surgeon only work on the most severely affected part of the urethra, coming back another day to manage less severely affected portions with an alternative strategy. Reconstruction is best viewed as a continuum, which may require multiple operations, multiple techniques, and revision surgery to achieve successful outcomes.

CHAPTER 40 SURGERY FOR URETHRAL TRAUMA INCLUDING URETHRAL DISRUPTION

TIMOTHY J. TAUSCH, JAY SIMHAN, AND ALLEN F. MOREY

Early recognition and diagnosis of urethral injuries are crucial to the successful management and prevention of long-term complications. Management of traumatic urethral injuries depends on the location of urethral stenosis. The urethra is divided into anterior (pendulous and bulbar urethra) and posterior (membranous and prostatic urethra) segments, with specific mechanisms of injury for either segment that will ultimately influence therapy and outcomes. Immediate management of anterior and posterior urethral trauma predominantly involves temporizing solutions to divert urine away from the urethral injury, although immediate surgical management of acute anterior urethral trauma may often be appropriate. Many patients with posterior injuries ultimately require formal surgical repair several months following the initial injury.

ANTERIOR URETHRAL INJURIES

The anterior urethra extends distally from the membranous urethra to the urethral meatus (Fig. 40.1). Contrary to the posterior urethra, the anterior urethra is encompassed by the corpus spongiosum, the deep (Buck) fascia, and the superficial (dartos) fascia along its entire length. The penoscrotal junction divides the shorter, proximal bulbar urethra from the longer, distal pendulous urethra. The bulbospongiosus muscle ventrally covers the bulbar urethra and terminates at the penoscrotal junction, prior to the origination of the distal pendulous urethra. The pendulous urethra closely approximates the corpora cavernosa during most of its length, with the lumen of the distal pendulous urethra dilating distally to form the fossa navicularis.

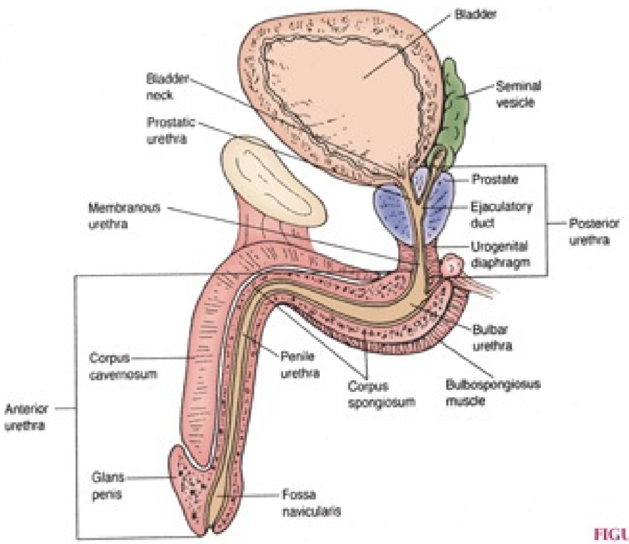

FIGURE 40.1 Anatomy of the anterior and posterior urethra.

Although susceptible to penetrating trauma (e.g., stab or gunshot wounds), injuries to the anterior urethra most commonly involve blunt compression (“straddle”) injuries, penile fracture with concomitant urethral disruption, iatrogenic trauma (e.g., after Foley catheterization or endoscopic urethral surgery), and constriction rings. Compression of the bulbar urethra against the pubic bone, or a “straddle injury,” is the most commonly encountered anterior urethral injury and occurs after a direct force to the perineum compresses the bulbar urethra against the pubic bone. Alternatively, penile constriction rings can damage the anterior urethra secondary to tissue ischemia, whereas Foley catheterization or endoscopic urethral surgery can damage the bulbar urethra, resulting in contusion or partial urethral disruption. The true extent of iatrogenic injuries, along with trauma from constriction rings, may not become evident until many years after the original event (1). Although rarely associated with pelvic fractures, anterior urethral injuries may be encountered in approximately 15% of penile fractures (2).

Diagnosis

A careful history and physical examination should raise suspicion for anterior urethral injury because these insults may arise immediately or after a substantial period of time. Straddle injuries often present in a delayed fashion with obstructive voiding symptoms and an idiopathic etiology. In a large series of 78 patients with straddle injuries, Park and McAninch (3) reported great variability in the time to presentation, with 40% of patients presenting to the emergency department in an acute setting and 60% of patients presenting 6 months to 10 years after the original injury. Hematuria, penile sleeve hematoma (injury confined to Buck fascia), difficulty voiding, and perineal “butterfly” hematoma (injury penetration of Buck fascia) are common presenting symptoms in the acute setting. In addition to a perineal butterfly hematoma, penetration of Buck fascia can allow the spread of urine and/or blood to the scrotum (dartos fascia), anterior abdominal wall (Colles fascia), and/or thighs (fascia lata).

All patients with a suspected anterior urethral injury should undergo a retrograde urethrogram prior to an attempt at urethral catheter placement. Ideally, the patient should be placed obliquely at a 30- to 45-degree angle with the bottom leg flexed at 90 degrees and the top leg kept straight (Fig. 40.2). In the acute setting, associated pelvic fracture may preclude this position; therefore, a supine retrograde urethrogram may be employed to determine whether the urethral lumen has been disrupted. Flexible cystoscopy may also be used to aid with the diagnosis of urethral trauma, although radiographic imaging is usually sufficient for a diagnosis of urethral trauma.

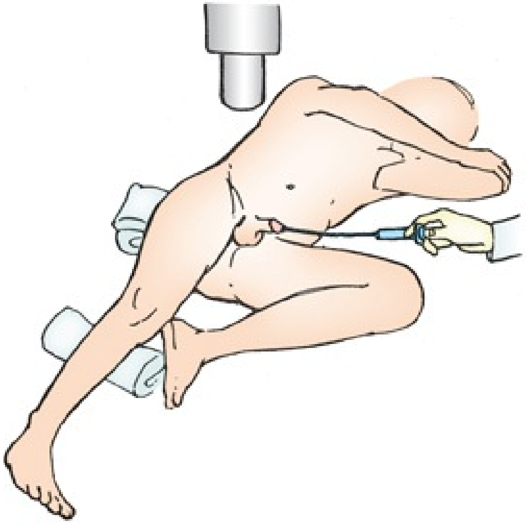

FIGURE 40.2 Proper positioning for retrograde urethrography. The patient is placed obliquely at a 45-degree angle with the bottom leg flexed and the top leg straight. Slight traction on the penis during injection of contrast helps avoid telescoping of the urethra and allows more accurate characterization of the injury.

The retrograde urethrogram should be performed with undiluted water-soluble contrast medium (full-strength [60%] ionic contrast medium). A scout film provides initial information on patient position, the potential presence of a foreign body, as well as any fractures to the bony structures of the pelvis. A 12Fr Foley catheter is then placed into the fossa navicularis, and the balloon is inflated with 3 mL of sterile water to prevent catheter dislodgment during the evaluation. The penis is positioned laterally on slight stretch to provide a more descriptive study, and 20 to 30 mL of contrast is then injected in a retrograde fashion. Dynamic fluoroscopy is ideal; however, in the setting of acute trauma in the emergency department, static radiographs will suffice. Although the anterior urethra can be visualized in its entirety during a retrograde urethrogram, the posterior urethra is typically excluded by reflex contraction of the external sphincter. If a catheter is present at the time of evaluation, a cystogram is recommended to confirm the catheter's presence in the bladder. After documenting the correct location of the urethral catheter, a pericatheter retrograde urethrogram may additionally be performed to delineate any possible urethral injury.

Anterior urethral injuries are classified into three groups based upon radiographic, clinical, or endoscopic findings. Although *contusions* may appear normal on retrograde urethrogram, these injuries are best determined with clinical suspicion through cystoscopy in the setting of a “normal” retrograde urethrogram. Alternatively, *partial disruptions* appear as extravasated urine on retrograde urethrogram with visualization of contrast in the urethra or bladder proximal to the injury. *Complete disruptions* appear as total extravasation without visualization of contrast in the more proximal urethra or bladder.

Indications for Surgery

Primary surgical repair of acute anterior urethral injuries is recommended in the context of penetrating injury. We also recommend an attempt at anterior urethral repair in the setting of penile fracture. Because these repairs are delicate and potentially time-consuming, any attempt at immediate repair is predicated on the stability of the patient. Injuries to the posterior urethra should be managed in a delayed fashion, without attempt at a formal urethroplasty in the acute setting. Posterior urethral injuries are discussed later in this chapter.

Alternative Therapy

Alternative options to surgical repair involve the temporary diversion of urine through the placement of a urethral or suprapubic catheter. Contusions to the anterior urethra should be managed with a urethral catheter for approximately 2 weeks followed by a voiding cystourethrogram to confirm urethral patency. The patient should be counseled on the possibility of delayed development of a urethral stricture at the site of contusion.

Partial urethral disruptions diagnosed by retrograde urethrogram may be managed via various algorithms. We prefer urinary diversion with formal repair after a minimum of 2 months to allow resolution of inflammation and maturation of scar tissue. Although some experts support one attempt at Foley catheter placement, the possibility of causing a complete urethral disruption during this attempt should be considered. If urethral placement is unsuccessful, percutaneous suprapubic tube placement should be performed. The preservation of urethral mucosa with partial disruptions may be adequate for re-epithelialization and eventual luminal recanalization; however, we would recommend periodic evaluation with uroflow studies and counseling patients regarding the possibility of future stricture development.

Surgical Technique

Open surgical repair is primarily reserved for stable patients after open or penetrating injury to the anterior urethra. The patient is placed in either the supine position or lithotomy position and draped widely to allow exploration of potential concomitant injuries to the penis, testes, perineum, and rectum. Clean wounds need only minimal debridement followed by urethral closure with interrupted or running 5-0 polyglyconate monofilament (polydioxanone) sutures over a 16Fr catheter. Contaminated wounds require thorough irrigation and debridement of devitalized tissues to ensure reapproximation of healthy tissue.

With open or penetrating bulbar urethra injuries, the patient is placed in the lithotomy position with adjustable stirrups, and a vertical perineal incision is performed along the raphe. As expected, only stable patients without injury precluding the lithotomy position should be offered acute surgical intervention. The urethra is exposed after division of Colles fascia and the bulbospongiosus muscle. A perineal retractor (e.g., perineal Bookwalter or Lone Star retractor, Cooper Surgical, Trumbull, Connecticut) is used to assist with perineal dissection. Surgeons should avoid acute repair of long bulbar urethral defects (>2 to 3 cm) because more complex intervention with grafts or flaps will be required. The most important factor promoting a successful outcome is the creation of a tension-free anastomosis; therefore, generous mobilization of the urethra is an important step to ensure adequate urethral length. Once adequate length is achieved, the urethral ends are spatulated (Fig. 40.3). The anastomosis is performed with interrupted 5-0 polyglyconate monofilament suture to create a tension-free, watertight closure. The dorsal surface is closed in one layer with 5-0 interrupted polyglyconate monofilament suture incorporating the urethral mucosa and spongiosal adventitia. Since the ventral bulbar urethra is vascularized by the spongy urethra, we advocate ventral spongiosum closure in two layers: the first, inner layer, closed with interrupted 5-0 polyglyconate monofilament suture and the second, outer layer, with a running 5-0 polyglyconate monofilament suture (Fig. 40.4). No further attempt is made to control bleeding from the spongy urethra during closure, as we believe that the added vascularity from the spongy urethra provides enhanced healing of the anastomosis. We also recommend that a first-stage marsupialization of healthy proximal urethra be considered if tension-free closure cannot be achieved or if there is significant wound inflammation or contamination.

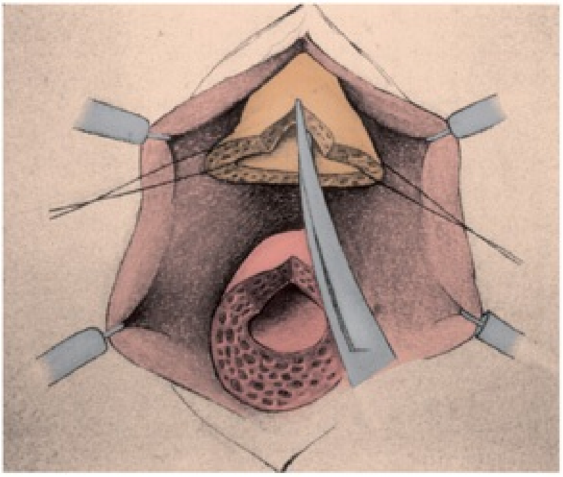

FIGURE 40.3 Repair of bulbar urethral injuries. The urethra is mobilized and spatulated in preparation for a tension-free end-to-end anastomosis.

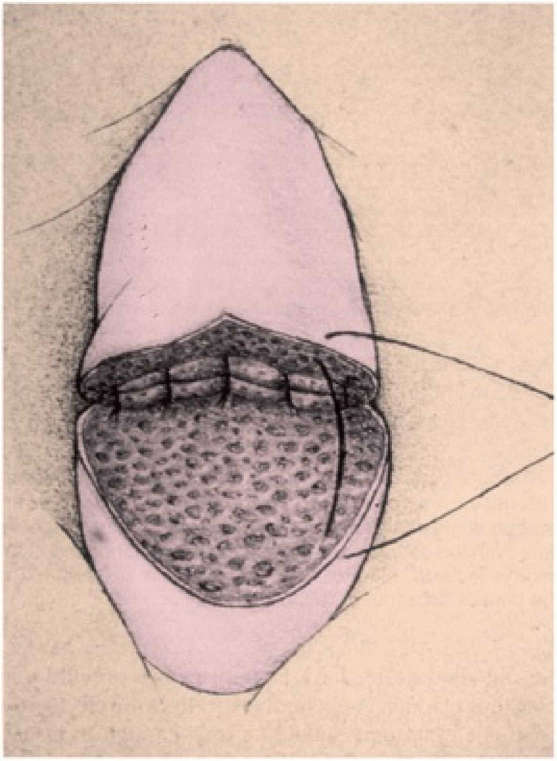

FIGURE 40.4 Repair of bulbar urethral injuries. Anastomosis is carried out with a single-layer dorsal closure and a two-layer ventral closure using interrupted 5-0 or 6-0 Maxon sutures.

For most penile urethral injuries, we prefer a longitudinal incision directly over the area of injury. Contrary to bulbar urethral injury, anastomotic repair should not be considered for defects >15 mm, as the risk of penile chordee is higher with penile anastomotic repairs. Instead, we prefer to use buccal mucosa in either an inlay, onlay, or combined approach. We routinely use 16Fr silicone Foley catheters at the time of urethral repair. Suppressive antibiotics are given while the catheter is in place to maintain urine sterility, with a voiding cystourethrogram performed after 2 to 3 weeks. If extravasation is noted, we gently replace the catheter for an additional period of time with repeat imaging at the time of urethral catheter removal.

Outcomes

Complications

The major complications relating to anterior urethral trauma include urethral stricture formation and infection. If untreated, persistent extravasation of infected urine or blood may lead to urethrocutaneous fistula, urethral abscess, or urethral diverticula. Prolonged urine extravasation into the corpus spongiosum may also lead to added spongiofibrosis, resulting in a longer urethral stricture. Consequently, a longer anterior urethral stricture translates to more complex management with a buccal mucosa graft or fasciocutaneous flap.

Patients with resultant urethral strictures are often subjected to endoscopic procedures such as dilations or urethrotomies that frequently need to be repeated. Such interventions can subject patients to pain and complications negatively impacting quality of life. Success of dilations is also low, with most patients eventually requiring definitive urethral repair.

With early urinary diversion, many anterior urethral strictures will never progress and remain amenable to excision. Incontinence and impotence, although common in posterior urethral injuries, are uncommon in anterior urethral injuries. Stricture recurrence is most common in the first 12 months, so close follow-up is required.

Results

Anastomotic urethroplasty can be performed successfully in a high percentage of patients who sustain a bulbar urethra (straddle) injury requiring surgery. The procedure has an overall success rate of approximately 95% when performed in a delayed setting (3). As mentioned previously, patients sustaining open or penetrating injuries associated with minimal inflammation are the best candidates for acute repair; otherwise, urinary diversion with suprapubic tube placement is recommended with formal repair at a later date.

POSTERIOR URETHRAL INJURIES

Posterior Urethral Anatomy

The urethra is divided into anterior and posterior anatomic segments by the urogenital perineal membrane. The posterior urethra consists of the membranous and prostatic urethra and is much shorter than the anterior urethra (Fig. 40.1). Extending from the bladder neck to the apex of the prostate, the prostatic urethra is secured to the pubic bone by the paired puboprostatic ligaments. During cystoscopy, the verumontanum marks the most distal aspect of the prostatic urethra. The bladder neck sphincter is an extension of smooth muscle fibers of the trigone and prostatic urethra cephalad to the verumontanum. The distal sphincter is approximately 2.5 cm long and consists of smooth muscle fibers caudad to the verumontanum, including the rhabdosphincter (slow-twitch skeletal muscle fibers) (4). The distal sphincter is only 3 to 4 mm thick and forms the entire thickness of the membranous urethra (5). In the absence of a functional distal urethral sphincter, the proximal urethral sphincter can maintain urinary continence in select patients; however, the bladder must be compliant and free from periodic elevations of detrusor pressure (e.g., detrusor overactivity).

Injury to the membranous urethra is not uncommon given its location between two relatively fixed points (prostate and bulbar urethra). Since the distal urethral sphincter is located in the membranous urethra, shear injuries leading to partial or complete membranous urethral disruption can result in distal urethral sphincter damage.

Injuries to the Posterior Urethra

Injuries to the posterior urethra are typically associated with major, often life-threatening, trauma, as a consequence of the significant blunt forces required to generate a pelvic fracture (e.g., intra-abdominal and vascular injuries to the pelvic vasculature). Posterior urethral trauma is almost always associated with pelvic fracture; conversely, only 10% to 15% of pelvic fractures are associated with urethral injury. Bladder injury has also been diagnosed in 10% to 20% of patients with pelvic fracture and urethral injury (6). Other etiologies include penetrating trauma and iatrogenic injuries secondary to endoscopic, open, or minimally invasive prostate surgery.

The clinical and surgical appearance of each form of posterior urethral injury may differ. Endoscopic or open prostate surgery is associated with continuity strictures and preservation of the distal external urinary sphincter. In contrast, pelvic fractures are associated with urethral disruptions of the membranous urethra. These injuries have been termed *pelvic fracture urethral injuries* (PFUIs). Interestingly, a report has found that 7 of 10 patients examined at autopsy had urethral disruption after pelvic fracture *distal* to the external urinary sphincter, disputing the historical view that these injuries occur at the interface of the fixed prostatic apex and the less supported membranous urethra (7). Additionally, urodynamic studies have demonstrated a functional rhabdosphincter at the prostatomembranous region in many patients after anastomotic posterior urethroplasty for PFUI (4).

Diagnosis

PFUIs are the most common presentations in the acute trauma setting. Given the strong association of more serious concomitant injuries with PFUI, the first goal is resuscitation of the patient. Suspicious findings after PFUI mirror those of anterior urethral injuries, namely, hematuria, blood at the meatus, perineal hematoma, and difficulty voiding. Additionally, a high-riding prostate on digital rectal exam and specific pelvic fractures are linked with PFUI, although these diagnostic clues are not uniformly present. The prostate can appear elevated in position on digital rectal exam due to displacement from a pelvic hematoma and/or digital confirmation of the prostate may be indistinguishable from the pelvic hematoma. Regarding pelvic fractures, displacement of the inferomedial pubic bone and pubic symphysis diastasis are independently associated with urethral injury (8).

In a patient with a suspected PFUI, a retrograde urethrogram should be performed prior to any attempt at catheter placement (Fig. 40.5). If normal, the catheter can be advanced into the bladder and a formal cystogram should be obtained to assess for bladder perforation. The technique for retrograde urethrogram was discussed previously. As part of a formal cystogram, three radiographic views should be obtained, including an anterior-posterior scout film, a full-bladder anterior-posterior film, and a drainage film. Passive filling to discomfort or 350 mL of contrast is recommended to avoid false-negative results. Other studies to further delineate posterior urethral injuries include flexible cystoscopy; however, we caution against advancing the cystoscope past the site of injury for fear of exacerbating the injury.

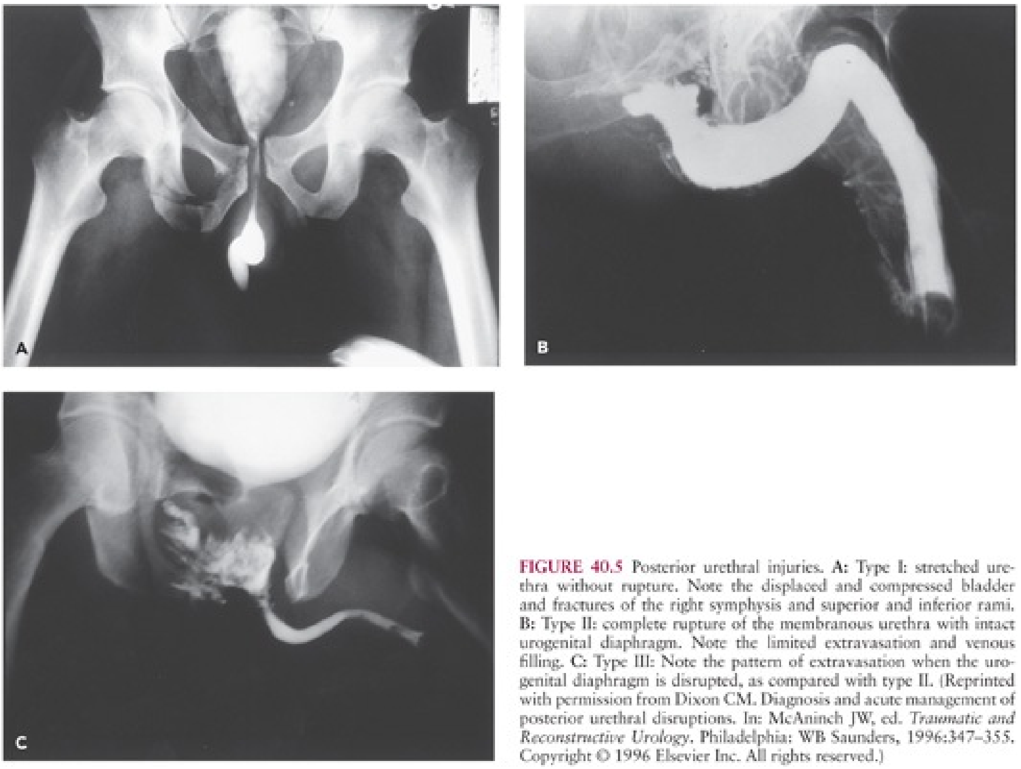

FIGURE 40.5 Posterior urethral injuries. **A:** Type I: stretched urethra without rupture. Note the displaced and compressed bladder and fractures of the right symphysis and superior and inferior rami. **B:** Type II: complete rupture of the membranous urethra with intact urogenital diaphragm. Note the limited extravasation and venous filling. **C:** Type III: Note the pattern of extravasation when the urogenital diaphragm is disrupted, as compared with type II. (Reprinted with permission from Dixon CM. Diagnosis and acute management of posterior urethral disruptions. In: McAninch JW, ed. *Traumatic and Reconstructive Urology*. Philadelphia: WB Saunders, 1996:347–355. Copyright © 1996 Elsevier Inc. All rights reserved.)

Posterior urethral injuries secondary to blunt trauma have historically been classified based on the Colapinto and McCallum system (9). A more recent modification maintains the original three classes of injury, revised system to include injuries that extend to the bladder neck and blunt anterior urethral injuries (Table 40.1) (10).

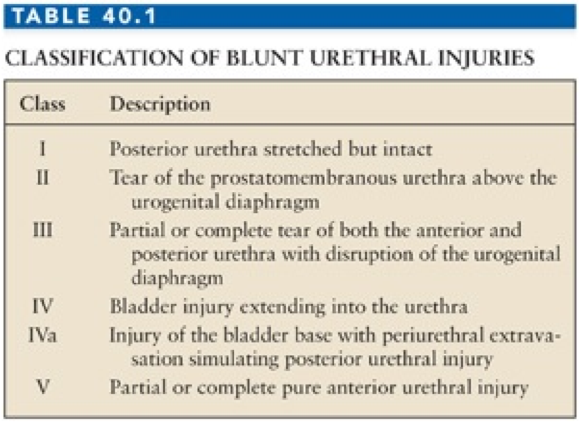

TABLE 40.1

CLASSIFICATION OF BLUNT URETHRAL INJURIES

Class	Description
I	Posterior urethra stretched but intact
II	Tear of the prostatomembranous urethra above the urogenital diaphragm
III	Partial or complete tear of both the anterior and posterior urethra with disruption of the urogenital diaphragm
IV	Bladder injury extending into the urethra
IVa	Injury of the bladder base with periurethral extravasation simulating posterior urethral injury
V	Partial or complete pure anterior urethral injury

Indications for Surgery

Debate continues regarding whether primary endoscopic realignment (PER) or suprapubic tube (SPT) diversion (with delayed urethroplasty) is better for acute management of PFUI. There is no consensus among experts, with varying literature regarding the impact of each on eventual incontinence, impotence, and urethral stricture rates (11–25). The obvious benefit of primary alignment is a potentially lower stricture rate of 56% versus the 97% stricture rate seen with suprapubic catheter placement (25); however, a more recent series reported that PER is only successful in 21% (4/19) of patients (22). Additionally, a recent report of a large series showed that strictures that form after realignment can be shorter and therefore potentially easier to treat when undergoing urethroplasty (20).

One can conclude that urethral strictures after endoscopic alignment may be shorter, offering the possibility of a less invasive option, such as internal urethrotomy in lieu of formal perineal urethroplasty. Despite claims that periodic office urethral dilations are trivial to the patient, we strongly disagree with this assertion and counsel the patient early for posterior urethroplasty to definitively treat the persistent stricture (Fig. 40.6).

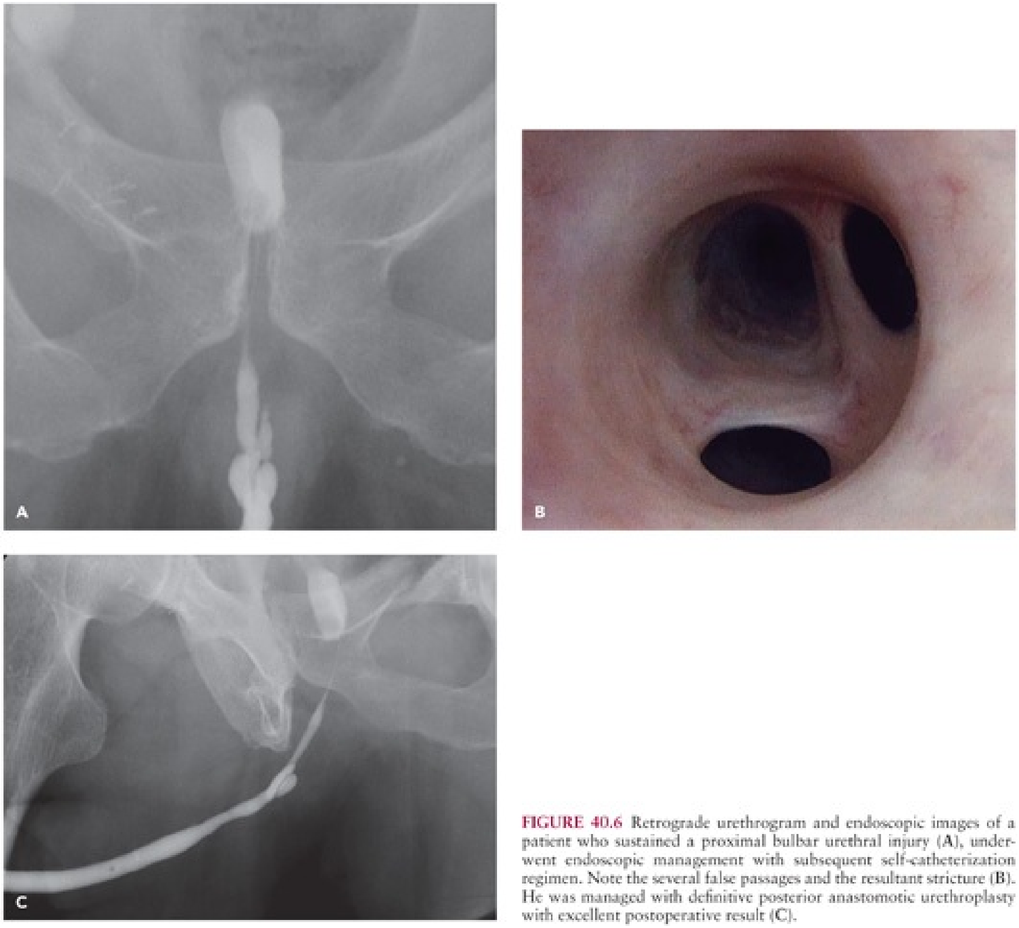

FIGURE 40.6 Retrograde urethrogram and endoscopic images of a patient who sustained a proximal bulbar urethral injury (A), underwent endoscopic management with subsequent self-catheterization regimen. Note the several false passages and the resultant stricture (B). He was managed with definitive posterior anastomotic urethroplasty with excellent postoperative result (C).

We would agree that PER and SPT placement are currently both acceptable for the acute management of PFUI. However, we prefer to manage these patients with SPT, with definitive and durable treatment via posterior urethroplasty 2 months postinjury. In the setting of a severely injured or unstable patient, one should perform percutaneous SPT placement as the more expeditious procedure.

Alternative Therapy

When concomitant bladder injuries occur, open suprapubic cystostomy allows for repair. If the patient is too unstable to allow operative exploration, then percutaneous SPT placement with or without ultrasound guidance is appropriate; however, percutaneous placement may be difficult if there is associated bladder injury. Therefore, open SPT placement can be performed after the patient is stabilized. Most bladder injuries associated with PFUI are extraperitoneal and heal spontaneously with catheter drainage; however, if surgical management of pelvic fractures is planned, operative repair of the associated bladder injury may reduce complication rates.

Primary suture repair of PFUI in the acute setting is associated with elevated impotence and incontinence rates. Primary suture repair of PFUI is not recommended for this reason, and also because of the more important risk of hemorrhage and contamination associated with evacuation of the retropubic hematoma to gain access to the injury site. The only clinical scenario in which we favor acute repair of PFUI is in the setting of concomitant extravasation at the bladder neck. We also recommend repair of rectal and vaginal lacerations in this clinical scenario.

Surgical Technique

Open Suprapubic Catheter Placement

For open suprapubic catheter placement, the patient is placed in the supine position. An infraumbilical incision is made to allow access to the prevesical space anterior to the bladder dome. After placing stay sutures around the anticipated cystostomy site, the bladder is opened vertically at the bladder dome, which will provide ample exposure to examine the bladder and urethra for injury. *Strict avoidance* of dissection into the space of Retzius and lateral perivesical space is essential to prevent pelvic hemorrhage and contamination. Therefore, in the presence of an associated bladder neck or bladder base injury, intravesical repair is recommended. An additional benefit of bladder neck repair is that it prevents the laceration from extending into the external urethra sphincter complex.

Bladder lacerations, if present, should be repaired in two layers with absorbable suture incorporating the detrusor muscle and a superficial absorbable suture incorporating the bladder mucosa. Open suprapubic catheter placement is performed in the bladder dome, and the bladder cystostomy site is fixed in place with a purse-string suture (Fig. 40.7). We do not favor Malecot catheters, as they have a higher propensity to be accidentally dislodged. Instead, we utilize a 20Fr to 24Fr Foley catheter with an inflation balloon. The vesicostomy is closed in two layers with 2-0 polyglactin suture. Regarding associated pelvic fractures, we recommend communicating with the orthopedic service to ensure that the SPT skin site does not interfere with future orthopedic operative endeavors. We do not use abdominal drains unless an associated bowel injury is present.

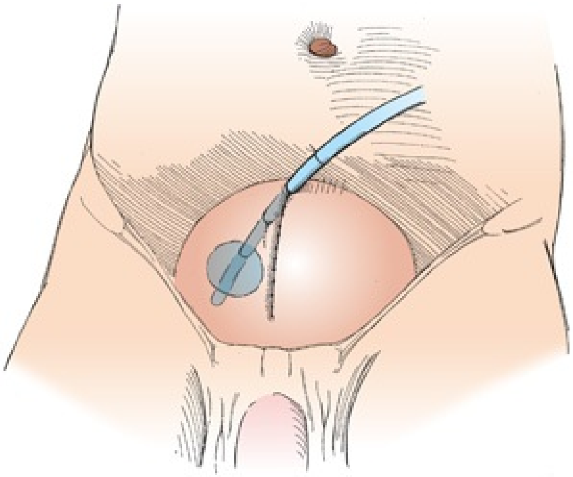

FIGURE 40.7 A large-caliber Foley catheter is placed in the bladder dome after inspection for concomitant bladder laceration. With the catheter placed through the superior end of the midline incision, bladder neck identification is facilitated at the time of subsequent reconstruction.

Delayed Posterior Urethroplasty

The principles of anastomotic urethroplasty are followed for repair of posterior urethral defects. These include epithelial apposition, establishment and/or preservation of blood supply to the anastomosis, resection of scar providing healthy tissue to hold sutures, and preservation of bladder neck competence. Our technique involves a midline perineal incision. Usually, the end result of a PFUI is a relatively short bulbomembranous gap, amenable to a straightforward primary anastomosis. We use 5-0 polydioxanone sutures on RB-1 needles in a 12-suture, “clock-face” configuration. Double-armed sutures are beneficial in ensuring mucosal edges are incorporated while also allowing for the knots to be tied on the extraluminal side of the urethra.

In rare cases of high prostatic dislocation, longer defects of >2 to 3 cm may result. For these cases, various maneuvers have traditionally been employed. Although a stepwise approach described by Webster and Ramon has been established (26), we have found that corporal splitting is rarely necessary, and the vasculature in that area can be spared providing better support of the anastomosis. Aggressive distal urethral mobilization nearly always yields enough length to achieve a tension-free anastomosis, and in severe cases, an inferior pubectomy can shorten the distance in order to complete the repair (27).

Outcomes

Complications

Complications after treatment of posterior urethral trauma are directly related to the severity of injury. Acute complications include pelvic hemorrhage and infection or abscess of the pelvic hematoma, which can occur after ill-advised retropubic exploration or attempts at pelvic hematoma evacuation. Delayed complications include incontinence, impotence, and urethral stricture formation.

Impotence and incontinence outcomes in the literature can be difficult to compare, with multiple reports claiming different results after endoscopic alignment and SPT with delayed urethroplasty. Sexual dysfunction is commonly associated with pelvic fracture, even in the absence of urethral injury (28). Management appears to affect postinjury erectile function and continence, with significantly better results with SPT and delayed urethroplasty compared to attempts at realignment. Realignment results in impotence rates as high as 44% and incontinence rates 20%, compared to delayed repair rates of 11.6% and 1.7%, respectively (29). Delayed return of potency has been reported after definitive urethroplasty; however, this would depend upon the severity of the initial injury (30).

Results

At our institution, delayed urethroplasty after SPT is the preferred management algorithm for PFUI. Posterior urethroplasty has been successful for resolution of stricture in 100% of patients initially managed by SPT and in 88% of patients who presented with strictures following attempts at PER. Stricture length was similar between these two groups (2.6 versus 2.8 cm, respectively); however, those patients undergoing attempts at PER had a significantly longer time course to durable resolution (7 versus 129 months, respectively). PER patients also experienced a mean of six endoscopic interventions prior to definitively urethroplasty. Endoscopic realignment may be an appropriate management strategy in the acute setting; however, urologists should carefully consider the better and timelier outcomes of SPT placement and referral for definitive posterior urethroplasty.

CHAPTER 41 ■ CARCINOMA OF THE URETHRA (MALE AND FEMALE)

EUGENE J. PIETZAK AND THOMAS J. GUZZO

Primary urethral cancer is a rare tumor that accounts for less than 0.5% of all malignancies and only 1% of all genitourinary malignancies (1). Given the rarity of the disease, there exist no randomized controlled trials to guide management. Furthermore, the majority of literature on urethral cancer comes from retrospective analysis from single centers with cases spanning several decades. Many recommendations for treatment are based on general oncologic principles and extrapolation from other diseases.

Urethral cancer is also a heterogenous disease. There are various histologic subtypes including urothelial cell carcinoma (UCC) (54% to 65%), squamous cell carcinoma (SCC) (16% to 22%), adenocarcinoma carcinoma (10% to 16%), as well as a very small number of other tumor types (i.e., melanoma, clear cell carcinoma, sarcoma, etc.) (1). SCC was historically thought to be the most common subtype of urethral carcinoma, but data from both the European RARECARE project and Surveillance, Epidemiology, and End Results (SEER) have found UCC to be the most common (2,3). UCC of the urethra represents a “field defect” within the lower urinary tract, which mandates an evaluation of the upper urinary tract and consideration of excision of the bladder along with the entire urethra. Although histologic subtype has not been shown to affect outcomes, prognosis and treatment options do vary with the location and stage of the tumor (1). Distal tumors have a more favorable prognosis than proximal tumors in both men and women. Local control has been linked to improved cancer-specific survival; therefore, effective treatment of the primary tumor to reduce locoregional recurrence is of the utmost importance (4).

Historically, urethral cancer was once thought to be the only genitourinary cancer more common in females than males, but this was based on single center experiences (5). More recent data contradicts those findings and suggests the male-to-female ratio for urethral cancer is nearly 3:1 (2,3). Urethral carcinomas in men and women differ in several important aspects, including treatment, and therefore are discussed in separate sections of this chapter.

URETHRAL CARCINOMA IN MEN

Epidemiology, Risk Factors, and Presentation

The rate of urethral carcinoma is 4.3 cases per million for men, and only 1.5 cases per million in women according to an analysis of SEER data (3). The peak incidence of urethral carcinoma is between 75 and 84 years of age (3). Urethral cancer is exceedingly rare in those younger than 55 years old.

In men, urethral carcinoma is associated with several risk factors. Most common is a history of urethral stricture disease, which is present in over 50% of men with urethral cancer (1). Furthermore, over 25% have a history of sexually transmitted diseases (1). There is likely a causal relationship with human papillomavirus (HPV) 16 (1). Chronic urethritis and radiation exposure have also been implicated in urethral carcinoma development (1).

Nearly all patients with urethral carcinoma present with symptoms. The most common symptoms in men include hematuria/urethral bleeding, obstructive voiding symptoms, and a palpable mass. A high incidence of suspicion is required to reduce the delay to diagnosis.

Diagnosis and Staging

Physical examination of a patient with suspected urethral cancer should include inspection of urethral meatus with palpation of the entire urethra, looking for induration and fixation. Digital rectal examination and bimanual examination should be performed to determine the extent of tumor involvement. If needed, this can be done under anesthesia at time of cystoscopy with biopsies.

Tumor-node-metastasis system is the preferred staging system (Table 41.1), as prognosis is directly correlated with depth of tumor invasion, as well as nodal and distant metastatic involvement. In general, lymphatic drainage for distal tumors is to the superficial and deep inguinal lymph nodes, whereas proximal tumors drain to pelvic nodes. Because 20% to 30% of patients have nodal involvement at presentation, palpation of the bilateral inguinal lymph nodes must be done.

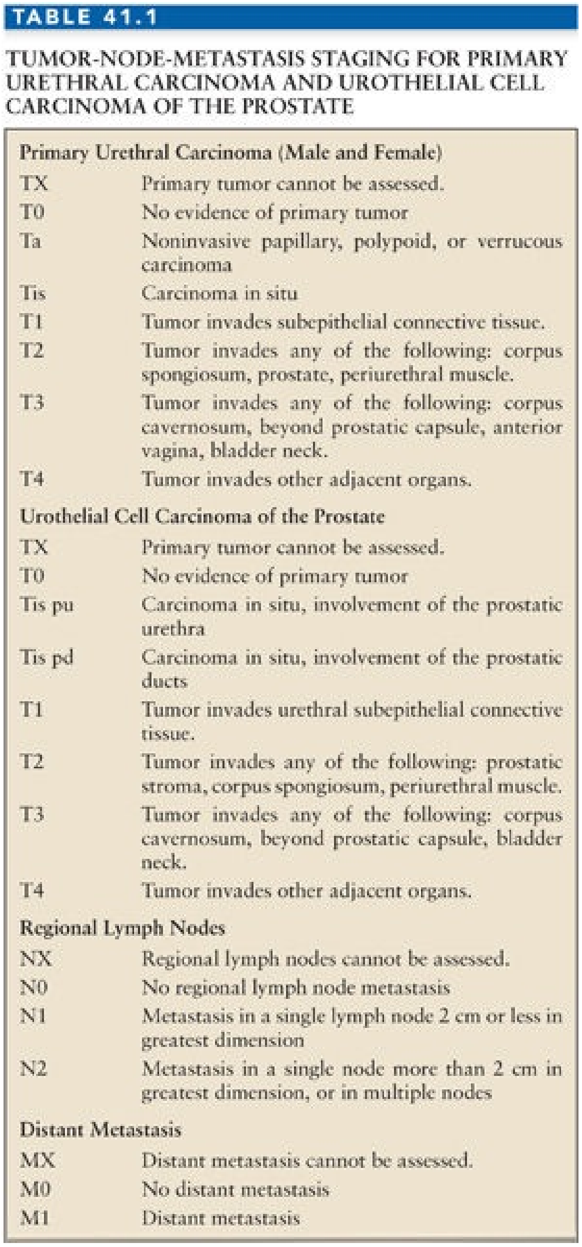

TABLE 41.1

TUMOR-NODE-METASTASIS STAGING FOR PRIMARY URETHRAL CARCINOMA AND UROTHELIAL CELL CARCINOMA OF THE PROSTATE

Primary Urethral Carcinoma (Male and Female)	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Ta	Noninvasive papillary, polypoid, or verrucous carcinoma
Tis	Carcinoma in situ
T1	Tumor invades subepithelial connective tissue.
T2	Tumor invades any of the following: corpus spongiosum, prostate, periurethral muscle.
T3	Tumor invades any of the following: corpus cavernosum, beyond prostatic capsule, anterior vagina, bladder neck.
T4	Tumor invades other adjacent organs.
Urothelial Cell Carcinoma of the Prostate	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis pu	Carcinoma in situ, involvement of the prostatic urethra
Tis pd	Carcinoma in situ, involvement of the prostatic ducts
T1	Tumor invades urethral subepithelial connective tissue.
T2	Tumor invades any of the following: prostatic stroma, corpus spongiosum, periurethral muscle.
T3	Tumor invades any of the following: corpus cavernosum, beyond prostatic capsule, bladder neck.
T4	Tumor invades other adjacent organs.
Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node 2 cm or less in greatest dimension
N2	Metastasis in a single node more than 2 cm in greatest dimension, or in multiple nodes
Distant Metastasis	
MX	Distant metastasis cannot be assessed.
M0	No distant metastasis
M1	Distant metastasis

Cystourethroscopy should be performed to assess tumor extent and location. Cold-cup biopsies or transurethral resection should be performed to determine tumor histology. Biopsies distal and proximal to the tumor can provide useful information if organ-sparing surgery is considered. Complete cystoscopic examination should be done to rule out concomitant bladder tumors.

Radiographic imaging is obtained with the goal to accurately determine local tumor involvement and the presence of metastasis in lymph nodes and distant sites. Magnetic resonance imaging (MRI) is superior to computerized tomography (CT) scan regarding determining the extent of local tumor involvement including corpora cavernosa invasion (6). Either MRI or CT scan can be used for assessing regional metastasis in inguinal and pelvic lymph nodes. CT of the chest and abdomen is preferred for patients with invasive tumors to identify distant metastasis. In the absence of nodal involvement, a chest X-ray is likely adequate. Imaging of the upper urinary tract should be obtained for patients with urethral UCC to rule out any additional urothelial lesions.

Anatomy and Histopathology

The male urethra is approximately 22 cm long. The bulbar urethra should be considered part of the proximal segment with the prostatic and membranous urethra because treatment and prognosis is similar. Distal urethral tumors are those occurring in the penile urethra, fossa navicularis, and urethral meatus. Distal tumors have a superior survival rate to proximal tumors and distal tumors and may be more amenable to organ-sparing procedures (1). The difference in survival is thought to be from earlier detection of distal lesions that tend to present with symptoms at smaller size due to the narrower caliber lumen and the ease of self-palpation for the distal urethra.

The prostatic and bulbomembranous urethra are lined with urothelial cells, whereas the penile urethra is lined with pseudostratified columnar epithelium, and the meatus is lined with stratified squamous epithelium.

The proportions of histologic subtypes vary with location. Tumors within the prostatic urethra are almost exclusive UCC, with only 10% of prostatic urethral tumors being SCC, likely from squamous metaplasia in setting of chronic inflammation. Tumors of the bulbomembranous urethra are 80% SCC, 10% UCC, and 10% adenocarcinoma. For the penile urethra, 90% of tumors are SCC and 10% are UCC (7).

Urothelial Carcinoma of the Prostate

Urothelial carcinoma of the prostate represents a separate disease, which is reflected in the fact that there is a unique T staging for UCC of the prostate (Table 41.1). Cases of noninvasive UCC and urothelial carcinoma in situ (CIS) can be managed with a urethra-sparing approach with extensive transurethral resection (TUR) and subsequent bacille Calmette-Guérin (BCG) therapy (1). The addition of TUR with BCG improves freedom from urethral recurrence from 65.7% to 95.3% at median follow-up of 52 months; however, similar rates of overall recurrence are seen when bladder recurrence is considered (8). If prostatic urethra UCC is refractory to conservative treatment, or if stromal invasion is present, then radical cystoprostatectomy with pelvic lymphadenopathy should be performed. Neoadjuvant chemotherapy with methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) may be beneficial particularly if the tumor is locally advanced.

Concomitant urethrectomy at time of cystoprostatectomy for prostatic urethral carcinoma is controversial. Local recurrence within the urethra occurs in between 0.5% and 11.1% of patients with bladder cancer after cystoprostatectomy (7), and UCC of the prostatic urethra increases this risk. Some authors have argued, however, that provided the distal urethral margin is normal at the time of cystoprostatectomy, urethrectomy is not immediately indicated. If the urethra is left in situ, the surveillance after cystectomy is also highly contentious. A complete discussion of this topic is beyond the scope of this chapter.

Alternative Treatments

The primary treatment for urethral carcinoma in men is surgical excision; however, many men may potentially benefit from multimodal therapy. Given the rarity of urethral carcinoma, the optimal treatment paradigm has yet to be established, and patients with urethral carcinoma should be discussed in multidisciplinary team meetings, which involve the participation of urologic oncologists, medical oncologists, radiation oncologists, radiologists, and pathologists. In many situations, management of urethral carcinoma is extrapolated from experiences with other more common tumors (i.e., urethral

UCC with bladder UCC and urethral SCC with anal SCC).

Radiation monotherapy can be used in men who refuse surgery with early-stage distal tumors. Although radiation can be penile-sparing in these select patients, common side effects include skin ulceration, necrosis, and urethral strictures (7). Little is known of the long-term outcomes of this approach, but the risk of new tumor occurrence is present. Radiation is often used as part of multimodal approach for advanced disease in the neoadjuvant and adjuvant setting.

Given the rarity of urethral cancer, little is known regarding the role for adjuvant and neoadjuvant chemotherapy. No consensus exists for the particular regimen, but often, cisplatin, bleomycin, and methotrexate or radiosensitizing 5-fluorouracil and mitomycin C is used for SCC urethral tumors, and MVAC is used for urethral UCC (7).

Case series using definitive chemoradiation have also been reported for advanced urethral carcinoma. The most impressive results come from a series using 5-fluorouracil and mitomycin C with 45 to 55 Gy to the pelvis with a 12 to 15 Gy boost for gross disease. For a group with considerably advanced disease, the outcomes of this series were excellent with a 5-year cancer-specific survival rate of 72% when surgery was used for salvage purposes (9).

Surgical Treatment of Distal Tumors of the Male Urethra

The aggressive nature of urethral carcinoma and the frequent delay in diagnosis results in many patients with advanced disease at the time of initial presentation. Radical surgery is often required for local control. Surgery alone will not be curative in many with advanced disease, which underscores the need for multidisciplinary care.

Compared to proximal lesions, distal tumors have a far more favorable prognosis (10). Organ preservation may be possible in highly selected cases of early-stage tumors in the distal urethra. The objective of penile-sparing surgery is functional preservation (ability to void standing, maintenance of erectile function with adequate length for penetration) and acceptable cosmesis without compromising cancer control. Penile preservation is certainly not appropriate for all cases of urethral carcinoma.

If penile-sparing surgery is considered, accurate staging is even more vital, and an MRI is recommended to ensure corpora cavernosal invasion is not present. If corpora invasion is present, then standard treatment is partial or total penectomy with at least a 2-cm margin. Some authors have suggested a margin of only 5 mm may be adequate for local control, but these results from small case series must be interpreted with caution (1,11). Both partial and total penectomy are described in other chapters in this book.

For penile preservation, urethrectomy is the preferred technique, but local control can be attempted with endoscopic ablation for poor surgical candidates or patients who refuse surgery. As previously described by Zeidman et al. (12), TUR of urethral carcinoma is best performed with an initial cold-cup biopsy followed by complete resection of the tumor on cutting current. Aggressive resection is often preferred; so the catheter is left in place for several days, often with a pericatheter retrograde urethrogram prior to removal. Elective management of small-volume, low-grade tumors can be done with TUR or laser ablation, but the data available with this approach is limited.

Penile-Preserving Anterior Urethrectomy with Perineal Urethrostomy (Fig. 41.1)

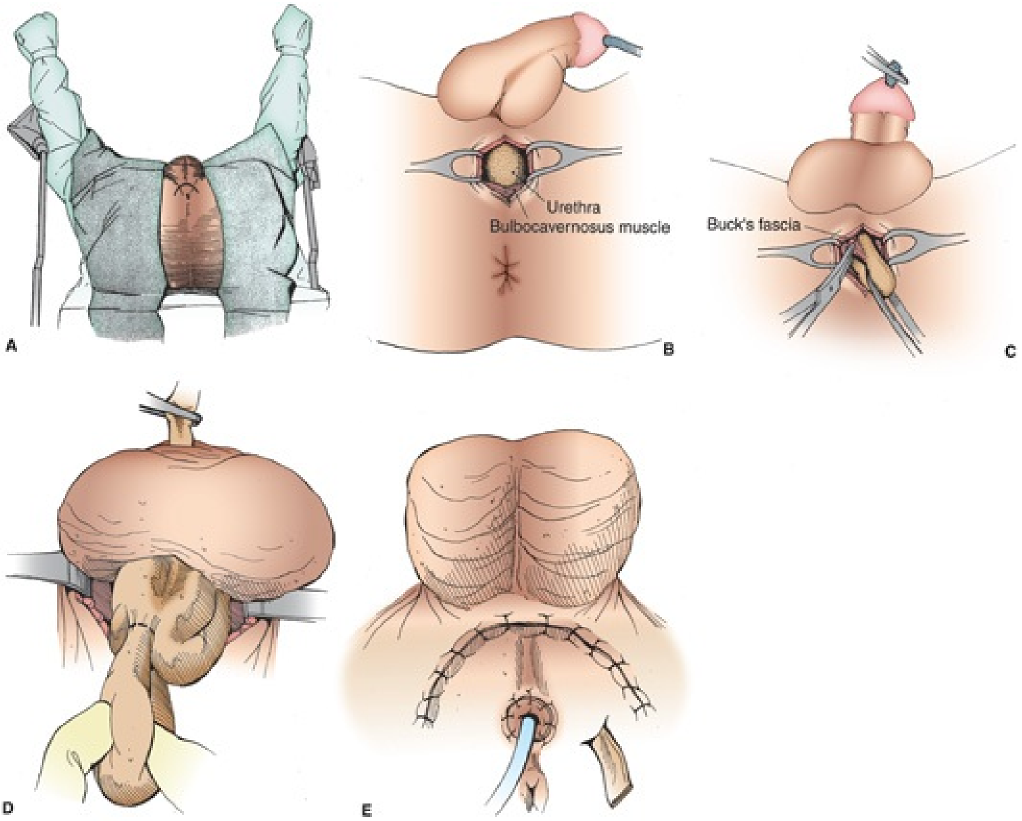

FIGURE 41.1 Technique of Anterior Urethrectomy with Perineal Urethrostomy

Urethrectomy with perineal urethrostomy is appropriate for select patients with tumor confined to the corpora spongiosum for whom a negative margin is achieved in the proximal urethra. Accurate staging with MRI should be done to ensure the absence of corpora invasion.

The patient is positioned in high dorsal lithotomy in “candy cane” stirrups with the hips rocked backward by a sacral bump (a beanbag and Gel-foam pad). Careful attention must be made to adequately pad all pressure points. A 16Fr Foley catheter is used to facilitate dissection of the urethra from the corporal bodies. Tacking stitches may be placed within the scrotal skin on both sides to facilitate exposure of the perineum.

A vertical midline perineal incision is made just below the scrotum and carried downward approximately 5 cm. Alternatively, an inverted U incision can be made with the apex of incision in the midperineum. Dissection using electrocautery is performed through the superficial fascia and fatty tissue until the bulbospongiosus muscle is identified. We prefer a Lone Star ring retractor system be used to facilitate exposure of the bulbar urethra. Using Metzenbaum scissors, the bulbospongiosus muscle is divided to exposure the bulbar urethra. Dissection of the bulbar urethra is continued on both sides using sharp dissection until the urethra is detached from the corpus cavernosum circumferentially. It is during this part of the dissection that the Foley catheter is most helpful in developing the plane between the corpus spongiosum and corpus cavernosum. A Penrose drain can be passed around the urethra and used as a “handle” as the dissection is carried distally to separate the urethra from the corpora. The penis will need to be progressively invaginated into the perineal incision to reach the distal aspects of the resection. As mobilization of the urethra continues distally, it is common for the plane between the urethral spongiosum and corpora to be lost near the fossa navicularis. At this point, the penis is then everted to its regular position and attention is turned to the urethral meatus.

Using a scalpel, an inverted T-shaped incision is made over the glandular urethra (Fig. 41.2). The remaining urethra with a small cuff of glandular tissue is resected until the entire length of the anterior urethra is freed. The urethra is then maneuvered into the perineal incision and amputated at least 2 cm proximal to the tumor. Frozen-section analysis must be performed to confirm that the proximal margin is free of disease. Further resection of the proximal urethra may be needed to ensure a negative margin.

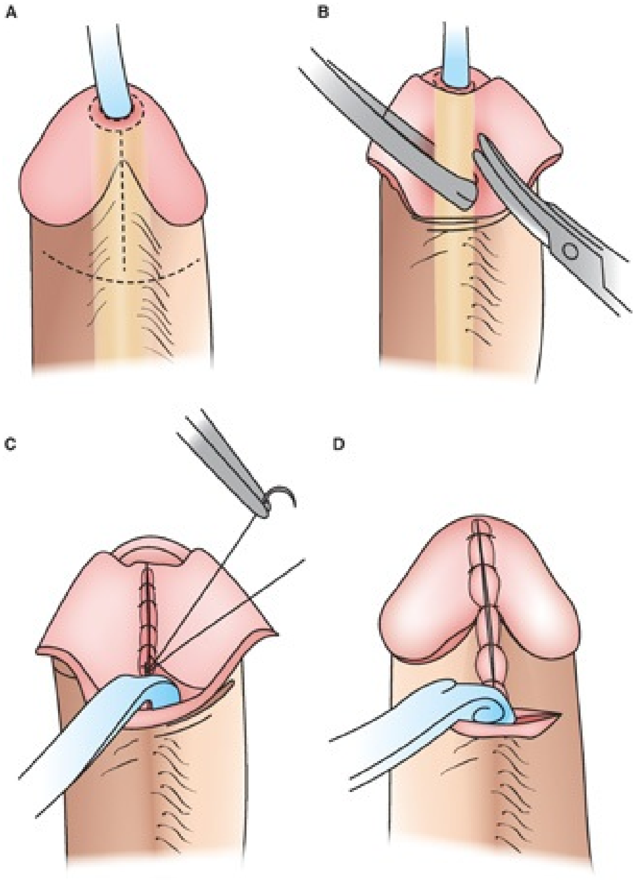

FIGURE 41.2 Distal dissection for urethrectomy.

Attention is then directed to the creation of a perineal urethrostomy. The proximal urethral stump is generously spatulated on its ventral aspect for at least a distance of 1 cm and then sutured to the perineal skin with interrupted 3-0 absorbable suture near the anastomotic apex. The remainder of the urethrocutaneous anastomosis is matured with the placement of equally spaced interrupted 4-0 absorbable sutures. To better preserve the blood supply to the corpus spongiosum, instead of taking full-thickness urethral bites, only the urethral mucosal edge and the adventitial edge are sutured together with the skin edge (13). Because the urethrostomy has a tendency to contract, the opening should be at least 30Fr. After the urethrocutaneous anastomosis is matured, a 20Fr or 22Fr Foley catheter is inserted into the bladder.

The perineal incision is closed in multiple layers with a perineal Penrose drain exiting from a separate stab incision. The Foley catheter is left in place for 7 to 10 days. The urethrostomy is monitored for signs and symptoms suggestive of stenotic changes such as urinary tract infections (UTIs), a low urinary flow rate, or a high postvoid residual urine volume.

Urethral Cancer Recurrence after Radical Cystectomy

Approximately 5% to 10% of patients after radical cystectomy will develop a subsequent urethral recurrence. A similar technique to anterior urethrectomy is used for a total completion urethrectomy for these patients with a history of bladder cancer who develop urethral cancer recurrence after treatment with radical cystoprostatectomy. The anterior urethra is completely mobilized from the corpora cavernosa as previously described; however, instead of creation of a perineal urethrostomy, the urethra is dissected proximally to the level of the urogenital diaphragm. The urethral hiatus within the diaphragm will need to be enlarged carefully to ensure the entire urethra is excised en bloc without injury to nearby neurovascular bundle (if nerve sparing was achieved at time of cystectomy).

Cautious dissection must also be performed because bowel is frequently present just superior to the urogenital diaphragm, and adhesions are not uncommon following cystectomy. The bulbourethral arteries will be encountered posterior to the bulbar urethra at the 4 and 8 o'clock position.

Partial Urethrectomy

For truly distal lesions, a partial urethrectomy could be performed to avoid a perineal urethrostomy and potentially allow a patient to stand to void. Adequate urethral length must be possible after resection or if a future reconstruction is planned; otherwise, it is better to proceed with a perineal urethrostomy. If considering a partial urethrectomy, it is important to ensure there are no more proximal tumors on cystourethroscopy.

With the patient in the supine position, a circumferential incision is made just beneath the corona and the penis is "degloved" along Buck fascia. Using a scalpel, the distal urethra with corpus spongiosum is excised along with a small cuff of glandular tissue. Frozen-section analysis must be performed to ensure the proximal urethra is disease-free. If negative margins are unable to be achieved, then an anterior urethrectomy, glansectomy, or partial penectomy should be performed to provide appropriate local control. In most cases in which negative margins are achievable, a penile urethrostomy is created. Depending on length of urethral defect, this can be left as a hypospadiac meatus or repaired at a later time using the same principles of a two stage urethroplasty for urethral stricture disease (14). It is prudent to wait at least 1 year prior to reconstructive surgery to confirm a recurrence-free state. Techniques of urethroplasty are described elsewhere in this book.

Surgical Treatment of Proximal Tumors of the Male Urethra

Most tumors of the proximal urethra are at a more advanced stage on initial presentation. Rarely there is a patient who is appropriate for endoscopic resection or segmental urethral excision with end-to-end anastomosis. For most cases of posterior urethral carcinoma, radical extirpative surgery is required to achieve disease control. Multidisciplinary care is highly encouraged to determine the role for chemotherapy and radiation therapy in individual patients.

Surgical treatment typically requires radical cystoprostatectomy with total urethrectomy or total penectomy, along with pelvic lymphadenectomy. If locally advanced, pubic rami resection and the adjacent urogenital diaphragm can be excised for wider margins to improve local control. This can be a morbid undertaking but provides the patient with the best opportunity for cure. The assistance of a plastic surgeon may be required for pelvic reconstruction usually with a myocutaneous flap, such as a gracilis muscle flap.

Bladder-sparing extirpative procedures have been described in carefully selected patients with tumors that do not involve the bladder neck. Bladder sparing requires closing the bladder neck with the creation of a catheterizable or noncontinent small bowel efferent limb (Monti procedure) to the abdominal wall or a permanent suprapubic tube. Any benefit of avoiding ureteroenteric anastomosis is, however, offset by the difficulties associated with bladder neck closure, particularly in irradiated patients or those who may require adjuvant or salvage pelvic radiation given the high risk of recurrence with surgery alone. The experience with radical urethrectomy and creation of continent catheterizable stoma is more robust and accepted in women with urethral carcinoma (15) and is further discussed in the following section.

Radical Cystoprostatectomy with En Bloc Urethrectomy

Our preoperative preparation is the same as we do for a radical cystectomy for bladder cancer. This consists of a clear liquid diet and oral magnesium citrate the day prior to surgery. Broad-spectrum antibiotics are given before incision to cover gram-positive, gram-negative, and anaerobic bacteria. Perioperative antibiotics are usually continued for 24 hours after surgery. Prophylactic subcutaneous heparin is given prior to induction of anesthesia and is continued throughout hospital stay along with early ambulation for thromboembolic prevention.

The patient is positioned in the low lithotomy position to allow simultaneous access to the abdomen and perineum. A two-team approach may be used to reduce operative time. The abdominal portion of the procedure is begun first via a vertical midline incision between the umbilicus and the pubis. The preperitoneal space is developed bluntly, and the bladder is mobilized in the usual fashion of a radical cystectomy, with the exception of the preservation of the puboprostatic ligaments. Fixed retraction with a Bookwalter device is used. Extended pelvic lymphadenectomy is performed from above the bifurcation of the iliac vessels to the node of Cloquet. Nodal packets are sent for permanent pathologic examination.

Next, the peritoneum is entered, the abdomen explored, and the bowel packed clear of the pelvis. Similar to a radical cystectomy for bladder cancer, the bladder is further mobilized and the ureters are divided as distal as possible while sparing as much periureteral tissue as possible. Frozen sections of the distal ureter should be sent to verify the absence of urothelial CIS. Dissection of the prostate is performed in an antegrade fashion without division of the puboprostatic ligaments, in the event en bloc resection of the pubis is required. Please see the chapter on cystoprostatectomy for a complete description of this surgical technique.

With the bladder and prostate widely mobilized, attention is directed to the perineal dissection (Fig. 41.3). An inverted U incision should be made with the apex of incision in the midperineum extending out to the ischial tuberosities to allow for the wide dissection often required to achieve negative margins. Deeper fixed retraction with an Omni-Tract or Thompson perineal retractor may be of benefit. Dissection is carried through the fascia and fatty tissue of the perineum. Blunt dissection is performed within the bilateral ischiorectal fossae, which are connected medially so that a tunnel anterior to rectum is developed beneath the central tendon in a similar fashion to a radical perineal prostatectomy. The central tendon is divided with electrocautery, followed by dissection of the rectourethralis muscle. With continued dissection, the rectum should be safely mobilized and the communication with the abdominal portion of the dissection should start to come into view. It is advisable to assess for unrecognized rectal injuries by inserting a finger into the rectum.

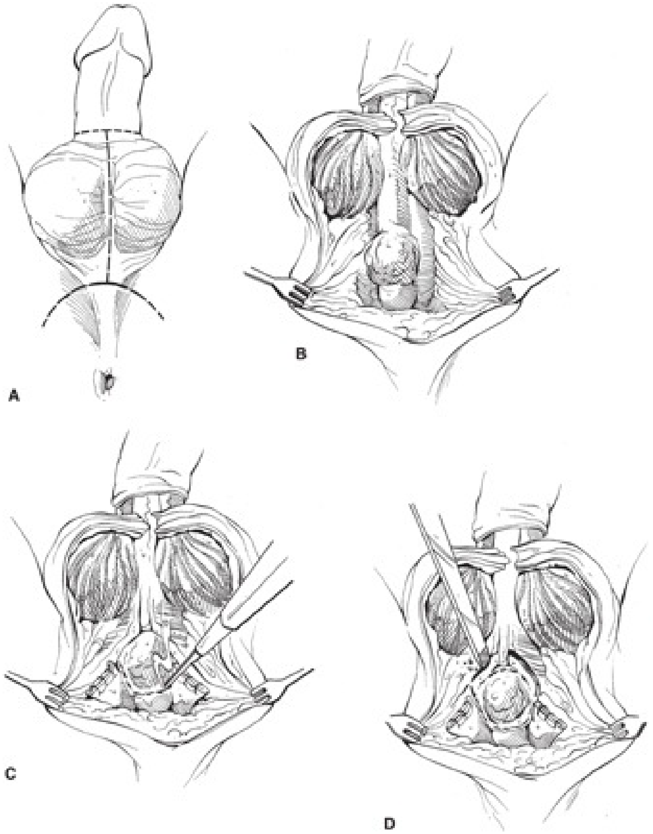

FIGURE 41.3 Perineal portion of radical cystoprostatectomy with en bloc penectomy and inferior pubectomy. **A and B:** Incision used to gain access to the perineum for total penectomy, total urethrectomy, radical cystoprostatectomy, and cutaneous urinary diversion. **C:** Electrocautery and suture ligatures are used to resect the urethral mass. **D:** If pubic bone invasion is present, the public arch is first scored with electrocautery; then, an orthopedic hammer and chisel are used to resect the inferior public arch to ensure a negative margin.

If total penectomy is required, the penile cura are dissected off their origin beneath the inferior pubic rami, and the division of the suspensory ligament further mobilizes the penis. The scrotum can be incised along the median raphe for increased exposure. If the tumor is invasive into the surrounding tissue, portions of the scrotum or perineal skin can be excised. Superficial thigh pouches can be created for the testicles if required.

It should also be determined if the inferior pubic rami needs to be resected en bloc to achieve negative margins. If so, orthopedic consultation is warranted. If only superficial involvement with tumor is present, only resection of the periosteum with electrocautery may be required. Deeper involvement of the pubic bone will require removal of the inferior portion of the pubic arch with orthopedic rongeurs, osteotome, reciprocating motor saw, or a Gigli saw. With the penis free, a negative surgical margin on the pubic arch and the cystoprostatectomy completed, the entire specimen is removed en bloc.

If pubectomy and penectomy are not required to achieve negative margins, then attention is given to mobilizing the membranous urethra from the urogenital diaphragm via the abdominal dissection using sharp and blunt technique. The puboprostatic ligaments are generally divided at this time, and control of the dorsal venous complex will need to be obtained. If penile preservation is attempted with the intention of nerve sparing, then electrocautery should be minimized at this point, as the neurovascular bundle runs posterolateral to the urethra. Once the entire cystoprostatectomy specimen with very proximal urethra is mobilized, anterior urethrectomy is completed via the perineal incision as described earlier. The specimen is removed en bloc (Fig. 41.4). Frozen sections should be sent to determine if addition resection is required.

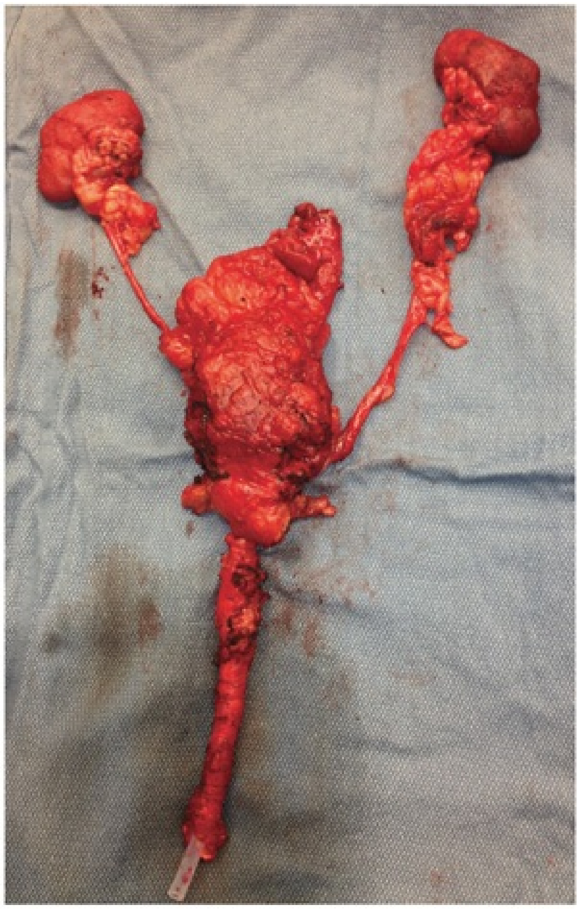

FIGURE 41.4 Radical Cystoprostatectomy with En Bloc Urethrectomy for proximal urethral adenocarcinoma. This patient was already on hemodialysis for end stage renal disease therefore bilateral nephroureterectomy was also performed

After the extirpative portion of the procedure is complete, a continent or noncontinent cutaneous urinary diversion is created depending on the individual patient. A complete discussion of the various types of urinary diversions is beyond the scope of this chapter but is covered in detail in other chapters within this book.

In the event of a large perineal defect after resection, consultation with a plastic surgeon is advisable because patients may benefit from a myocutaneous flap, such as a gracilis muscle flap. If only a small perineal defect is present and the perineal incision can be closed primarily, then thick skin flaps should be mobilized without undermining the cutaneous perforators to preserve a good vascular supply to the skin flap.

A least one perineal and one abdominal Jackson-Pratt drains should be used and brought out through a stab incision. The abdominal drain should be in close proximity to the ureteroenteric anastomoses. The superficial perineal fascia, deep dermis, and skin are closed with a running absorbable suture.

Complications

Major complications are uncommon after anterior urethrectomy, but perineal hematoma and superficial wound infections can occur. In addition, if pressure points are not properly padded in the lithotomy position, then peroneal nerve palsies or compartment syndrome can occur.

Complications from radical cystoprostatectomy with en bloc urethrectomy are common and are largely attributed to the morbidity associated with cystectomy and urinary diversion. Please refer to those chapters for a detailed discussion of those complications.

Resection of inferior pubis increases the risk of bleeding and stress urinary incontinence. Pelvic instability is typically minimal, as the superior pubic rami are usually enough to provide adequate support.

URETHRAL CARCINOMA IN WOMEN

Epidemiology, Etiology, and Risk Factors

Urethral carcinoma is an uncommon cancer in women. Like in men, the peak incidence of urethral carcinoma for women is in the eighth decade of life, and the tumor is also exceedingly rare before the age of 55 years. Also similar to men, the majority of women with urethral carcinoma are symptomatic at presentation (approximately 95% of patients). Symptoms of urethral carcinoma in women include irritative voiding, urinary obstruction, hematuria, a palpable urethral or anterior vaginal mass, and dyspareunia. Because the symptoms of urethral carcinoma overlap with many symptoms of benign diseases (urethral diverticula, caruncles, and urethral stenosis), there is often a delay in presentation of over 3 to 4 months (16). Symptoms, which do not respond to conservative measures, should be investigated to rule out a urethral cancer.

Few epidemiologic studies exist to completely understand the pathogenesis of the disease, but chronic inflammation, tobacco exposure, HPV infection, and recurrent UTIs have all been implicated. Unique to women is the development of carcinoma within a urethral diverticulum, although this is rare overall (1).

Diagnosis and Staging

A complete pelvic examination must be performed for a patient with suspected urethral cancer. Not only should the entire length of the urethra be inspected with palpation but a bimanual examination and rectal exam should also be performed. Other gynecologic and colorectal malignancies, which are often more common than urethral carcinoma, must be ruled out. If the tumor appears locally advanced and likely to require extensive resection, then preoperative plastic surgery consultation would be beneficial.

The drainage of the female urethra is similar to that in men; therefore, palpation of bilateral inguinal lymph nodes must also be done. The 15% to 30% of patients with urethral cancer will have nodal involvement at initial presentation (1).

Just as in men, cystourethroscopy should be performed to assess tumor extent and location with cold-cup biopsies or TUR to determine tumor histology. Biopsies distal and proximal to the tumor can provide useful information if organ-sparing surgery is considered. Complete cystoscopy examination to rule out concomitant bladder tumors is also mandatory. If bladder sparing is considered, it is important to also determine the distance of the tumor from the external sphincter and the bladder neck. The location of the ureteral orifices should also be noted along with a cystoscopic estimate of the bladder capacity.

Just as in men, MRI gives better information on soft tissue involvement and tissue planes over CT scan; therefore, MRI is beneficial to determine the depth of invasion of the tumor and to detect involvement of adjacent organs and structures in women. Some advocate for the usage of a transvaginal MRI coil. MRI or CT scan of the abdomen and pelvis should be performed to detect regional lymph node involvement. In the absence of lymph node involvement, a chest X-ray alone is adequate for staging. A bone scan is only required if signs or symptoms of bony metastasis are present.

Anatomy and Histopathology

The female urethra is 3 to 4 cm long from bladder neck to vaginal vestibule. It is arbitrarily divided into the proximal one-third (composed of urothelial cells and columnar squamous cells) and the distal two-thirds (composed of stratified squamous epithelium) (17). Similar in men, tumors in the distal female urethra have more favorable prognosis than proximal tumors (4). Tumor stage and nodal involvement are primary determinants of prognosis (4).

Although SCC was historically thought to be most common subtype of urethral carcinoma in females (18), it appears that UCC accounts for 30% to 45% of cases of urethral cancer, adenocarcinoma for 29%, and SCC for only 19% to 28% (1). The remaining 5% to 6% of urethral carcinoma are of various types including melanoma, sarcoma, etc. (1).

Patients with UCC of the urethra should be viewed as having a “field defect” within the lower urinary tract. We believe patients with invasive urethral UCC should not be candidates for urethral or bladder-sparing procedures and are best treated with radical cystourethrectomy. Cross-sectional upper tract imaging should also be obtained.

Alternative Treatments

As with men, the optimal management approach has yet to be established for women. Individual cases of urethral carcinoma should be discussed in multidisciplinary team meetings.

Distal urethral tumors have a more favorable prognosis and may be amenable to urethral sparing. Although the primary management of urethral carcinoma in men is usually surgery, radiotherapy is more often used in the treatment of female urethral carcinoma.

The most promising results for radiation therapy have been with a combination approach involving external beam radiotherapy and brachytherapy. A 5-year survival rate of 77% has been reported with combination radiotherapy, which is comparable to surgical series (16). Complications from radiation include urethral, vaginal, and rectal stenosis; fistula formation; cystitis; hemorrhage; and necrosis.

Urethra sparing with minimally invasive approaches, such as neodymium or holmium:YAG lasers, have also been reported but is discouraged in guideline discussion because of the high rate of local failure and the poor cancer-specific survival (1).

For more advanced urethral tumors, the failure of single-arm therapies to improve long-term outcomes has led to an interest in multimodal approaches. Although no optimal strategy yet exists, improved local control over surgery alone has been shown in most series looking at adjuvant radiation and neoadjuvant radiation (19). Neoadjuvant or adjuvant chemotherapy is used in patients with advanced disease, but this is guided by extrapolation from other cancers.

Surgical Treatment of Distal Tumors of the Female Urethra

Distal Urethrectomy

Tumors involving the distal third of the urethra, and especially those of the urethral meatus, are amenable to a distal urethrectomy. These patients and tumors must be carefully selected. Distal urethrectomy should be reserved for low stage ≤T2 tumors that are far enough distally from the external urinary sphincter that a safe margin of approximately 1 cm can be excised without jeopardizing urinary continence.

The patient is placed in high lithotomy position with the perineum at the end of the operating room table. After preparation and draping, visualization of the vaginal introitus is improved with the use of a weighted vaginal speculum, silk retraction suture for the labia, and a Lone Star retraction device. Trendelenburg position also improves visualization of the anterior vagina. A 16Fr Foley catheter is inserted to improve palpation and localization of the urethra and tumor during dissection.

The procedure is initiated with a circumcising incision around the urethral meatus (Fig. 41.5). The objective is to dissect out a full-thickness tissue plane of distal urethra from the surrounding tissue and achieve a negative margin. Grasping the urethral tissue with an Allis clamp allows for retraction and manipulation during dissection. The epithelium of the anterior vaginal wall can be incorporated en bloc in the posterior urethral dissection to ensure margins will be negative. With the use of the Foley catheter as a guide, both electrocautery and sharp dissection is used to free the urethra circumferentially. When adequate proximal dissection to allow at least a 1 cm surgical margin is completed, the Foley catheter is removed and the urethra is tied off to avoid any inadvertent tumor spillage. The distal urethra is then transected and the proximal urethral margin is sent for a frozen-section analysis. The placement of stay sutures into the proximal urethra can prevent migration out of the operative field.

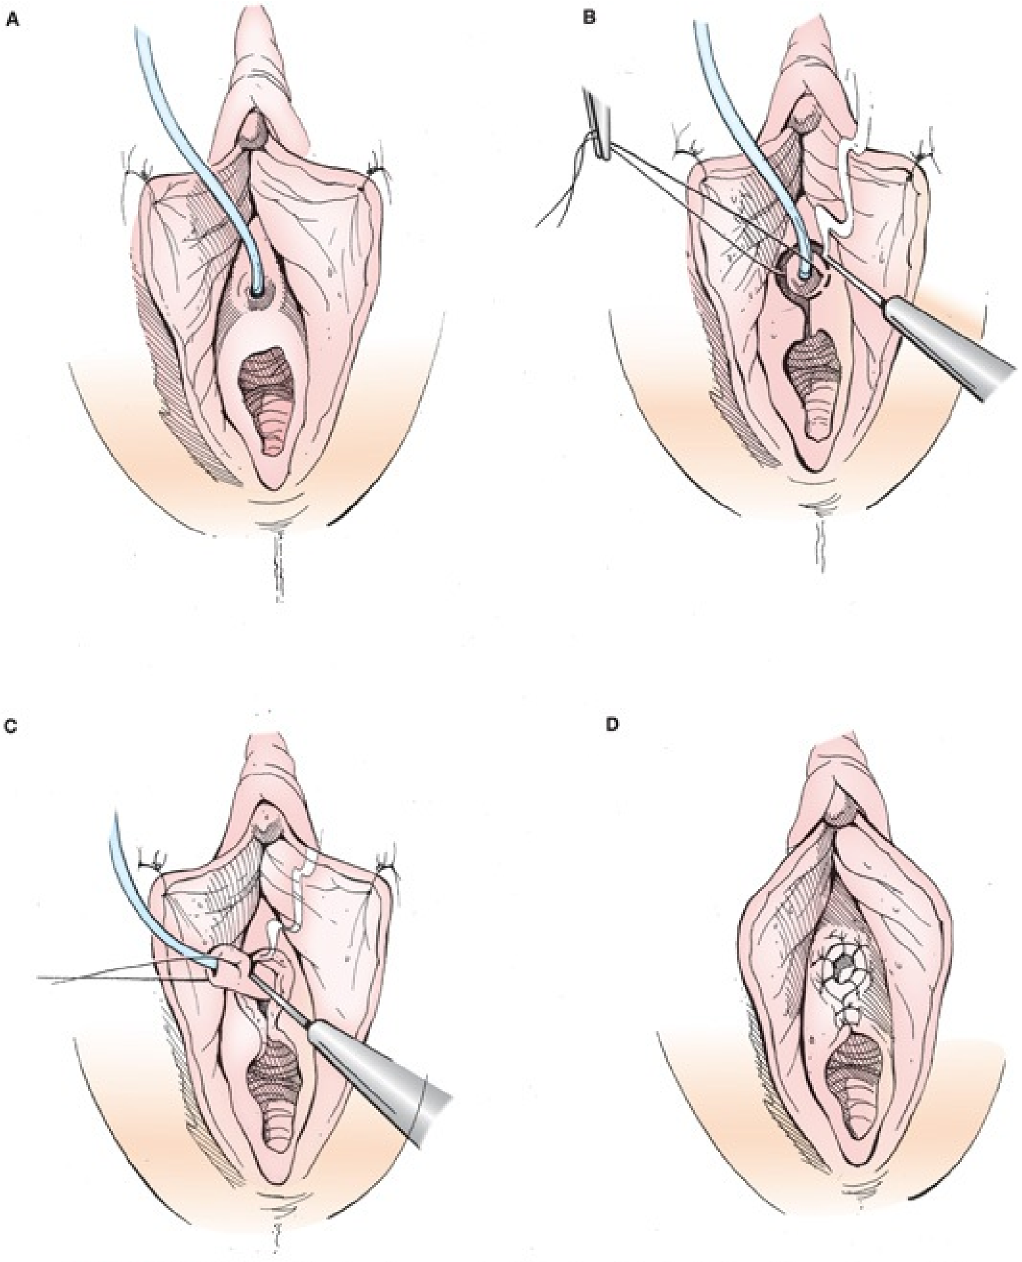

FIGURE 41.5 Technique of distal urethrectomy. **A and B:** A circumcising incision is made around the urethral meatus. **C:** The urethra is dissected free circumferentially to obtain at least a 1 cm surgical margin. **D:** The urethral stump is re-approximated to the edges of the vaginal incision with interrupted absorbable suture.

Next, the urethral stump is reapproximated to the edges of the vaginal incision with interrupted 3-0 Vicryl or other absorbable suture. The urethral stenosis can be prevented with the creation of wide neomeatus through spatulation of the ventral urethra. A new 16Fr Foley catheter should easily be inserted. The vaginal wall is then closed in two layers with 3-0 Vicryl sutures. Vaginal packing is placed and removed the following morning. The Foley catheter is removed in 7 days.

Distal urethrectomy does have a higher rate of recurrence (21%) but has an acceptable 5-year survival rate of 80% (15,16). The most common complications are urinary incontinence and meatal stenosis (15). Meatal stenosis should be minimized by adequate urethral spatulation. Urinary incontinence may be amenable to a urethral sling placed at a later time (16).

Radical Urethrectomy with Bladder Preservation

The high rate of local recurrence after distal urethrectomy can be reduced by radical urethrectomy with bladder sparing for distal urethral tumors not involving the bladder neck (15). Radical urethrectomy is certainly more appropriate than distal urethrectomy for larger tumors, but no comparisons against radical cystectomy exist.

With radical urethrectomy, all periurethral tissue up to pubic symphysis should be removed. Following resection of the diseased urethra, the bladder neck is closed and a urinary diversion is created (Fig 41.6). The diversion selected can be continent, such as a Monti procedure, or noncontinent, such as an ileovesicostomy. Because bowel is used for these diversions, the major gastrointestinal morbidity of a radical cystectomy is not avoided with this approach. Only the ureteroenteric anastomoses are avoided, but at a trade-off of bladder neck closure complications and unknown oncologic efficiency, because no comparisons between radical urethrectomy and radical cystectomy exist (20). A possible alternative is to use a permanent suprapubic tube as the urinary diversion, which avoids an intestinal resection and an abdominal incision if negative margins can safely be achieved through a vaginal approach only.

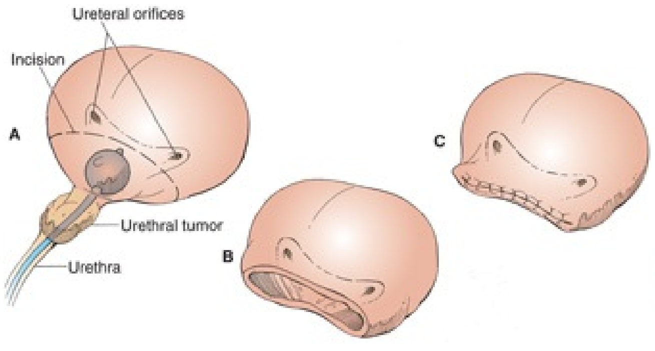

FIGURE 41.6 Technique of urethrectomy and bladder preservation by excision of the tumor at the level of the bladder neck, with subsequent bladder neck closure.

Radical urethrectomy with bladder preservation usually requires both an abdominal and vaginal approach. A simultaneous two-team approach may be used to reduce operative time. The patient is positioned in low lithotomy position. Prior to incision, cystoscopy is performed for additional confirmation that the bladder neck is uninvolved with tumor and for placement of bilateral ureteral catheters for later identification.

Abdominal exploration is begun through a lower midline incision. Pelvic lymphadenectomy can be performed at the start with lymph nodes sent for frozen-section analysis. Attention is then turned to mobilizing the bladder via dissection of the lateral pedicles and with incision of the endopelvic fascia, similar to a radical cystectomy. The urogenital diaphragm attachments to the urethra at the pelvic floor are excised with the use of electrocautery. The uterus and ovaries can be preserved if desired. Once sufficient mobilization of the bladder neck is achieved, attention is turned to the vaginal portion of the procedure.

The vaginal approach for a radical urethrectomy is the same as that described in the "Distal Urethrectomy" section except that dissection is continued proximally as high as possible. Because a radical urethrectomy is used for larger distal tumors, it is important to excise all periurethral tissues to ensure negative margins. As the abdominal and vaginal dissections meet, the pubourethral ligaments are divided to allow for en bloc removal of the entire urethra, anterior vaginal wall, and distal bladder neck.

Through the abdominal incision, the bladder neck is opened along its anterior surface. The ureteral orifices are identified with assistance of the ureteral catheters that were previously placed or placed at this point if cystoscopy was not done. At a safe distance distally from the ureteral orifices, the bladder neck is transected to allow for en bloc removal of the specimen. A frozen-section analysis should be taken from the bladder neck margin, and if positive, radical cystectomy should be done.

If the bladder neck margin is uninvolved with tumor, then the continent urinary division is created and the bladder neck is closed with running absorbable suture (see Fig. 41.5). A second additional layer of imbricating Lembert sutures for the bladder neck closure may be beneficial. An omental flap can be harvested to cover the suture line as an omental interposition to prevent fistula formation.

Several urinary divisions are possible for lower urinary tract reconstruction and a complete discussion of them is beyond the scope of this chapter, but readers are encouraged to review those chapters. After the abdominal stoma is matured, the vaginal defect is closed in two layers with absorbable suture. If a large vaginal wall defect is present, a regional flap may be necessary and consultation with a plastic surgeon is beneficial.

A 14Fr or 16Fr catheter should be traversing the stoma, a 20Fr or 22Fr suprapubic tube should be placed with at least one Jackson-Pratt drain near the bladder neck closure and omental interposition. Vaginal packing is placed and removed the following morning.

Surgical Treatment of Proximal Tumors of the Female Urethra

For patients with UCC, large tumors, or tumors involving the bladder base, anterior pelvic exenteration is indicated. Radical cystourethrectomy, pelvic lymph node dissection, and urinary diversion are performed in the standard fashion and are described in detail in other portions of this book. If the urethral tumor is large, then wide resection of anterior and lateral vaginal walls may be required. Similarly, en bloc resection of vulvar tissue may also be required to achieve negative margins (16). If inferior pubic rami resection is required, then the assistance of an orthopedic surgeon will be needed. Plastic surgeon consultation will also likely be needed for reconstruction of the pelvic floor for large resections.

Complications from radical cystourethrectomy are discussed in detail within the corresponding chapter, but common complications include wound infection and dehiscence, deep vein thrombosis/pulmonary embolism, and ileus/small bowel obstruction.

MANAGEMENT OF LYMPH NODES IN MEN AND WOMEN

In general, lymphatic drainage of proximal urethra is similar to bladder, which drains to obturator, iliacs, and presacral nodes for both males and females. The distal urethra drains to the superficial inguinal nodes followed by the deep inguinal and external iliac nodes. This is a similar pattern to penile SCC and vulvar cancer. Unlike penile cancer, enlarged inguinal lymph nodes are usually from metastatic spread and not from inflammation or infection (1). Between 15% and 30% of patients will present with nodal involvement, although palpable disease is not always present.

For both men and women, ilioinguinal lymphadectomy is indicated for clinically positive nodes without evidence of distant spread. The role for prophylactic inguinal lymphadectomy has yet to be established for urethral cancer (1).

ACKNOWLEDGMENTS

We would like to acknowledge the authors of the corresponding chapters in the previous edition of this book, Dr. Peter L. Steinberg and Dr. William Bihrle, whose work we have built on.

CHAPTER 42 INJECTABLE THERAPIES FOR INCONTINENCE IN WOMEN

STEPHEN MOCK, MELISSA R. KAUFMAN, W. STUART REYNOLDS, AND ROGER R.

Injecting material into the wall of the urethra to bulk the submucosal tissue layer, increase urethral resistance, and improve urethral coaptation is nothing new. Initially described in 1938, Murless et al. (1) reported on 22 women who had either morrhuate sodium or cod liver oil injected into the anterior vaginal wall to provoke an inflammatory response resulting in scar formation and contracture of tissue around the urethra. Seventeen patients reported being cured or improved, but pulmonary infarction and cardiopulmonary arrest were reported (1). In 1955, Quackels (2) reported on the first injections into the urethra using paraffin wax. Two patients were treated successfully without complications. In 1963, Sachse (3) used Dondren, a sclerosing agent, to treat 7 women and 24 men. Four women and 12 men were reported as cured, but several patients experienced pulmonary embolism (3). In the 1970s and 1980s, polytetrafluoroethylene (PTFE; Teflon) was used extensively (4) but was never approved for use in the United States, owing to safety concerns including distant particulate migration and foreign body reaction (5). Autologous fat was studied and in a randomized double-blind controlled trial of women with urethral hypermobility was found to be as effective as the saline control group at 6 months (6). Additionally, serious adverse events including systemic embolization and death have been reported (7,8). Ethylene vinyl alcohol copolymer (Tegress), a permanent, hypoallergenic, nonimmunogenic implant, demonstrated equivalence in outcomes with collagen (9,10) and was approved by the U.S. Food and Drug Administration (FDA) in 2004. However, the high rate of urethral erosion, although generally self-limited with spontaneous resolution, contributed to bothersome dysuria and necessitated multiple office visits (11), and as a result, the manufacturer voluntarily withdrew Tegress from the market in 2007. As illustrated, these bulking agents were far from ideal. Such an ideal agent would be nonimmunogenic; hypoallergenic; biocompatible; permanent; nonerosive; heal with minimal fibrosis; be nonmigratory; easily stored, handled, and injected; painless; and retain its bulking effect over a long period of time (be durable) (12,13). The components of the agent should not separate or dissociate on injection, and if the agent contains microcrystalline or micropolyermic components, they should be reasonably uniform spheres of particle sizes above 110 μm so as to minimize the risk of migration. If the substance used is not successful, it should not interfere with subsequent surgical intervention (12). To date, no agent has satisfied all these requirements, and the search continues for improved materials and modes of delivery.

MECHANISM OF ACTION

Injectable agents work by forming a “hermetic seal” through restoration of mucosal coaptation during the storage phase and maintain this coaptation during periods of increased abdominal pressure. It is generally thought that these agents improve intrinsic sphincter function, as evidenced by an increase in postinjection abdominal leak point pressure (ALPP), which is the amount of abdominal pressure necessary to overcome the bladder’s continence mechanism (14). They have several advantages over surgical procedures in treating stress urinary incontinence (SUI). Compared to surgical procedures that create a functional obstruction, injectable agents restore continence by increasing urethral resistance at rest. With bulking agents, the urethra maintains its ability to funnel and open, keeping urethral resistance low during micturition. This spares a resultant increase in detrusor pressure, which could lead to overactive bladder symptoms and/or upper tract damage. In comparison, surgical procedures may result in increased resistance at rest and during micturition by not allowing the urethra the same physiologic movement. Most bulking agents are placed at the level of the bladder neck within the smooth muscle in the area of the continence mechanism. Since the placement is within the urethra, *intraurethral* is a more accurate term than the commonly used terms *periurethral* or *submucosal*.

CRITERIA FOR SELECTION

Traditionally, intraurethral bulking agents were reserved for women who have SUI due to intrinsic sphincter deficiency (ISD), a normal contractile bladder, and limited urethral mobility (<30 degree change in axis on cotton swab test from rest to strain). However, multiple reports have demonstrated clinical efficacy in patients with urethral hypermobility. In one study, both those with and without hypermobility had equal success, although more injections and a greater amount of material were injected in the group with urethral hypermobility (15). In a later study by Herschorn and Radomski (16), no statistically significant difference was found between those with and without urethral hypermobility. Over time, 72% remained dry at 1 year, 57% at 2 years, and 45% at 3 years, with no significant difference between the type of incontinence and time to failure. Others have documented similar findings (17–20).

Currently, good candidates for bulking agents include those who are poor surgical candidates and are at high anesthetic risk, are elderly and at greater risk of retention after a sling procedure, must continue anticoagulation at all times, are unable to follow postoperative activity limitations required after anti-incontinence procedures, are young and desire more children in the future, have mild persistent SUI after an anti-incontinence procedure, have SUI and poor bladder emptying, have mild SUI associated with exercise, do not wish to undergo more invasive procedures, and are willing to accept an improvement rather than a cure of their SUI symptoms (13). Patients must understand that efficacy and duration of these agents are inferior to surgery and follow-up injections may be required.

Urodynamics should be performed to rule out other causes of urinary incontinence, such as detrusor overactivity. Urethral function can be assessed by measuring the ALPP, and the definition of ISD by ALPP has varied from a low ALPP (60 cm H_2O) to an ALPP <100 cm H_2O. An absolute value for ALPP suggesting ISD has become unimportant due to limitations in urodynamic testing as well as different values used by different clinicians. With videourodynamics, radiographic evidence of an open bladder neck and proximal urethra without detrusor contraction during the storage phase of the bladder is felt to imply ISD.

As more is understood about the continence mechanism, it appears that most women with SUI have some component of ISD, since there are numerous women with urethral hypermobility who do not leak with significant intra-abdominal pressures. Women who do have a fixed, nonmobile urethra are, however, more likely to have a greater degree of ISD (21). Exclusion criteria for intraurethral bulking would include urinary incontinence due to abnormal detrusor contractions, active urinary tract infection (UTI), or allergy to the material used as a bulking agent.

Key Concepts

- *Ideal patients for intraurethral bulking have SUI due to ISD, a normally contractile bladder, and urethral mobility less than 30 degrees.*
- *The efficacy and duration of bulking agents are inferior to surgery and follow-up injections*

may be required.

- *Most women with SUI have depressed ALPP and some components of ISD.*

INJECTION TECHNIQUES

Bulking agents are generally administered with cystoscopic assistance under local anesthesia. The two most accepted techniques are periurethral and transurethral and both are retrograde suburothelial approaches. The transurethral approach is more commonly performed today. Antegrade placement has also been described but is rarely used today because it necessitates suprapubic access. Precise placement of the bulking material into the wall of the proximal urethra near the bladder neck in the area of the continence mechanism is of the utmost importance. The plane of delivery, the tissue quality at the injection site, and the cause of incontinence are all important factors in successful therapy. If material is delivered too distally, the treatment is likely to fail and may cause irritative voiding symptoms. Prior to injection, patients are placed in lithotomy position and prepared in standard sterile fashion. Preoperative and postoperative antibiotics are frequently administered. A local anesthetic in the form of 20% benzocaine ointment or cream may be applied to the vestibule covering the urethra, and a topical 2% lidocaine jelly may be applied to the urethra. Perimeatal blebs are raised with 1% or 2% lidocaine at the 3 and 9 o'clock or 4 and 8 o'clock positions 3 to 4 mm lateral to the urethral meatus using a 25-gauge needle and then, approximately 4 mL of 1% or 2% lidocaine is injected periurethrally.

Key Concepts

- *Precise placement of the bulking material into the wall of the proximal urethra near the bladder neck in the area of the continence mechanism is of the utmost importance.*

TRANSURETHRAL INJECTION

The transurethral technique consists of the bulking agent injected submucosally via a needle inserted through a conventional cystourethroscope under direct vision (22). Endoscopic instrument companies have an array of equipment designed for transurethral injections. The needle size depends on the viscosity of the agent, and some require special ratcheted injection guns to generate enough pressure to overcome this viscosity. A 0-, 12-, or 30-degree lens is best for providing a good view of the urethra as well as the injection needle. Once the cystourethroscope is placed into the urethra and passed into the bladder, the bladder is usually drained because the patient's bladder may become distended toward the end of the procedure. The endoscope is then backed to the midurethra, at which time the needle can be deployed. Injections have been described at different locations (e.g., 3 and 9 o'clock; 4 and 8 o'clock) such that coaptation, either horizontal or concentric, is achieved. For the initial injection, the 6 o'clock position is often an ideal starting point. The distance from the point of penetration of the urethra to the bladder neck has to be greater than the length of the needle to prevent extravasation of the agent into the bladder. The needle is then inserted submucosally into the urethral muscle beyond the midurethra and advanced to the proximal urethra near the bladder neck. Once the desired positioning is achieved, the bulking agent is slowly delivered to allow it to spread underneath the urethral mucosa. Once the mucosa on that side has expanded to the midline, the needle is slowly withdrawn while injecting. In general, the amount of material needed is the amount that achieves complete coaptation. Of note, once this point is reached, the cystoscope should not be advance past the bulked-up urethra and bladder neck so as to avoid possibly compressing or causing extravasation of the injected agent.

Key Concepts

- *Injections have been described at different locations (e.g., 3 and 9 o’clock; 4 and 8 o’clock) such that coaptation, either horizontal or concentric, is achieved.*
- *In general, the amount of material needed is the amount that achieves complete coaptation.*

PERIURETHRAL INJECTION

Injections may also be performed periurethrally via a needle placed percutaneously lateral to the urethral meatus and parallel to the urethra. While the needle is placed, the urethra is visualized through a cystourethroscope (23). Localization of the needle tip may be facilitated by preinjecting the urethra with methylene blue during the periurethral approach (24). With the periurethral approach, there is often less bleeding, which can improve visualization. There is also less extrusion of the material injected, although this also depends on the type of material injected. The desired amount of coaptation is the same as when performed via a transurethral technique. After the periurethral block, a 20-gauge spinal needle is placed at the 3 or 4 o’clock position into the periurethral tissue within the lamina propria. Urethroscopy is then performed as the needle is further inserted with minimal resistance up to the level of the bladder neck. The surgeon can hold the cystoscope in one hand and advance the needle with the other, but in our experience, an assistant is beneficial. The needle is then rocked in a horizontal plane to assess the location of the needle tip and ensure placement at the proper depth. The material is then injected slowly while observing for coaptation, similarly to the transurethral technique, and the process is repeated at the 8 or 9 o’clock position. If material is noted in the lumen of the urethra, the needle is removed and relocated to a more anterior position, where the injection is repeated again. Once sufficient coaptation is noted, the procedure is ended. A needle with a “bent tip” has been manufactured (Boston Scientific Inc, Natick, Massachusetts) to facilitate placement into the proper plane. With advancement of the needle, the tip is brought more medially. These needles are of a larger bore size (18 or 20 gauge) and were originally designed to ease the injection of the larger caliber particles of Durasphere, but they certainly can be used for the periurethral injection of other bulking agents.

The differences between the transurethral and periurethral techniques were reviewed by Faerber et al. (25), and they found similar outcomes with no significant differences in adverse events using collagen as the test bulking agent. Of significance, the amount of material injected was less using a transurethral approach. A prospective, randomized comparison was later performed in women with no noted differences in efficacy, but a higher rate of urinary retention and an increased volume of injected material were seen in the periurethral group (26). It appears that a periurethral approach tends to use larger volumes of material and has been noted to have a longer learning curve than the transurethral approach. This is important as greater volumes are associated with higher cost and may increase the potential for postoperative complications.

Key Concepts

- *The desired amount of coaptation is the same as when performed via a transurethral technique.*
- *Efficacy is similar between periurethral and transurethral techniques, but the periurethral approach tends to use larger volumes of material and has been noted to have a longer learning curve than the transurethral approach.*

POSTOPERATIVE CARE

Immediate postoperative complications are rare. After completion of the procedure, the patient should demonstrate the ability to void. If the patient is in acute urinary retention, most often the patient will be able to urinate shortly after the periurethral block loses effect. In the meantime, the patient is usually catheterized with a small 10Fr to 14Fr catheter to relieve the patient's full bladder after cystourethroscopy. An indwelling Foley catheter should be avoided since there is a theoretical risk of the bulking agent molding around the catheter and losing its effect, although there is no evidence to support that short-term catheterization decreases the efficacy of intraurethral bulking. If long-term catheterization is necessary, a suprapubic catheter until return of voiding would be best to avoid disrupting the placement of the bulking agent. Although there are no randomized trials on the use of prophylactic treatment with antibiotics, a fluoroquinolone or trimethoprim-sulfamethoxazole for 24 hours or less can be recommended (27). An additional 2 to 3 days has also been suggested (28).

Many patients will require more than one treatment session to achieve maximal continence. Different waiting periods are required for each individual bulking agent. Bulking agents such as glutaraldehyde cross-linked bovine collagen (GAX-collagen) can be repeated after 7 days (in the original multicenter study, a 4-week waiting period was used), but most clinicians wait 4 weeks or longer to assess response and the need for reinjections (28). With Teflon, a 4-month wait is required because improved coaptation occurs with time. Macroplastique injections can be repeated after 12 weeks. Durasphere can be reinjected after a minimum of 7 days and Coaptite can be reinjected after 1 month or less. On repeat injection, if erosion is noted, injection into that side should be avoided until re-epithelialization occurs.

Irritative voiding symptoms may also develop after placement of bulking agents. Surprisingly, in a study by Steele et al. (19), 50% of patients were reported to have developed de novo detrusor overactivity. In a study by Cross et al. (29), 28% of patients were found to have de novo urge incontinence without ISD when undergoing urodynamics for posttreatment incontinence. Stothers et al. (30) reported a 12.6% rate of de novo urgency with urge incontinence in 337 women enrolled in a prospective trial of which 21% failed anticholinergic treatment.

Reports have been published on rare complications including urethral mucosal prolapse, abscesses, periurethral pseudocyst formation, and urethral diverticuli (13). Additionally, the periurethral approach is associated with higher injection volumes, which may contribute to higher urinary retention rates (26).

Key Concepts

- *Although uncommon, if a patient is in acute urinary retention, catheterization with a small 10Fr to 14Fr catheter to relieve the patient's full bladder is indicated.*

INJECTABLE AGENTS

Many different agents have been studied for use as bulking material with varying success and adverse events (Table 42.1). A Cochrane review from 2012 that identified 14 clinical trials and over 2,000 women found trials to be small and of moderate quality. They concluded that due to the “lack of long term follow up and health economic data . . . injection therapy cannot be recommended as an alternative for women fit for other surgical procedures,” but for “women with extensive co-morbidity precluding anesthesia, injection therapy may represent a useful option for relief of symptoms, at least for a 12 month period” (31). Patients should be counseled that greater symptomatic improvement is observed after surgery but at the expense of higher risks. Women should be made aware that repeat injections are likely to be required, efficacy diminishes over time, and that this therapy is inferior to more invasive techniques.

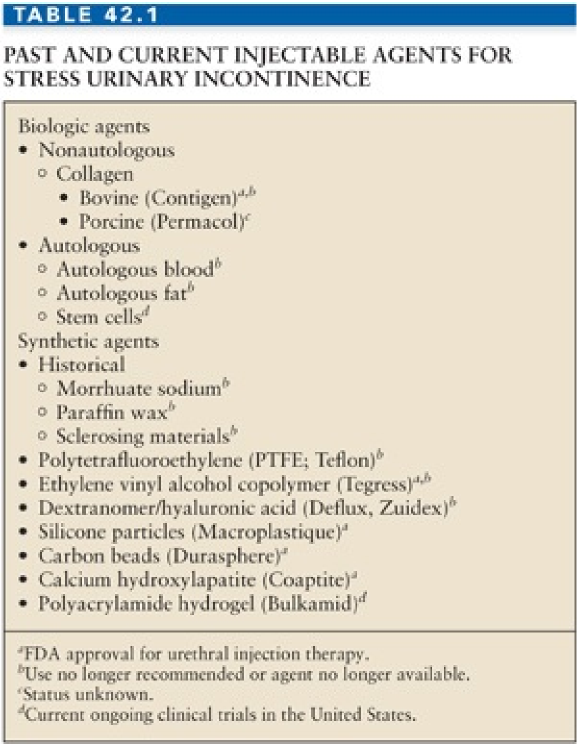

TABLE 42.1

PAST AND CURRENT INJECTABLE AGENTS FOR STRESS URINARY INCONTINENCE

Biologic agents
- Nonautologous
  - Collagen
    - Bovine (Contigen)[a,b]
    - Porcine (Permacol)[c]
- Autologous
  - Autologous blood[b]
  - Autologous fat[b]
  - Stem cells[d]

Synthetic agents
- Historical
  - Morrhuate sodium[b]
  - Paraffin wax[b]
  - Sclerosing materials[b]
- Polytetrafluoroethylene (PTFE; Teflon)[b]
- Ethylene vinyl alcohol copolymer (Tegress)[a,b]
- Dextranomer/hyaluronic acid (Deflux, Zuidex)[b]
- Silicone particles (Macroplastique)[a]
- Carbon beads (Durasphere)[a]
- Calcium hydroxylapatite (Coaptite)[a]
- Polyacrylamide hydrogel (Bulkamid)[d]

[a] FDA approval for urethral injection therapy.
[b] Use no longer recommended or agent no longer available.
[c] Status unknown.
[d] Current ongoing clinical trials in the United States.

Comparing the different injectable agents is a difficult task. There are few controlled, long-term studies involving commonly used bulking agents. Even within those rare studies, there are many variables that make it difficult to compare them. Not all studies differentiate the results in patients with and without urethral hypermobility and/or ISD. The procedures themselves are also varied due to different technical factors such as injection technique and instrumentation. Additionally, reported results have been largely subjective rather than objective, creating a difficult situation to compare data. Variability also exists within the reported outcomes, as different criteria have been used to define cured or improved. Also, because agents can be repeated if not successful, the time frame in the determination of a successful outcome can impact overall rates. For example, if the duration of results is reported from initial treatment or is not specified, success rates may be overestimated because failures can be retreated and can be considered a success within the follow-up period.

BIOMATERIALS

Glutaraldehyde Cross-Linked Bovine Collagen (Contigen)

Of all the injectable agents, GAX-collagen is probably the most commonly used, with numerous publications describing its safety and efficacy. It has been considered the gold standard of urethral bulking material such that the FDA required direct comparison to collagen for any new bulking agents in clinical trials (32). GAX-collagen is derived from bovine collagen that is cross-linked with glutaraldehyde to create a stabilized, fibrillar collagen that confers resistance to denaturation by collagenases, thus increasing the durability of the implant (33). It consists of 35% purified bovine collagen in a phosphate buffer. The collagen itself is composed of 95% type I collagen, which is the type found predominately in ligaments and confers structural strength; however, between 1% and 5% is composed of type III collagen, which is the type abundant in vaginal tissue, giving added flexibility (34).

When injecting this material, the surgeon inserts the exact amount needed to achieve the desired effect, since there is no expansion or shrinking after injection. Acting as a matrix, the material promotes ingrowth of new collagen within the implant (35). Since GAX-collagen is both biocompatible and biodegradable, only minimal inflammatory changes occur (36). It is not known to migrate. After 12 weeks, the collagen starts to degrade, but it persists until 19 months (37). Despite the fact that GAX-collagen is degraded, it maintains effectiveness in 80% of those who become continent, a result that is thought to be secondary to the ingrowth of new collagen (38).

In a multicenter clinical study involving 127 women with ISD who had GAX-collagen injection, at 2 years, 46% of patients were dry and 34% were significantly improved, requiring only a single pad or tissues. Urodynamic studies also revealed a rise of 40 cm H_2O in ALPP. A mean volume of 18.4 mL of GAX-collagen with a mean of 2.1 (+/− 1.5) treatment sessions was given to those who achieved continence (39). Other independent studies have supported these results (40,41). As time progresses, a noted decline in efficacy has been witnessed. Forty-five percent of elderly women were improved at 24.4 months in a report by Winters et al. (18), but of note in this group, 40% required more injections after an average of 7.9 months. At 50 months, Corcos and Fournier (42) reported a cured rate of 30% and an improved rate of 40% in 40 women, although 4 women in the cured group and 5 women in the improved group required “maintenance” injections (42). In a study up to 5 years, Gorton et al. (43) reported that only 26% of 53 women reported continued improvement. Herschorn et al. demonstrated the probability of remaining dry after the last collagen injection was 72% at 1 year, 57% at 2 years, and 45% at 3 years (44).

Few complications have been found with the use of GAX-collagen. In the U.S. clinical trials (45), 15% developed transient urinary retention, 5% had a UTI, and 1% experienced irritative voiding symptoms. Rates of de novo urgency and frequency have been reported to be as high as 10% (42). There has been no evidence of foreign-body response or migration (36), partly because of the small amount of glutaraldehyde in GAX-collagen, which creates minimal immunoreactivity and cytotoxicity (46). GAX-collagen is biocompatible and allows fibroblasts to deposit native collagen as well as allow neovascularization to occur as the implant is degraded over 12 weeks (47). After 10 to 19 months, all of the implant has completely degraded (37). There have been several case reports of sterile abscesses at the injection sites, some of which required drainage (48).

One potential hazard of GAX-collagen involves an allergic reaction to the bovine protein, although this is reduced by cross-linking and skin testing, which all patients must undergo 30 days before treatment. Approximately 4% of female patients will have a positive skin test, with 70% showing the reaction within 3 days, which indicates a preexisting sensitivity to bovine dermal collagen through dietary exposure. The remaining 30% do not respond until later so a 4-week period is required. A positive test precludes them from treatment (39), but a negative test does not preclude the development of a hypersensitivity reaction to subsequent treatment.

Overall, due to its complete degradation with minimal inflammatory response and lack of migration, GAX-collagen has been the most popular intraurethral bulking agent used to treat incontinence. However, despite its long track record, although with modest results, the manufacturer ceased production in 2011, and the implant is no longer available.

Key Concepts

- *As time progresses, a noted decline in efficacy has been witnessed.*
- *Approximately 4% of female patients will have a positive skin test, which precludes them from treatment.*
- *The manufacturer has ceased production, and GAX-collagen is currently no longer available.*

SYNTHETIC MATERIALS

Silicone Polymers (Macroplastique)

Macroplastique (Uroplasty Inc, Minneapolis, Minnesota) is made of vulcanized polydimethylsiloxane macroparticles suspended in a carrier hydrogel consisting of polyvinylpyrrolidone (povidone) that also serves as a lubricant for the injection system. It is absorbed by the reticuloendothelial system and is excreted unchanged in the urine. Macroplastique consists of particulates of various shapes and sizes with marked variability: The particles can range from less than 50 μm to 400 μm in largest dimension, but 99% of the particles are greater than 100 μm. Still, the concern for potential particulate migration is present, especially for small particles less than 70 μm. In a study to determine the migratory properties of this material performed on dogs, small particles were found in the lungs, kidney, brain, and lymph nodes within 4 months of injection. In comparison, only one large particle was found in the lung without any associated reaction (49).

Macroplastique requires no pre-administration hypersensitivity testing, and the material does not require refrigeration or special handling. It is supplied in preloaded 2.5 mL syringes, and because the substance is fairly viscous, it requires high-pressure injection accomplished via an 18-gauge Uroplasty rigid endoscopic needle gun along with standard cystoscopic equipment. Alternatively, a proprietary, nonendoscopic transurethral injection device, the Macroplastique implantation system (MIS) can be used. The MIS consists of a multichanneled needle positioning device with three angled needle entry ports orientated at 2, 6, and 10 o’clock positions for injections of 1.5 mL, 2.5 mL, and 1.5 mL of material, respectively. This is also the recommended endoscopic injection technique for Macroplastique. The MIS is currently not available in the United States.

Silicone polymer was first used for the treatment of SUI in 1992 with encouraging short-term follow-up. Like other agents as time progressed, the cure rate fell from an initial 82% to 70% at 14 months (50). A recent North American multicenter randomized trial randomized, 247 patients with ISD to transurethral injection of either Macroplastique or Contigen. After 12 months, there were significant clinical improvement and dry/cure rates in 61.5% and 36.9% of patients treated with Macroplastique, respectively, versus 48% and 24.8% of patients treated with Contigen, respectively. This indicated that Macroplastique was noninferior to Contigen ($P < .001$). There were no differences in pad weight testing, quality of life scale, or adverse events between the two groups (51). Two-year follow-up reporting of the Macroplastique group demonstrated, of those who had a benefit at 12 months, 84% maintained that level of cure or improvement to 24 months. Based on this, of the original 122 patients at the beginning of the study, 51.7% had a good outcome at 2 years (52).

Complications with the use of this material included urinary retention at a rate of 5.9% to 17.5%, urinary frequency at a rate of 0% to 72.4%, dysuria from 0% to 100%, and UTI from 0% to 6.25% (53).

Key Concepts

- 🟩 *Due to its viscous nature, Macroplastique requires a special ratchet needle gun for administration.*
- 🟩 *Particle migration is rare but is a theoretical risk given the small percentage of particles less than 70 μm.*
- 🟩 *Macroplastique is noninferior in efficacy to Contigen.*

Durasphere

Durasphere is composed of nonabsorbable pyrolytic carbon-coated zirconium oxide beads suspended in a 2.8% beta-glucan water-based gel. The bulking effect lasts for at least 2 years as the beads are encapsulated into the periurethral tissue. Compared to collagen, it is an inert and nonimmunogenic material and eliminates the need for skin testing. It gained FDA approval for use in patients with ISD in 1999. Standard cystoscopic equipment and proprietary 18-gauge injection needle device can be used. A bent needle (18 or 20 gauge) is available for periurethral injection. It comes in 1 mL or 3 mL filled syringes. Because of the safety concerns of particle migration, Durasphere was designed with larger caliber particles (>80 *μ*m) to prevent migration. The bead size ranges from 212 to 500 *μ*m, but as a consequence, Durasphere can be more technically difficult to inject given its higher viscosity, with the beads clogging the needle, leading to increased resistance with resulting higher pressures required to inject the material. A modified injection technique was introduced to overcome this difficulty by injecting a local anesthetic into the mucosa to raise a circumferential bleb into which Durasphere is injected (54). Additionally, as a way to remedy this, the manufacturer introduced Durasphere EXP in 2006, whose smaller bead size (range 90 to 212 *μ*m), facilitates injection but still larger than the threshold for migration. As of late 2013, no clinical results have been published with this new formulation nor does there appear to be any open clinical trials ongoing.

Durasphere was compared to GAX-collagen in a multicenter, randomized, controlled, double-blind study. At the 1 year follow-up, the Durasphere group achieved improvement in one Stamey grade or more in 80% of patients compared to 69% of patients in the GAX-collagen group, although the difference did not reach statistical significance. Pad weights at 12 months were equivalent between the two groups. The Durasphere group had significantly less volume of material injected and was more successfully treated with a single injection, but 45% of the study patients who had 1 year follow-up after the last injection were not accounted for (55). Long-term data have been reported, and as in the case of many injectable agents, there is a decrease in clinical success. Durasphere was effective in 33% of patients at 24 months and in 21% at 36 months. Those who received GAX-collagen reported effectiveness in 19% of patients at 24 months and in 9% at 36 months. However, when controlled for differences in follow-up time, the time to failure between the two groups did not reach statistical significance. Interestingly, one-third of each group felt that treatment was successful (56).

In the trials for FDA approval, the most common adverse events were acute retention ≤7 days at 13%, dysuria at 12%, UTI at 9%, hematuria at 6%, and retention >7 days at 6%. Other adverse events occurred at ≤4% (57). From the multicenter randomized trial of Durasphere versus GAX-collagen, adverse events were similar between the two groups, except for a higher incidence of urgency and acute retention in the Durasphere group (24.7% and 16.9%, respectively) than in the collagen group

(11.9% and 3.4%, respectively), but regarding the urgency symptom, a higher percentage (90%) resolved by study end in the Durasphere group than in the collagen group (65%), (*P* = .021) (55). There have also been case reports of sterile abscess formation and urethral prolapse (58,59).

Key Concepts

- *Durasphere EXP, a modification of the original Durasphere that allows lower pressure injection due to its smaller bead size (range 90 to 212 μm) was introduced to facilitate injection but is still larger than the threshold size for migration.*
- *Durasphere achieved improvement in one Stamey grade or more in 80% of patients compared to 69% of patients in the GAX-collagen group, although the difference did not reach statistical significance.*

Calcium Hydroxyapatite (Coaptite)

Approved in December 2005, calcium hydroxyapatite is a synthetic agent that consists of carboxymethylcellulose and glycerin in the form of an aqueous gel. Calcium hydroxyapatite is manufactured into particles of spherical mean diameter of 100 μm (75 to 125 μm), which is above the threshold for migration. The gel facilitates injection and provides the initial bulking effect but is designed to degrade over time and allowing for ingrowth of tissue around the particles. It is a normal constituent of bone and teeth and has been used in orthopedic and dental applications as well as soft tissue augmentation of vocal cord, face, and the ureteral orifice for vesicoureteral reflux with excellent biocompatibility (60,61). As a result, a pre-procedure skin test for hypersensitivity is not required. It does not require refrigeration or special handling.

The implant is currently dispensed in 1 mL prefilled syringes and can be performed via standard endoscopic instruments with a supplied 21-gauge rigid injection needle with either an end-firing or side-firing capability. Ease of injection is a noted advantage. Approximately 2 to 4 mL of material is required for coaptation. Calcium hydroxyapatite is radiopaque and can be seen on radiographic images, which may aid in accurate localization and placement (12).

In a study with 1-year follow-up, 7 of 10 women reported substantial improvement in continence, a 90% decrease in mean pad weight, and an increase in mean Valsalva leak point pressure from 39 to 46 cm H_2O (62). In the data for FDA approval, 158 patients received Coaptite with a mean follow-up of 11.2 months, and no statistical difference was found in change in Stamey grade, pad weight, or quality of life when compared to GAX-collagen as the control (63). A large multicenter randomized clinical trial randomizing 296 women with ISD to either Coaptite or collagen has been reported. At 12 months, 63.4% of the Coaptite group showed improvement of one Stamey grade or more versus 57% in the collagen group (*P* = .34). There was no difference in cure rates (39% Coaptite versus 37% collagen). Up to five injections were performed in the first 6 months of the trial. More patients in the Coaptite group required only one injection (38%) compared with the collagen group (26.1%) (*P* = .03), and the total average injected volume was lower (4.0 mL versus 6.6 mL, $P < .0001$) (64).

Common adverse events included urinary retention (41%), hematuria (19.6%), dysuria (15.2%), and UTI (8.3%). Changes in voiding occurred with urinary urgency at 7.6%, frequency at 7.0%, and urge incontinence at 5.7%. Two serious adverse events occurred: erosion through the vaginal wall requiring surgery and dissection into the bladder causing tissue bridging, for which no surgical correction was needed. It was posited that these were unlikely the result of direct tissue toxicity of

Coaptite but rather due to increased prolonged tissue pressure effects from its greater particle density than collagen. No long-term sequelae of these two events were noted. The overall erosion rate was 1.3% (63).

Key Concepts

- *No statistical difference was found in change in Stamey grade, cure rates, pad weight, or quality of life when compared to GAX-collagen as the control; however, significantly more patients in the Coaptite group required only one injection and the total average injected volume of material was lower.*

Polyacrylamide Hydrogel (Aquamid, Bulkamid)

Aquamid and Bulkamid are polyacrylamide hydrogels that are nontoxic and nonresorbable sterile aqueous gels consisting of 2.5% cross-linked polyacrylamide and 97.5% nonpyrogenic water. It is homogenous and has a tissue-like viscosity and elasticity. It contains no solid particles thereby eliminating any risk of particle migration. Aquamid is used clinically as soft tissue filler in plastic surgery and reconstructive procedures in Europe. Bulkamid is the corresponding product for the SUI indication. It does not need refrigeration or any special handling and is supplied in preloaded 1 mL sterile syringes. It can be injected transurethrally using a 23-gauge needle and standard cystoscopic equipment or via a proprietary endoscopic system, the Bulkamid urethral bulking system. This system is specially designed to facilitate injections and consists of an 11-cm female urethra urethroscope and a disposable rotatable sheath with a working channel for the needle that allows for 360-degree rotation. Approximately 0.5 mL of material is injected each at the 3, 6, and 9 o’clock position to achieve full coaptation (13).

Bulkamid is used clinically for endoscopic treatment of SUI in Europe. An open, noncomparative, multicenter case series of 135 women was reported in 2010. Half the patients had mixed urinary incontinence. At 12 months, two-thirds of the women reported being cured or improved, and there were significant reductions in incontinence episodes per 24 hours and pad weight testing. Efficacy was similar between patients with pure SUI and those with mixed incontinence. There was a 35% reinjection rate. Minor adverse events noted included UTI (5%), transient urinary retention (3%), hematuria (1%), and transient de novo urgency and urge incontinence (1%) (65). In the 2-year follow-up analysis of this cohort, there was durability of success with 64% of women cure/improved, which was not significantly different compared with the 12 month data (66).

Bulkamid and Aquamid are currently not approved for use in the United States, but multicenter randomized clinical trials are ongoing in North America and Europe.

Key Concepts

- *Bulkamid is used in Europe for the treatment of SUI, but no randomized controlled data have been published. It is currently not approved in the United States, but trials are ongoing.*

Permacol

Permacol is a dermal implant made from nonreconstituted porcine dermal collagen and has been used in hernia repairs and pelvic reconstruction. Noncollagenous material, except elastin, is removed and a cross-linking process is performed. It maintains its original three-dimensional form, and when implanted, it allows for ingrowth of new tissue, which can potentially be permanent (67). Permacol is nonallergenic, obviating the need for skin hypersensitivity testing.

One study compared Permacol and Macroplastique in a randomized controlled trial that included 50 women with urodynamic SUI. A great majority of the injections (84%) were performed periuretherally in the Permacol group. At 6 months, 62.5% in the Permacol group were dry versus 37.5% in the Macroplastique group, but no statistical analysis was reported. Rates of adverse events were similar between both groups (68). Information on ongoing trials and current availability was unavailable from neither the manufacturer nor FDA Web sites.

FUTURE DIRECTIONS

Stem Cell Therapy

The development of regenerative medicine has enabled the application of autologous stem cells for SUI therapy. Multiple small series have been published. Most recently, a case series of 16 women who had sphincteric injection of muscle derived stem cells generated a cure/improved rate of 75% at 2 years of follow-up. There were no adverse events from either the deltoid muscle biopsy or from the injection (69). Cook MyoSite, a part of Cook Medical, has two active clinical trials underway with intrasphincteric injections of autologous muscle-derived cells (AMDCs) for the treatment of SUI. In unpublished pooled data with 12 months of follow-up from two phase I/II studies of AMDC at various doses ($n = 80$), injections appear safe with no reported adverse events and demonstrated significant improvements in UDI-6 and IIQ-7 scores at all doses. Additionally, efficacy data suggest a dose–response relationship with the higher dose groups demonstrating a higher percentage of patients with at least 50% reduction in stress leaks and pad weights. Although still considered experimental, stem cell therapy holds great promise and in the near future may very well be an additional option in therapy for the treatment of SUI (70).

CONCLUSIONS

Currently, injectable agents are best used for those who wish to avoid a surgical procedure or those who have problematic medical comorbidities that preclude them from undergoing surgical correction. Patients must be willing to accept an improvement rather than a cure of their SUI symptoms, and they must understand efficacy and duration of these agents are inferior to surgery, and follow-up injections may be required. Research continues the search for an effective, inert, nonmigratory, nonimmunogenic material that allows incorporation into native tissue, maintains its shape, and injects with ease. Currently, intraurethral bulking remains an art, as there is no exact measurement or amount of material used for each patient to achieve continence.

CHAPTER 43 URETHRAL SLINGS

ALEX GOMELSKY

A form of “sling surgery” to treat female stress urinary incontinence (SUI) has existed for over a century. Despite the sequential implementation of various autologous tissues, allografts, xenografts, and synthetic materials, the sling procedure has traditionally been associated with significant complications and has been commonly reserved for the treatment of refractory SUI. However, owing to an improved understanding of SUI pathophysiology through the work of groups led by DeLancey (1), McGuire and Lytton (2), Blaivas and Jacobs (3), and Petros and Ulmsten (4), the sling has emerged over the last two decades as a reproducible, efficacious, and safe surgical option. Furthermore, novel materials, methods of suspension, and routes of placement have only served to decrease operative time and shorten convalescence, contributing to the sling becoming a contemporary gold standard for the surgical treatment of women with SUI. The focus of this chapter will be to describe the surgical technique behind the autologous rectus fascia bladder neck sling (BNS) and the retropubic and transobturator approach to the midurethral sling (MUS). Although there are several commercial options for approaches to the MUS, the operative procedure and anatomic landmarks are relatively standardized. Thus, I will describe only one example product for each type of approach for the retropubic and transobturator MUS. There will be no additional discussion of other materials placed at the bladder neck, and the single-incision minisling is, likewise, not discussed in this chapter. A brief review of surgical outcomes, comparative studies, and complications follows.

PATHOPHYSIOLOGY OF STRESS URINARY INCONTINENCE

It is universally accepted that continence during increases in intra-abdominal pressure depends on a complex interaction between urethral support, intrinsic urethral properties, the sphincter complex, and adjunct pelvic floor musculature. Two current theories build the case regarding the location of the anatomic weakness that contributes to SUI. In his “hammock hypothesis,” DeLancey (1) postulated that the urethra is supported by a hammock-like layer consisting of the vaginal wall and endopelvic fascia that is stabilized by lateral attachments to the levator ani and the arcus tendineus fascia pelvis. Along with the urethropelvic ligaments, these structures envelop the proximal urethra and aid in closure of the urethral lumen during increases in abdominal pressure. Slings placed at the bladder neck and proximal urethra aim to address this weakness. Conversely, in the “integral theory,” Petros and Ulmsten (4) proposed that the midurethra is the linchpin in the continence mechanism. The authors postulated that contraction of the pubococcygeus muscle during increases in abdominal pressure pulls the anterior vaginal wall forward and closes off the urethral lumen, a response that is contingent on an intact attachment between the pubourethral ligaments and anterior vaginal wall. Laxity in this midurethral fulcrum may subsequently lead to funneling of the urethra and urinary incontinence. The midurethra is the location for placement of the “tension-free” synthetic slings.

DIAGNOSIS

The American Urological Association (AUA) guidelines on SUI state that the minimum workup for an index patient presenting with SUI symptoms should include a history, pelvic examination, urinalysis and culture (if indicated), objective demonstration of incontinence (e.g., during cough stress testing), and assessment of postvoid residual urine (standard) (5). The index patient is an otherwise healthy female who has elected surgical therapy for the correction of SUI, may be untreated or previously surgically treated, and may have urethral hypermobility and/or intrinsic sphincter deficiency (ISD). The panel made a recommendation to add additional diagnostic studies to assess the integrity and function of the lower urinary tract: pad testing and/or voiding diary, urodynamics, cystoscopy, and imaging. Likewise, the panel made a recommendation to consider further testing for the following indications: inability to make a definitive diagnosis based on symptoms and/or the initial evaluation, concomitant overactive bladder symptoms, prior lower urinary tract surgery (including failed anti-incontinence procedures), known or suspected neurogenic bladder, negative cough stress test, abnormal urinalysis such as unexplained hematuria or pyuria, excessive residual urine volume, grade III or higher pelvic organ prolapse, and any evidence for dysfunctional voiding. Although there is some controversy regarding the role of urodynamics in cases of primary SUI, these diagnostic studies may be especially helpful in cases of mixed urinary incontinence, concomitant pelvic organ prolapse, incomplete emptying or neurogenic micturition dysfunction, and prior surgical failure (5).

ALTERNATIVE THERAPIES

Several nonsling options exist for the treatment of SUI. In women with mild or nonbothersome SUI, active treatment may be postponed until the incontinence impacts the patient’s quality of life. If active treatment is elected, pelvic floor muscle training with the potential addition of biofeedback may provide the woman significant improvement. Furthermore, urethral bulking therapy is another option that may provide benefit with minimal anesthetic requirement and procedural morbidity. Although the long-term benefit of this mode of therapy varies significantly in the literature, this remains a viable option in a select population. Finally, several additional, albeit infrequently performed, procedures are available for the surgical correction of SUI. Of these, transvaginal needle suspensions and suburethral plications have been associated with poor long-term outcomes and were not included in the most recent AUA SUI guidelines (5). Although the AUA Guidelines Panel found little new data regarding the efficacy of retropubic bladder neck suspensions (e.g., Burch or Marshall-Marchetti-Krantz), they concluded that there continues to be evidence for the efficacy of these procedures in selected patients (5).

INDICATIONS FOR SLING SURGERY

The introduction of the MUS can be viewed as a watershed event in the century of sling surgery. The novel procedure championed by Petros and Ulmsten was not only unique in its anatomic placement but also in its minimally invasive nature and reproducible outcomes. The transobturator MUS has gained further popularity because this approach avoids entry into the space of Retzius, thus potentially minimizing the serious viscus or neurovascular injuries that may occur from errant trocar placement during the retropubic approach (6). Owing to these advantages, the MUS has largely supplanted the rectus fascia BNS for most patients. One scenario where a BNS may continue to serve as the primary surgical option is in women who are undergoing a concomitant debridement of a MUS that has eroded into the vagina or urinary tract. Initially, it was also felt that ISD may be another relative indication for a BNS, as cure rates less than 20% were cited in these women who had a MUS (7). However, several authors have since noted that the retropubic MUS is associated with durable cure rates over the long term (8,9), and these exceed the cure rates seen with the transobturator approach in the ISD population (10,11). Ultimately, sling choice will be determined by the surgeon’s training and experience as well as a detailed informed consent discussion with the patient.

A few details remain once the decision to pursue operative therapy has been made. Although not all elements of vaginal prolapse require repair, consideration must be given to addressing prolapse at or distal to the hymenal ring, or symptomatic prolapse of a lesser degree, at the time of sling surgery. Doing so may minimize the possibility of SUI recurrence, urinary retention, or worsening prolapse.

A discussion of the risks, benefits, and options to sling surgery is key in obtaining informed consent. Risks may be intraoperative (bleeding, potentially requiring transfusion; injury to the bladder or urethra; hematoma formation), early postoperative (<30 days: urinary retention and other voiding symptoms; urinary tract infection; de novo, persistent, and/or worsened storage symptoms), and late postoperative (>30 days: urinary retention; need for urethrolysis or sling revision; dyspareunia; recurrent or de novo prolapse and SUI; de novo, persistent, and worsened storage symptoms). Harvest site complications, including seroma formation and infection, are relatively unique to rectus BNS. The risk of complications such as sling erosion and extrusion should also be mentioned. Although these sequelae are most commonly associated with synthetic mesh placement, any sling may erode into the urethra if placed under excessive tension.

SURGICAL TECHNIQUE

Preoperative Considerations

The following considerations apply for both BNS and MUS. A preoperative bowel regimen is typically not ordered for a sling-only procedure but can be considered for surgeries including a concomitant hysterectomy, vaginal vault suspension, or posterior compartment surgery. Prophylactic intravenous antibiotics are given within an hour of surgical “cut” time (first- or second-generation cephalosporin, gentamicin and clindamycin, or a fluoroquinolone) (12). Antithromboembolic hose and/or sequential compression devices are applied prior to induction of anesthesia. Regional or general anesthesia may be used for all slings, whereas local anesthetic protocols may be used for MUS. The ultimate choice of anesthesia is at the discretion of the surgeon, anesthesiologist, and patient. The pubic hair is clipped in the operating room. The patient is positioned in slightly exaggerated dorsal lithotomy position in Allen stirrups. Skin preparation is performed from below the umbilicus to the midthigh, and the vaginal canal is also prepped. After draping, an indwelling urethral catheter is placed to continuous drainage. A weighted vaginal speculum and Scott/Lone Star retractor may be of assistance in obtaining exposure. Liberal irrigation of the vaginal incision is performed throughout the case often with neomycin sulfate–polymyxin B sulfate solution or an alternative solution. Many surgeons will submerge the chosen sling material in antibiotic irrigation until ready to use. If a concomitant transvaginal procedure is planned to repair an anterior compartment prolapse, I prefer to make a separate midurethral incision for a MUS; however, I would use a single vaginal mucosal incision to address both the incontinence and prolapse if a rectus fascia BNS is planned. The AUA Guidelines Panel recommended that tensioning of any sling should not be performed until prolapse surgery is completed (5). Thus, it is my routine to perform all of the prolapse surgery first and conclude with the sling procedure.

Rectus Fascia Bladder Neck Sling

Fascial Harvest and Abdominal Incision

A low transverse incision two fingerbreadths above the superior edge of the pubic symphysis provides excellent exposure and cosmesis. The rectus fascia is exposed after incising the skin, subcutaneous fat, and Scarpa fascia. It is important not to excessively undermine the areolar tissue overlying the rectus fascia because this may increase the possibility of postoperative seroma. A strip of fascia measuring approximately 1.5 cm × 7 cm is excised and 2-0 polypropylene sutures are attached to each end (Fig. 43.1). The sling is soaked in antibiotic solution until the vaginal incision is prepared. The fascial rent is closed with continuous or interrupted no. 1 delayed absorbable suture. The skin and Scarpa layer are left open for the upcoming passage of sling sutures. Although there is no consensus regarding optimal sling length, it is widely accepted that the sling should be long enough to reach the space of Retzius and provide both suburethral and paraurethral support. Alternatively, autologous fascia lata harvested from the thigh is an alternative to rectus fascia. The use of this tissue may require patient repositioning and special instrumentation.

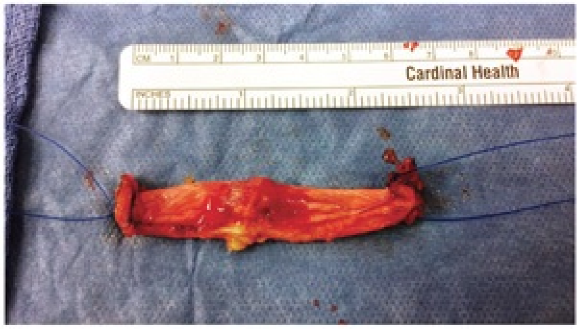

FIGURE 43.1 The rectus fascia graft is harvested and attached to 2-0 polypropylene sutures.

Vaginal Dissection

An inverted U incision provides excellent access to the bladder neck, with the apex of the U at the midurethra and the widely spaced legs of the U extending just proximal to the bladder neck.

Alternatively, a vertical midline incision may be used. The anterior vaginal wall may be infiltrated with normal saline or a hemostatic agent. The vaginal mucosa is dissected sharply off the underlying surface of the pubocervical and periurethral fascia, with lateral dissection proceeding up to the inferior edge of the pubic symphysis. The endopelvic fascia on each side of the urethra is perforated with Metzenbaum scissors and the space of Retzius is entered. The scissors should be aimed at the ipsilateral shoulder and remain just inferior to the pubic symphysis to minimize the possibility of bladder or vascular injury. Once the endopelvic fascia is perforated, paraurethral adhesions in the retropubic space may be released with an index finger.

Suture Passer Advancement

Any concomitant surgery to address anterior or apical compartment prolapse should be completed prior to suture passer advancement. Double-pronged needles (Cobb-Ragde) are used to pierce the rectus fascia approximately 2 cm lateral to the midline and remain immediately posterior to the pubic symphysis. A finger in the retropubic space from below may be used to guide the needle out of the vaginal incision on either side of the urethra (Fig. 43.2). Alternatively, a tonsil-tipped clamp, single-pronged (Stamey) or double-pronged (Raz) needle passer may be used. Ensuring that the bladder is completely empty prior to needle passage may minimize the possibility of bladder puncture.

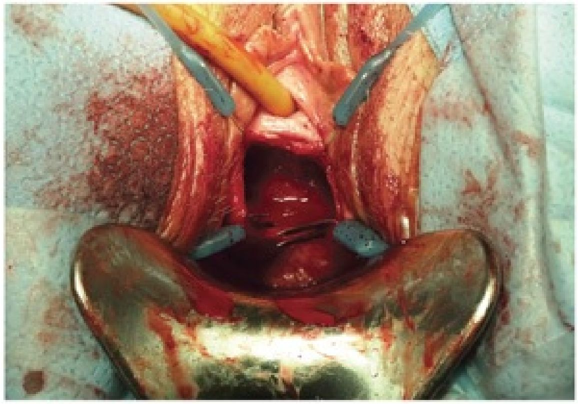

FIGURE 43.2 A double-headed needle is passed bilaterally through the rectus fascia and into the vaginal incision on either side of the urethra.

Cystoscopy

An ampule of indigo carmine dye is given intravenously. Ureteral integrity is confirmed on cystoscopy when blue-tinged urine effluxes from each ureteral orifice. A 70-degree lens may be helpful to visualize the dome and superolateral aspects of the bladder where penetration with passers is most likely to occur. It is vital to evacuate the air bubble and inspect that area carefully, as it may occasionally obscure the metal passers. It is also imperative to adequately visualize the entire path of the passer from the dome to the bladder neck and proximal urethra, as bladder integrity may be compromised anywhere along this path. If the bladder has been penetrated, the offending suture passer should be removed under direct vision, the bladder drained, and the needle should be passed again. Cystoscopy should be performed after each additional pass. Prolonged continuous catheter drainage should be considered to allow for additional bladder healing in the event of a bladder or urethral injury. The AUA Guidelines Panel concluded that intraoperative cystourethroscopy should be performed in all patients undergoing sling surgery (standard) (5).

Adjusting Sling Tension and Abdominal Wound Closure

The sling sutures are transferred into the abdominal incision, and the sling is then positioned over the bladder neck and the sling edges are anchored to the periurethral fascia with 4-0 delayed absorbable suture (Fig. 43.3). After irrigating with antibiotic solution, the vaginal incision is closed with 2-0 delayed absorbable suture.

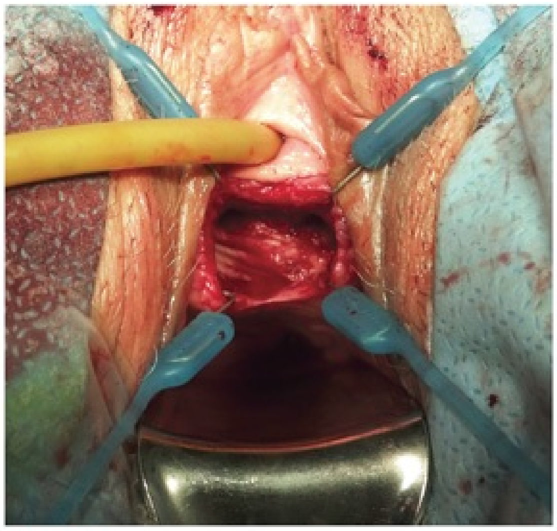

FIGURE 43.3 The sling is positioned flat at the bladder neck and anchored to the periurethral fascia to keep it from slipping during the tensioning process. The vaginal incision is then closed.

Prior to suture tensioning, the patient's legs are lowered to a comfortable lithotomy position and all retractors and speculums are removed. One pair of sutures is tied to the contralateral pair over the rectus fascia under no tension. Typically, the assistant will insert their index and middle fingers as a spacer between the suture knot and the rectus fascia. After two knots, the knot is gently clamped with a rubber shod and tension is tested by removing the urethral catheter and inserting a cystoscope sheath into the bladder. If there is no hitch in passing the sheath into the bladder, then the sling tension is adequate, and additional knots may be now added to the sutures. If there is a hitch, then the knot should be undone and more laxity given to the sling. This is repeated until the cystoscope sheath is passed into the bladder without a hitch.

The abdominal wound is irrigated with antibiotic solution and Scarpa fascia is reapproximated with interrupted 3-0 delayed absorbable sutures. The skin is closed with subcuticular 4-0 delayed absorbable sutures. The vagina is carefully packed with gauze impregnated with estrogen cream, Betadine, or saline.

Top-Down Retropubic Midurethral Sling

As for the BNS, the anterior vaginal wall may be infiltrated with a hemostatic solution or with normal saline for the purposes of hydrodissection. The mucosa is then incised in the midline for approximately 2 cm, with the incision beginning 1 cm proximal to the urethral meatus and proceeding in the direction of the proximal urethra (Fig. 43.4). Allis clamps placed on the edges of the incision may facilitate retraction and exposure. Using Metzenbaum scissors, lateral vaginal flaps are developed until the inferior edge of the pubic symphysis can be easily palpated on either side of the urethra (Fig. 43.5). For the SPARC sling (American Medical Systems, Inc, Minnetonka, Minnesota), two stab incisions are made in the suprapubic skin (Fig. 43.6). Each is approximately two fingerbreadths (or 2 to 3 cm) lateral to the midline and overlies the superior edge of the pubic symphysis. The skin may be infiltrated with 1% lidocaine or 0.25% Marcaine for additional local anesthesia. The SPARC trocars are then advanced through each suprapubic incision and pierce the rectus fascia in a perpendicular direction (Fig. 43.7). Each trocar is then guided toward the ipsilateral vaginal dissection taking care to remain behind and in contact with the pubic symphysis at all times.

Passing the trocar just underneath the symphysis is facilitated by rotating the passing hand cephalad and displacing the handle of the needle posteromedially. An index finger of the nonpassing hand is inserted into the ipsilateral area of vaginal dissection to simultaneously protect the urethra from puncture and to “bring out” the passer (Fig. 43.8). As with BNS procedures, complete bladder emptying may decrease the chance of bladder puncture from trocar passage. If care is taken to follow these steps, the possibility of inadvertent bladder puncture can be minimized even in the obese patient or those with who have failed previous retropubic surgeries.

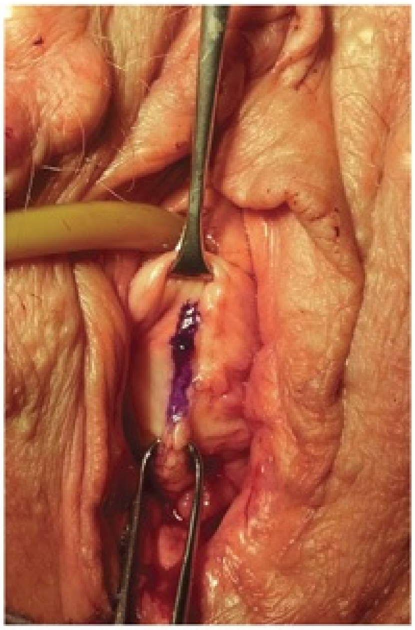

FIGURE 43.4 The mucosal incision begins 1 cm proximal to the urethral meatus and proceeds for approximately 2 cm proximally.

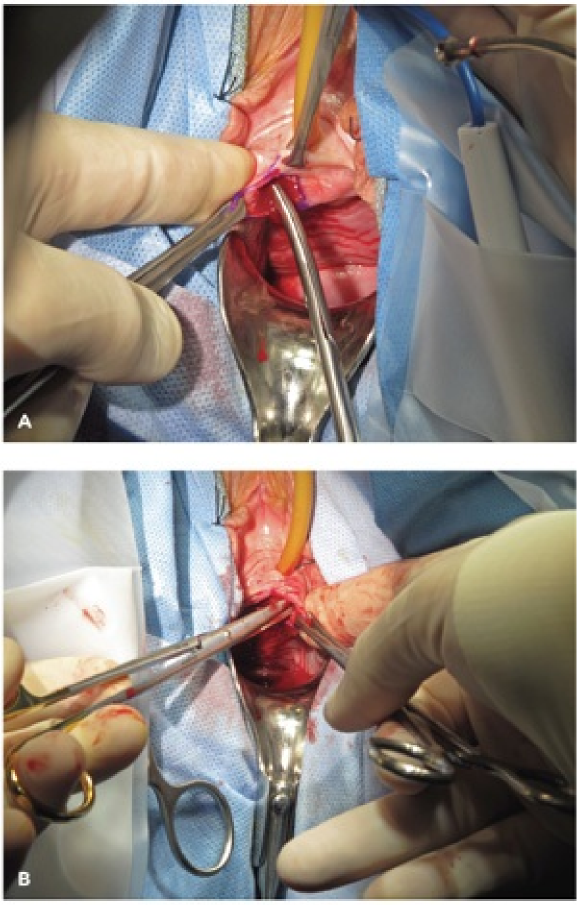

FIGURES 43.5 **A and B:** Lateral vaginal flaps are developed until the inferior edge of the pubic symphysis can be easily palpated on either side of the urethra.

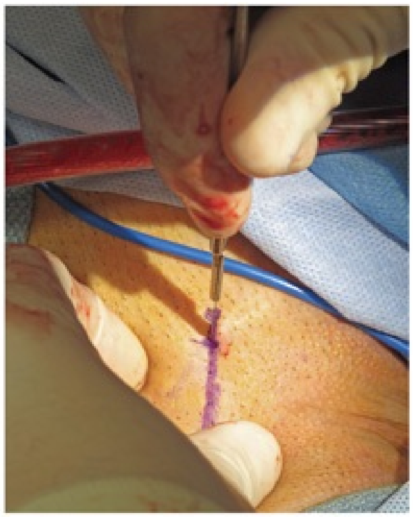

FIGURE 43.6 Two stab incisions are made in the suprapubic skin over the superior edge of the pubic symphysis and each approximately two fingerbreadths lateral to the midline.

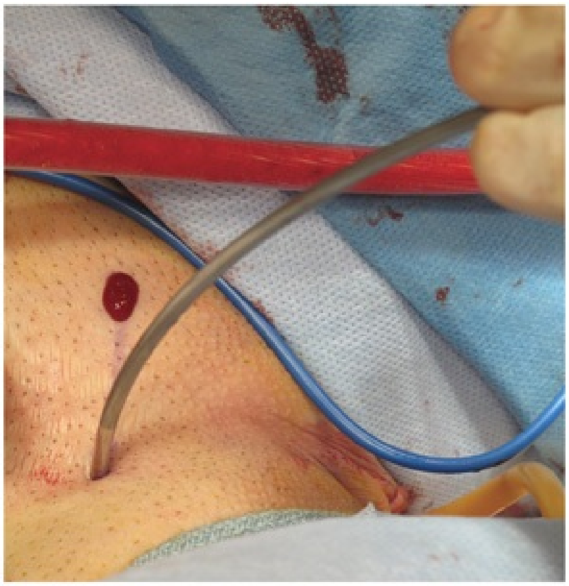

FIGURE 43.7 The SPARC trocars pierce the skin and rectus fascia in a perpendicular direction and remain behind and in contact with the pubic symphysis at all times.

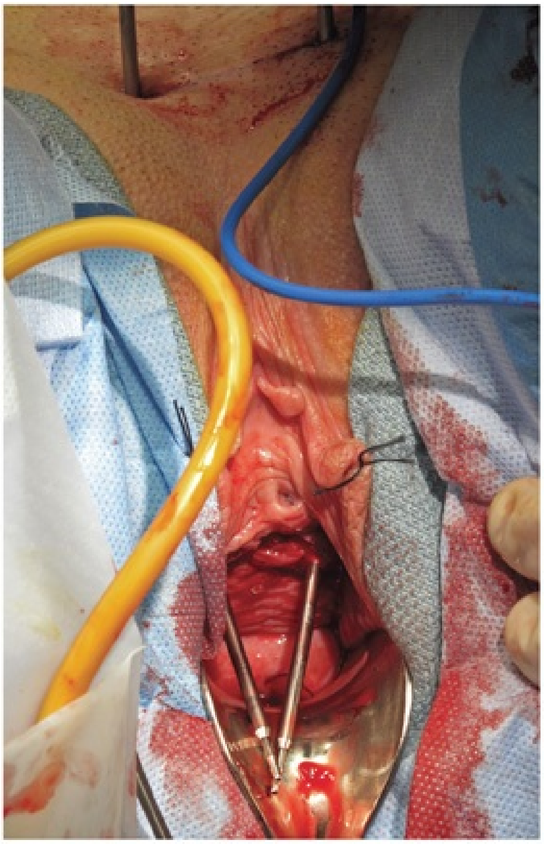

FIGURE 43.8 Both trocars have been guided through the vaginal incision on either side of the urethra.

Cystoscopy is performed after both needles have been advanced and the details of the cystoscopic evaluation are summarized in the section on rectus fascia BNS. If a bladder puncture occurs after trocar passage, the offending trocar is removed and repassed after bladder decompression (Fig. 43.9). Cystoscopy should be performed after each new pass. If a urethral injury occurs during dissection or trocar passage, the injury should be repaired and the procedure terminated until sufficient healing has occurred (5).

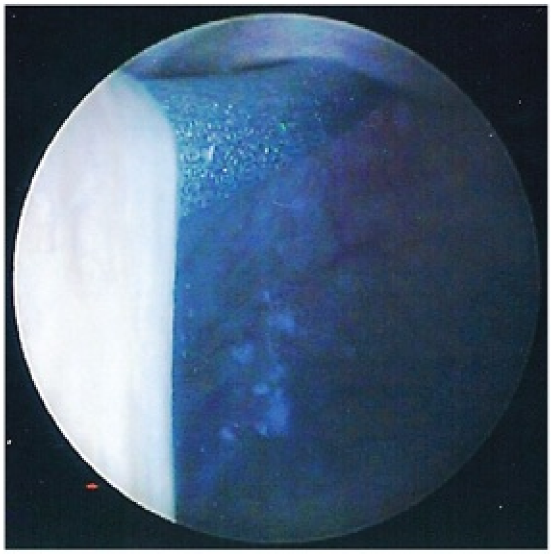

FIGURE 43.9 A trocar puncture is seen at the patient's right superolateral side of the bladder. The trocar should be removed, bladder drained, and the trocar should be repassed slightly laterally. Repeat cystoscopy should be performed to rule out repeat bladder puncture.

Each end of the sling is connected firmly to the trocars and the sling ends are advanced through the abdominal incisions by removing the trocars (Fig. 43.10). Care is taken to position the sling in a flat position under the midurethra and ensure that no twisting has occurred. The plastic sheath over the sling is cut off below the blue mark, as the mesh and sheath are fused above the mark, and an edge of the sheath is grasped with a clamp on each side. Tensioning technique varies greatly between surgeons, and no single technique has been determined to be superior. Common spacing devices between the sling and the urethra include scissors, a Kelly clamp, or Hegar dilators (Fig. 43.11). The common thread of any tensioning technique is to ensure placement of the sling without tension in a flat position at the midurethra. Once the sling is tensioned to the satisfaction of the surgeon, the sheath is removed and redundant sling ends are cut at the surface of the suprapubic skin. The SPARC has an interwoven tensioning suture which may aid in adjusting tension after the sheath has been removed. I will typically lower the legs to a comfortable lithotomy position and recheck tension-free placement before incision closure. If the procedure is performed under local anesthesia, the bladder may be filled and a cough or Valsalva maneuver may be performed on the table; however, it is important to note that many women will not have visible leakage in the lithotomy position. The suprapubic incisions can be reapproximated with benzoin or Dermabond, but if excessive bleeding is encountered at the skin edges, it may be controlled with cautery or with subcuticular 4-0 delayed absorbable sutures. The vaginal incision is closed with a 2-0 delayed absorbable running suture, and vaginal packing may be applied at the surgeon’s preference.

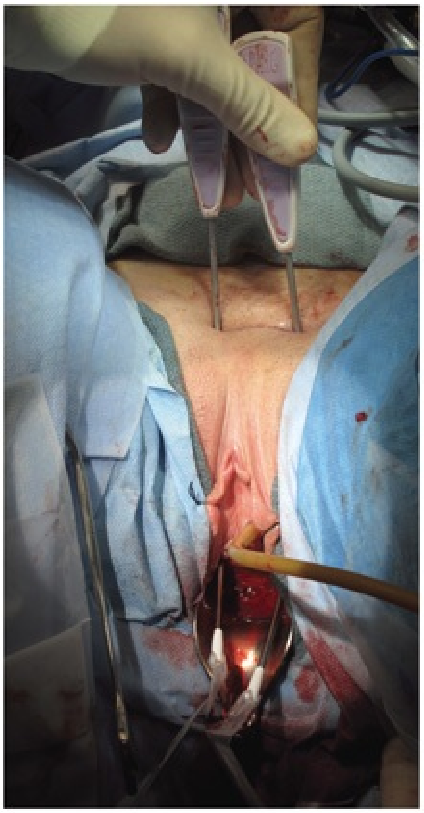

FIGURE 43.10 The sling is connected firmly to the trocars and the ends are advanced through the abdominal incisions by withdrawing the trocars.

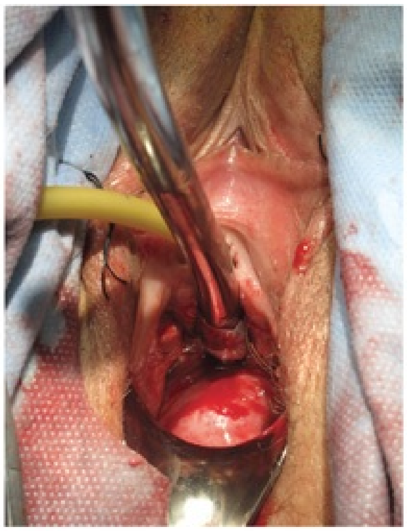

FIGURE 43.11 A Hegar dilator is placed between the sling and the urethra to ensure tension-free placement of the sling.

Bottom-Up Retropubic Midurethral Sling

The operative steps for placement of a tension-free vaginal tape (TVT, Ethicon) are similar to the top-down sling (SPARC) through the steps on vaginal dissection and suprapubic incisions. A catheter guide is placed through the urethral catheter after complete bladder drainage, and the guided catheter is used to tent up the contralateral bladder dome to minimize ipsilateral bladder puncture. The TVT trocar is then placed in the vaginal incision and aimed at the ipsilateral scapula, beginning to curve the trocar superiorly after advancing it beyond the inferior edge of the pubic symphysis. The trocar is then brought out through the ipsilateral suprapubic incision, and the procedure is repeated on the contralateral side. Cystoscopy, sling tensioning, and closure of the incisions is performed as previously described.

Outside-In Transobturator Midurethral Sling

For a Monarc Subfascial Hammock (American Medical Systems, Inc, Minnetonka, Minnesota), a vertical midline incision is made as described previously for the retropubic MUS. The vaginal epithelium is then dissected laterally toward the inferior edge of the inferior pubic ramus. The incision should allow the tip of the surgeon's index finger to extend under the inferior pubic ramus (Fig. 43.12). A 5- to 10-mm vertical skin incision is made at the intersection of a horizontal line 2 cm superior to the urethral meatus and 2 cm lateral to the folds of each thigh (Fig. 43.13A). This location often corresponds to the level of the clitoris and is located at the notch along the internal edge of the inferior pubic ramus and adductor longus tendon. Hyperflexion of the hips may be helpful in identifying the adductor longus tendon, and the skin incisions typically correspond to the location of the thumb when the tendon is pinched between the thumb and index finger (Fig. 43.13B). A helical passer is initially inserted perpendicular to the skin and then rotated medially under the inferior pubic ramus to meet the surgeon's contralateral index finger in the vaginal incision (Fig. 43.14). The finger is used for guidance as well as for protecting the urethra from inadvertent puncture.

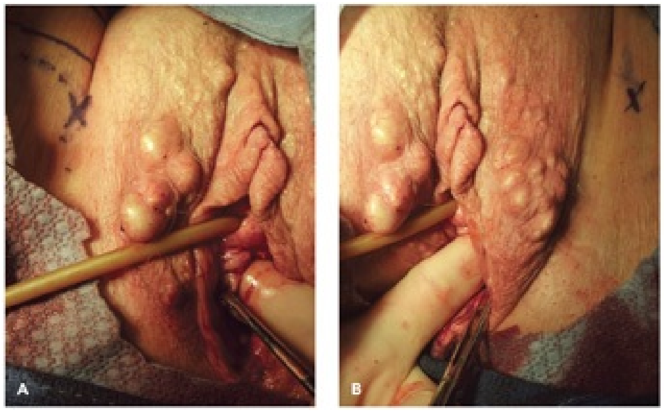

FIGURE 43.12 **A and B:** The optimal depth of lateral dissection allows the tip of the surgeon's index finger to extend under the inferior pubic ramus. In each figure, an Allis clamp is on the ipsilateral edge of the vaginal mucosa and the blue *X* marks the site of the planned incision over the transobturator skin.

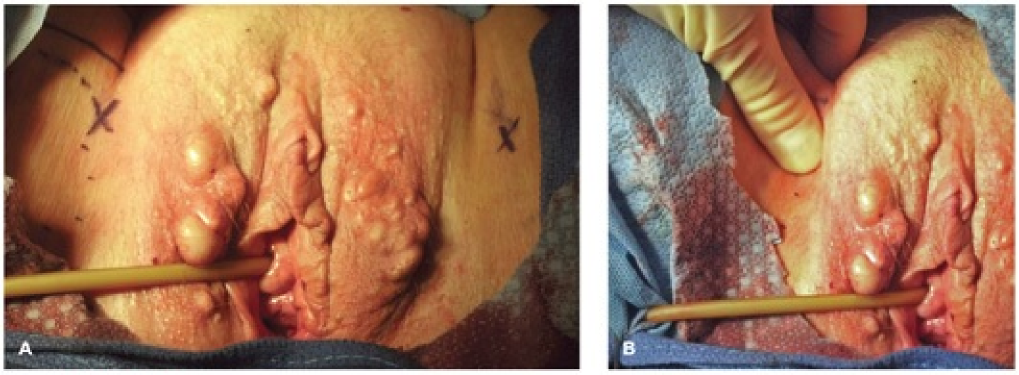

FIGURE 43.13 **A and B:** Skin incisions often correspond to the level of the clitoris and the notch along the internal edge of the inferior pubic ramus and adductor longus tendon. The location of the thumb when the tendon is pinched between the thumb and index finger is another useful landmark for the skin incisions.

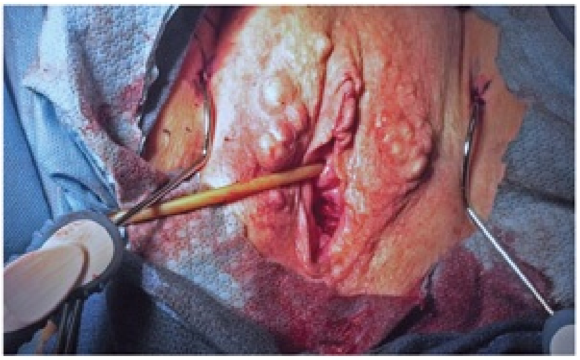

FIGURE 43.14 Helical passers are advanced perpendicular to the skin and then rotated medially under the inferior pubic ramus to exit lateral to the urethra.

Although the incidence of bladder and urethral puncture is extremely low during the transobturator approach, it is my practice to perform cystoscopy after trocar advancement on all women undergoing this procedure. As opposed to the retropubic sling, the most likely areas of bladder penetration are inferolateral (5 and 7 o'clock positions). As with other sling procedures and approaches, any trocar penetrating the bladder should be removed and repositioned with cystoscopy confirming safe placement after each additional pass.

The mesh sheath may be snapped onto the passer once the tip is visible in the vaginal incision and then withdrawn out of the skin incision (Fig. 43.15). Tensioning and wound closure is accomplished as previously described (Fig. 43.16).

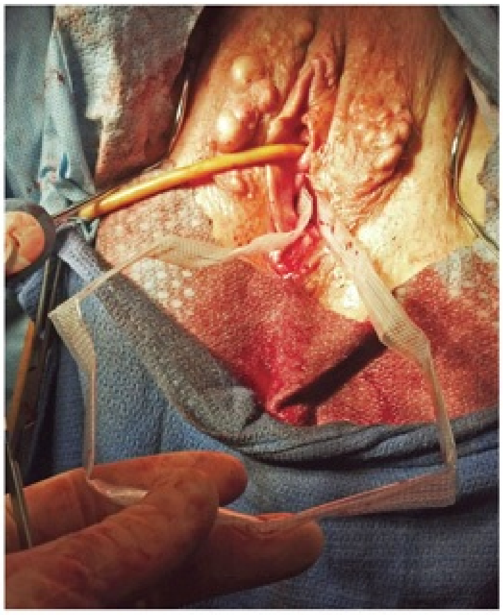

FIGURE 43.15 The mesh sheath may be snapped onto the passer once the tip is visible in the vaginal incision and then withdrawn out of the skin incision.

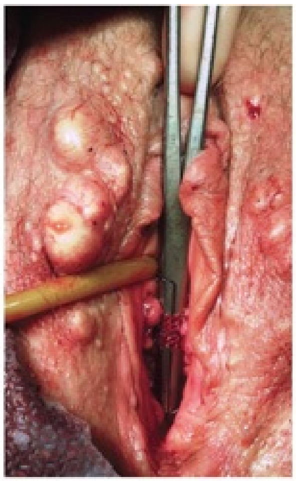

FIGURE 43.16 Tension-free positioning may be optimized with a spacer, such as a Kelly clamp, between the sling and the urethra.

Inside-Out Transobturator Midurethral Sling

For the tension-free vaginal tape obturator procedure (TVT-O, Ethicon), vaginal incision and lateral dissection are similar to the outside-in approach. The obturator membrane is sharply perforated with Metzenbaum scissors, indicated by a loss of resistance to dissection. An included winged metal guide is then inserted into the obturator membrane at the same angle as the scissors. If additional length is necessary, the winged guide can be extended from 6 to 7 cm in length. A similar incision is made in the skin overlying the obturator foramen, and a helical passer is advanced into the groove of the winged guide until the obturator membrane is entered. The guide is removed and the passer handle is rotated until it is perpendicular to the floor and the tip of the passer emerges from the obturator incision. The passer is removed and the mesh is clamped. The procedure is repeated on the opposite side. Cystoscopy, sling tensioning, and wound closure is accomplished as previously described.

Postoperative Considerations

Women undergoing concomitant prolapse surgery are typically admitted for overnight observation;

however, women undergoing MUS only are often discharged the same day. Although overnight observation is common for those women undergoing rectus fascia BNS, select patients may be discharged the same day. Vaginal packing is removed and a voiding trial may be performed the following morning. If postvoid residual volumes are elevated, an indwelling catheter is replaced and an outpatient voiding trial is performed in the next few days. Alternatively, the patient may be preoperatively instructed in clean intermittent catheterization to begin at home. A longer period of continuous bladder drainage may be considered if the bladder was penetrated with a suture passer during the procedure. All patients are discharged with analgesics and a stool softener.

OUTCOMES

The surgical success rates of rectus fascia BNS is typically high in the short term. An evaluation of several retrospective studies of the rectus fascia sling reveals early "cure" rates ranging from 72.9% to 94% (13–17). However, cure rates may wane with follow-up exceeding 4 years (17). In long-term follow-up of patients who were randomized to Burch colposuspension or rectus fascia BNS, urinary continence rates decreased during postoperative years 2 to 7 from 52% to 27% in the sling group (18). The long-term success after the retropubic MUS in several retrospective studies appears to be stable, with both subjective and objective cure criteria exceeding 75% at 10 to 17 years of follow-up (19–21); however, some authors have noted a decline in cure rates with longer periods of follow-up (22). Likewise, the subjective and objective outcomes after the transobturator MUS at 5 years of follow-up remain durable (23). It is important to note that comparing "cure" rates between various studies is challenging due to variations in the definition of success, outcome criteria, length of follow-up, inclusion and exclusion criteria, incidence of concomitant surgery, and reporting of perioperative complications. In a study by Rapp and Kobashi (24), 39% of their patients were completely dry, whereas an additional 33% claimed to have less than one leakage episode per week. Additionally, 52% used no pads, whereas 27% used 1 to 3 liners per day. When subjective satisfaction was assessed using a 10-point scale, 34% of women scored their level a 10 while 24% scored it a 9.

In their recent meta-analysis, Novara et al. (25) identified several randomized controlled trials (RCTs) comparing autologous pubovaginal sling to TVT. TVT and autologous slings were associated with similar overall continence rates (OR 0.80; 95% CI, OR 0.51 to 1.26; $P = .35$) and subjective continence rates (OR 1.28; 95% CI, OR 0.74 to 2.23; $P = .38$). The Cochrane review echoed these findings in 2009 (26). The review by Novara et al. (25) evaluated 24 studies that compared retropubic MUS to transobturator MUS and concluded that the retropubic MUS was associated with higher objective cure rates (OR 0.8; 95% CI, 0.65 to 0.99; $P = .04$); however, the subjective cure rates were similar (25). Additional RCTs published since these reviews have predominantly supported the aforementioned findings (27).

COMPLICATIONS

As with reports of surgical outcomes, detailed accounts of complications after sling surgery are often incomplete and inconsistent. In a summary of complications between a contemporary cohort of women randomized to rectus BNS and Burch, there was no significant difference in the percentage of women who had serious adverse events (13% versus 10%, $P = .20$) (28). However, surgical procedures to reduce voiding symptoms or improve urinary retention were performed exclusively in the sling group, in which 19 patients underwent 20 such procedures. Adverse events were also more common in the rectus BNS group (63% versus 47%, $P < .001$), and this difference was due primarily to urinary tract infections (UTIs). When UTIs were excluded, the rates of adverse events were similar in the two groups. The incidence of bladder injury during BNS surgery is less than 1% and complications related to the harvest site approach 15% (13,28–30). The rate of bladder puncture with the retropubic MUS approaches 10% and is extremely rare during the transobturator MUS (8). All sling procedures are associated with potential voiding difficulty or persistent or worsened storage symptoms. Thus, patients should be counseled preoperatively about the possibility of sling revision for extrusion, obstruction, or refractory storage symptoms.

In a meta-analysis encompassing 33 RCTs, Novara et al. concluded that the TVT and BNS were associated with similar complication rates (31). In comparing the top-down to the bottom-up approach, SPARC was associated with higher rates of voiding lower urinary tract symptoms (LUTS) (P = .02) and reoperations (P = .04) when compared with the TVT. The occurrence of bladder perforations (P = .007), pelvic hematoma (P = .03), and storage LUTS (P = .01) were significantly less common in patients treated by transobturator MUS when compared with women undergoing retropubic MUS.

CONCLUSIONS

Several conclusions can be drawn regarding the slings described in this chapter. First, all of the available options have been shown to be effective in improving or curing SUI in women. Second, all slings are not created equal and each has its own risk to benefit profile. Although the rectus BNS employs autologous tissue and incites a minimal inflammatory response, it requires fascial harvest that may be associated with incisional complications and additional convalescence. The MUS procedures are less invasive and the outcomes are durable; however, trocar-related injuries and the potential for vaginal extrusion due to the synthetic material may be unique to the MUS procedure. Third, reports of success vary significantly based on the definitions used and should be evaluated with “a grain of salt.” Finally, the decision to pursue sling surgery, as well as the choice of sling and approach, should be tailored to the individual patient and should take into account the patient’s wishes and the surgeon’s experience. A detailed discussion of specific risks, benefits, and options to sling surgery is essential to obtaining preoperative informed consent and cannot be overemphasized.

CHAPTER 44 ■ ABDOMINAL RETROPUBIC APPROACHES FOR FEMALE INCONTINENCE

LESLIE M. RICKEY

Urinary incontinence (UI) is common, with approximately 30% of women reporting any incontinence; about 25% to 50% of these cases are estimated to be stress urinary incontinence (SUI) (1–3). In addition, the number of women seeking care for UI is increasing. Office visits for UI more than doubled from 815,832 visits in 1992 to 1,932,768 visits in 2000 (4). A recent analysis of population growth and future demand for care concluded that consults for pelvic floor disorders will increase by 45% from 2000 to 2030 (5). In terms of surgical management, one out of nine women will have surgery for a pelvic floor disorder in their lifetime, and this number represents only a subset of women who have the condition (6). About one-third of the surgeries were for SUI alone, and another 20% of surgeries were performed for combined SUI and pelvic organ prolapse (POP).

Although the exact mechanism that leads to SUI is not known, proposed theories include loss of proximal urethral support, or the “hammock” theory, and intrinsic deficiency of the external urethral sphincter. Surgical procedures are directed toward correction of the deficiency, either reestablishing support of the proximal urethral or improving urethral closure. The suburethral sling procedure can be performed using autologous fascia (rectus fascia or fascia lata) or synthetic material. The sling procedures are covered in other chapters.

Urethral position depends on anterior vaginal wall support. Retropubic colposuspension, or urethropexy, aims to improve the support of the vesicourethral junction by elevating the periurethral tissue toward the pubic bone, thus restoring the proper anatomy. The procedure is believed to treat incontinence by providing improved resistance to increases in intra-abdominal pressure, resulting in more effective urethral compression. The Marshall-Marchetti-Krantz (MMK) procedure involves suturing the periurethral tissue at the level of the bladder neck directly to the periosteum of the pubic symphysis. Burch, a gynecologist, modified this technique by altering the suspension laterally to the iliopectineal line or Cooper’s ligament. The Burch technique was further modified by Tanagho, a urologist, to include a suture bridge instead of direct apposition of the anterior vaginal wall to Cooper’s ligament. The Burch urethropexy has traditionally been performed via a small Pfannenstiel incision, but the laparoscopic approach has been used as well.

The MMK is largely a historical procedure as the Burch appears to be slightly more efficacious. In addition, the complication of osteitis pubis is specific to the MMK approach due to the placement of suture directly into the periosteum. Although the Burch urethropexy may be regarded as an outdated procedure as well, it is still a reasonable option for a woman desiring an incontinence procedure, particularly if she is undergoing a concomitant abdominal surgery. In addition, as will be discussed later in the chapter, it is indicated for an asymptomatic, stress-continent woman undergoing an abdominal sacrocolpopexy for prolapse.

DIAGNOSIS

A thorough and detailed patient history should elicit whether the patient has stress incontinence, urge incontinence, or mixed incontinence. It is important to ascertain a history of previous incontinence or pelvic surgeries, as this may affect surgical decision making. Prolapse symptoms should also be queried, as almost two-thirds of women with SUI have coexisting POP (7), and additional procedures may be necessary at the time of the incontinence surgery. Finally, it is prudent for physicians performing pelvic surgery to inquire about whether the patient’s Pap screening is up to date.

The physical examination should include a bimanual and speculum examination to assess the vaginal tissue and vaginal support and to rule out any pelvic masses. A positive empty supine cough stress test is highly predictive of urodynamic stress incontinence (8). Urethral hypermobility is typically confirmed before considering a Burch urethropexy. Traditional teaching has used the cotton-tipped swab test to measure urethral hypermobility. A cotton-tipped swab is inserted transurethrally to the proximal urethra, and the patient is asked to maximally Valsalva. A deflection of >30 degrees from the resting angle during Valsalva is considered to reflect urethral hypermobility. The surgeon should inspect the lower abdominal wall for scars indicative of previous pelvic surgery and correlate with the patient's surgical history.

If the patient relates SUI symptoms and desires surgical treatment, many surgeons choose to perform urodynamics (UDS) to confirm the diagnosis. It is believed that the Burch is not as effective in women with "intrinsic sphincter deficiency," typically defined by indirect measures of urethral function, including leak point pressure <60 mm Hg or urethral closure pressure of 20 mm Hg or less. However, a randomized trial comparing Burch to sling in women with low urethral closure pressures (20 cm H_2O or less) did not show a difference in subjective success between the two procedures at a mean 5 years of follow-up (84% versus 93%, respectively, $P = .47$) (9). Although the study was not powered to detect small differences between the treatment groups, the findings still demonstrate that the Burch procedure can be effective in women with low urethral closure pressures. Valsalva leak point pressure (VLPP) has not been shown to be a significant predictor of success after the Burch procedure (10). In addition, a retrospective review of women who underwent a Burch urethropexy with preoperative VLPPs of <60 cm H_2O showed an objective success rate of 91.7%, indicating that a low VLPP is not necessarily predictive of Burch failure (11). Direct measurement of striated urethral sphincter physiology using electromyography suggested that women with better innervation of their urethral sphincters were more likely to be cured by the Burch urethropexy (12). In summary, there are no UDS parameters clearly predictive of Burch success or failure. Therefore, traditional urodynamic testing does not seem to aid in the surgeon's decision of which incontinence procedure to perform. However, the study can provide helpful information about the coexistence of detrusor overactivity, clarify confusing symptomatology, and confirm diagnoses in patients who have undergone previous incontinence surgeries.

INDICATIONS FOR SURGERY

The main indication for an incontinence procedure is the presence of symptomatic SUI that adversely affects the woman's quality of life. The patient should also have the sign of transurethral loss of urine with a cough stress test or during formal urodynamic testing. Additionally, the patient must be sufficiently healthy to undergo regional or general anesthesia, be able to be placed in dorsal lithotomy position, and have a habitus that allows a suprapubic incision. There appears to be a risk of worsening POP after a Burch procedure (13–15); therefore, a Burch urethropexy probably should not be performed as a solitary procedure if there is significant apical descent. Lack of urethral hypermobility and a previously failed retropubic approach would be considered indications for a suburethral sling by most pelvic surgeons.

A Burch urethropexy is also appropriate for an asymptomatic woman (without SUI) undergoing a sacrocolpopexy for POP. A randomized controlled trial showed that performing a concomitant Burch urethropexy at the time of abdominal sacrocolpopexy resulted in a decrease of new-onset postoperative SUI from 40% to 20% in stress-continent women (16).

ALTERNATIVE THERAPY

Conservative therapies for SUI may involve use of pessaries or physical therapy for pelvic floor muscle (PFM) rehabilitation. In women successfully fitted with a pessary for UI, rates of continued use and satisfaction range from 16% to 59% at 1 year (17,18). PFM physical therapy includes both strengthening and instruction on timing of activation of PFMs to avoid leakage. A Cochrane review in 2007 supported that PFM training should be included in first-line conservative management for women with UI (19). In women with SUI who participated in a course of PFM exercise, 44% to 56% of patients were satisfied with symptom improvement and desired no further treatment (20,21).

SURGICAL TECHNIQUE

Open Burch Urethropexy

The patient is placed in the low dorsal lithotomy position and the vagina and abdomen are prepped and draped for combined access. A Foley catheter is placed and a Pfannenstiel incision is made. Dissection of the space of Retzius is performed (Fig. 44.1). The first and second fingers of the surgeon’s nondominant hand are placed in the vagina, with one finger on each side of the urethral catheter. The bladder is retracted medially so that the perivaginal tissue lateral to the vesicourethral junction is exposed. Using the vaginal finger as a guide, a peanut sponge can be used to carefully sweep away the overlying fat until the glistening white perivaginal “fascia” is visualized. Care must be used as vaginal and pelvic veins are often encountered in this area. Palpation of the Foley balloon will help delineate the vesicourethral junction. Two figure-of-eight sutures are placed in the periurethral vaginal tissue, one at the vesicourethral junction and another more distally at the level of the midurethra. Avoid placing the sutures through any fatty tissue. Placement of the sutures into the vagina is aided by elevation of the anterior vaginal wall using the hand in the vagina (Fig. 44.2A). The vaginal finger should be used as a guide to ensure that the sutures are sufficiently lateral to the urethra. The suture bite should encompass vaginal tissue without perforating the vaginal epithelium (Fig. 44.2B). The procedure is repeated on the other side. A total of four permanent, nonabsorbable sutures such as no. 0 or no. 1 polyester (Ethibond) or polytetrafluoroethylene (Gore-Tex) sutures are placed (two on each side; Fig. 44.3A). Cooper’s ligament is identified and any overlying tissue is gently swept off using a peanut sponge.

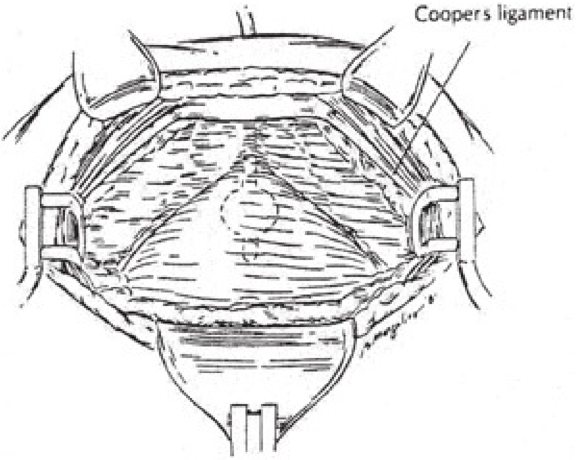

FIGURE 44.1 Retropubic space showing the bladder neck, Foley balloon, and Cooper’s ligament.

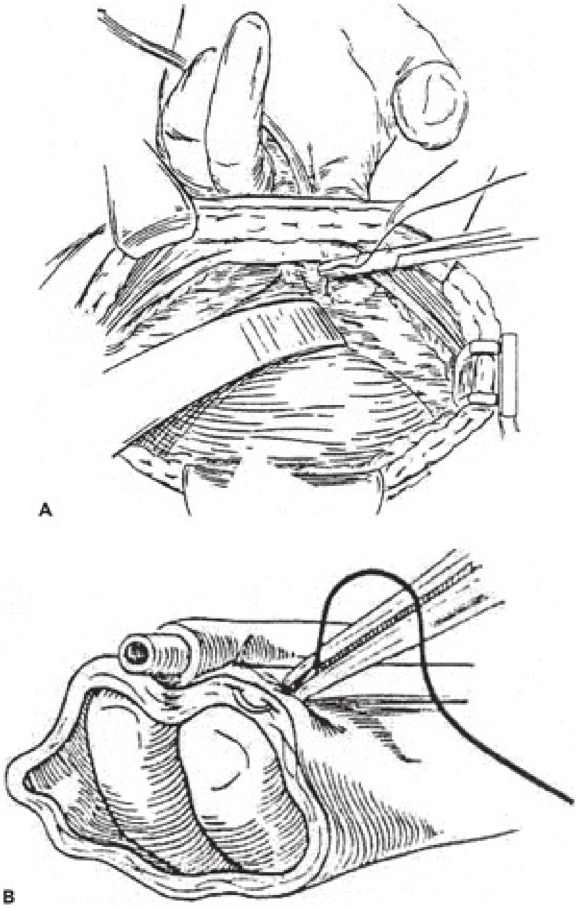

FIGURE 44.2 **A:** The first suture at the level of the vesicourethral junction. The surgeon's finger in the vagina helps guide the suture lateral to the urinary tract. **B:** The finger in the vagina also helps exclude the suture from the vaginal epithelium.

The sutures are then placed through Cooper's ligament on the respective sides (Fig. 44.3B). Note that the sutures are tied off the midline. The proximal sutures will be placed slightly lateral to the more distal midurethral sutures. The obturator vessels and nerve pass through the obturator fascia; this obturator "notch" is the lateral limit for suture placement into Cooper's ligament and should be avoided. The assistant ties the sutures down while the operator's fingers remain in the vagina to ensure the proper degree of suspension. The operator should feel that the anterior wall is slightly lifted without overcorrection of the urethrovesical junction. It is imperative that the sutures are tied such that there is distance between Cooper's ligament and the vaginal tissue (Fig. 44.3B) seen as a suture bridge of approximately 2 cm. This prevents overcompression of the urethra, which can cause obstruction. The placement of these sutures and how tightly they are tied differ from the initial description of Burch in which the sutures were tied down with complete approximation of the perivaginal tissue onto Cooper's ligament. After tying the sutures, cystoscopy is performed to ensure that the sutures did not perforate the bladder and that the ureters are patent. Methylene blue can be used to help identify efflux of urine from the ureteral orifices.

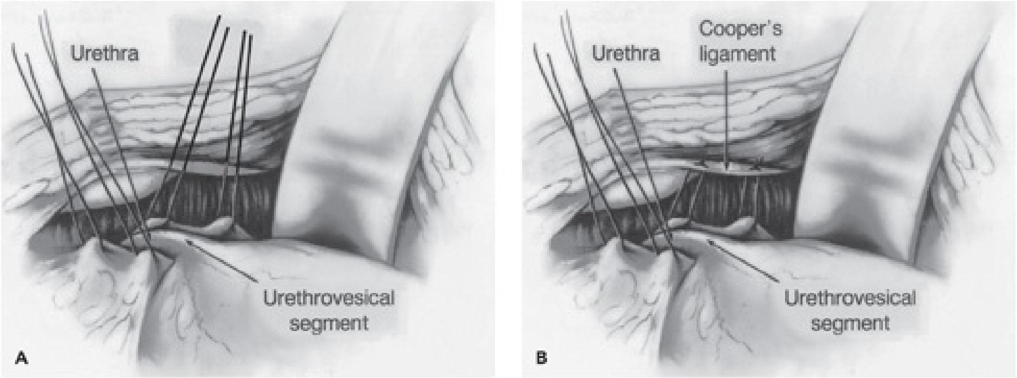

FIGURE 44.3 **A:** A total of four sutures are placed in the periurethral tissue. **B:** The two right-sided sutures are passed through Cooper's ligament and tied; note that there is a gap between the vaginal tissue and Cooper's ligament, creating a suture bridge.

Laparoscopic Burch Urethropexy

Apart from the incisions, the laparoscopic Burch is performed in an identical manner to the open Burch procedure. There are a variety of port placement strategies described. A common approach is to place a 10-mm laparoscopic port at the umbilicus and two 5-mm ports in the lower lateral abdominal wall, approximately two fingerbreadths superior and medial to the anterior superior iliac spine. An additional suprapubic port is sometimes used. As in the open approach, cystoscopy should be performed at the end of the procedure to exclude intravesical suture and ensure ureteral patency. The laparoscopic procedure is covered in more detail in the chapter dedicated to laparoscopic surgery for UI.

OUTCOMES

Results

A recent Cochrane review showed overall cure rates between 69% and 88% for open retropubic colposuspension (22). A randomized controlled trial comparing Burch to suburethral sling showed stress-specific success of 49% (compared to 66% for the sling group) at 2 years using a very strict definition of success (23). However, there was also a lower rate of adverse events in the Burch group. The overall patient satisfaction was slightly lower in the Burch group (78% versus 86%, $P = .02$). When the patients were followed out to 5 years, continence rates continued to decrease, and surgical retreatment was significantly higher in the Burch group (26% versus 2% in the sling group; $P < .001$). Patient satisfaction remained higher in the pubovaginal sling group (83% versus 73%, $P = .04$) (24). Preoperative variables that predicted recurrent UI included increasing age, prior UI surgery, menopausal status, and urge incontinence symptoms (25).

Another randomized trial comparing Burch to tension-free vaginal tape (TVT) revealed 63% of women reporting cure after the Burch (versus 70% in TVT group, $P = .54$) at 5 years, but overall, 90% of women who had undergone colposuspension were satisfied or very satisfied with the results of surgery (14). Using a negative 1-hour pad test (<1 g change in weight) for definition of cure, and using pad test data from the last available follow-up visit for missing data, the cure rates were computed as 69% for colposuspension versus 75% for TVT ($P = .28$). Finally, a systematic review and meta-analysis of retropubic procedures for the treatment of SUI showed a significantly higher overall cure rate for midurethral slings over Burch urethropexy, although subjective continence rates were similar. Bladder perforation was more common after midurethral sling; however, other complications, including retropubic hematoma and urinary tract infections, were similar (26) in a randomized controlled trial comparing laparoscopic to open Burch, there were no significant differences seen at 24 months in patient-reported cure of stress incontinence (66%), although the study was not powered to detect a difference of <20% (27). There was not a significant difference in perioperative complications. Out of six cases of suture penetration into the bladder, five occurred in the laparoscopic group, but this difference did not reach statistical significance ($P = .11$). Mean operating time was less in the open group (87 versus 42 minutes, $P < .0001$), and blood loss was less in the laparoscopic group (126 versus 170 mL, $P = .03$). There was no difference in length of hospital stay, but the average return to normal activities was 5 days less in the laparoscopic group (24.6 versus 19.7 days, $P = .01$). A meta-analysis of studies comparing laparoscopic versus open Burch had similar findings of longer operating times, marginally less blood loss, decreased hospital stay, and faster return to normal activity in the laparoscopic group (28). There was not a significant difference in subjective or objective cure rates up to 2 years postoperatively.

Finally, a randomized trial comparing laparoscopic Burch to TVT with a median follow-up of 65 months concluded that the two procedures have similar long-term efficacy (29). Although only 52% of subjects in the TVT group and 43% in the Burch group reported no urine leakage under any circumstances, bothersome urine leakage was present in only 8% and 11%, respectively ($P = .26$), and overall patient satisfaction rates were similar as well (79% versus 88%). Operating time was less in the TVT group, but there was no difference in blood loss or hospital stay. In terms of bladder injury, there were two cystotomies in the TVT group and two patients with bladder sutures detected intraoperatively in the laparoscopic Burch group.

COMPLICATIONS

Delayed bladder emptying was seen in 2% of patients after undergoing a Burch urethropexy in a large multicenter study, but no additional procedures were required for urinary retention (23). These patients may require temporary intermittent self-catheterization. Occasionally, the periurethral sutures must be released transvaginally to relieve the urethral obstruction if there is not adequate bladder emptying at 4 to 6 weeks postoperatively. New-onset urge UI occurs in 3% to 4% of patients, and 5% report de novo urgency (14,23). In a patient with significant postoperative urgency and frequency, urinary retention, and urinary tract infection should be ruled out: As many as 30% of patients may develop a urinary tract infection in the postoperative period (23).

Ureteral injuries occur in <1% of patients. Bladder injury is more common, with incidental cystotomy rates of 2% to 4%, usually due to suture passage into the bladder. A recent study showed that 2 of 329 (0.6%) patients sustained a ureteral injury and 10 out of 329 (3.3%) had an incidental cystotomy when undergoing a Burch urethropexy (23). A cystoscopy at the time of surgery can aid in identifying intravesical sutures, and ureteral patency can be confirmed as well.

Approximately 8% to 13% of women are found to have vaginal vault or uterine prolapse during the follow-up period after Burch (14,15,30). The clinical significance of the prolapse has been unclear; however, a randomized controlled trial comparing Burch to TVT showed that surgery for prolapse was more common after the Burch colposuspension (7.5% versus 1.8%, $P = .025$) (14). Therefore, a sling may be a more appropriate choice for a woman desiring an incontinence procedure who has asymptomatic prolapse with apical descent of several centimeters or more.

CONCLUSION

A Burch urethropexy should be considered for a woman desiring an incontinence procedure, particularly if she is undergoing a concomitant abdominal surgery, or for a stress-continent woman undergoing an abdominal sacrocolpopexy.

CHAPTER 45 THE ARTIFICIAL URINARY SPHINCTER

ANGELO E. GOUSSE, HARI S. G. R. TUNUGUNTLA, NEAL PATEL, AND IZAK FAIENA

INTRODUCTION AND EPIDEMIOLOGY

Normal lower urinary tract function is critical in maintaining urinary continence at low bladder pressure. Up to 16 to 20 million Americans have some type of urinary incontinence with potential major psychosocial consequences. Urinary incontinence is prevalent in men, although the overall numbers are lower than in women. The Epidemiology of Lower Urinary Tract Symptoms (EpiLUTS) study examined rates of urinary incontinence in both men and women in the United States, United Kingdom, and Sweden (1). Prevalence of any urinary incontinence was as high as 46% for men and 68% for women reporting urinary incontinence. However, this included various forms of urinary symptoms in addition to incontinence. When categorized by type, 5.6% of men reported urgency urinary incontinence only, 0.8% stress urinary incontinence only, 1.4% mixed urinary incontinence, 6.3% had urgency urinary incontinence and another form of urinary incontinence, and 1.2% had stress and another form of urinary incontinence.

Etiology for urinary incontinence includes neurologic disorders, iatrogenic following surgery on the lower urinary tract (e.g., radical prostatectomy and transurethral resection of the prostate), and bladder dysfunction. Urinary incontinence secondary to intrinsic sphincter dysfunction can potentially be cured by artificial urinary sphincter (AUS), an implantable prosthetic device consisting of a pressure-regulating balloon (PRB), a cuff and a pump mechanism (Figs. 45.1 to 45.3). There are several choices of PRB including those with a preset pressure of 51 to 60, 61 to 70, or 71 to 80 cm H_2O. Selection of the PRB is based on the location of the cuff. Although 61 to 70 cm H_2O pressure balloon is the most commonly used PRB, a higher pressure (71 to 80 cm H_2O) is sometimes used for recurrent stress urinary incontinence and when a bladder neck cuff is used. The cuff is available in sizes ranging from 3.5 to 5.5 cm, the selection of which depends on its location at the bulbar urethra versus bladder neck. The choice of cuff size needs a subtle calculation sometimes in that an additional 2 to 3 mm may be added to the measured urethral circumference to account for the inaccuracy in measuring the actual circumference at the insertion site. A smaller cuff becomes necessary in patients with recurrent incontinence following cuff atrophy. A 5.0-cm and sometimes 5.5-cm cuff may be used if it is inserted at bladder neck. The pump has a built-in deactivation button, manual pump, and delayed refill resistor. An activated cuff remains open for 2 to 4 minutes as fluid leaves the cuff, only to slowly return through the refill resistor in the pump, restoring continence. Transfer of fluid and the resultant transfer of pressure to the cuff is prevented by the deactivation button of the pump when this feature is used, thus leaving the device temporarily nonfunctional and the patient incontinent.

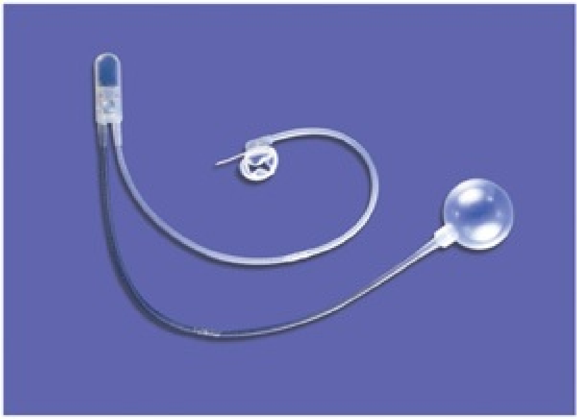

FIGURE 45.1 AUS with single cuff.

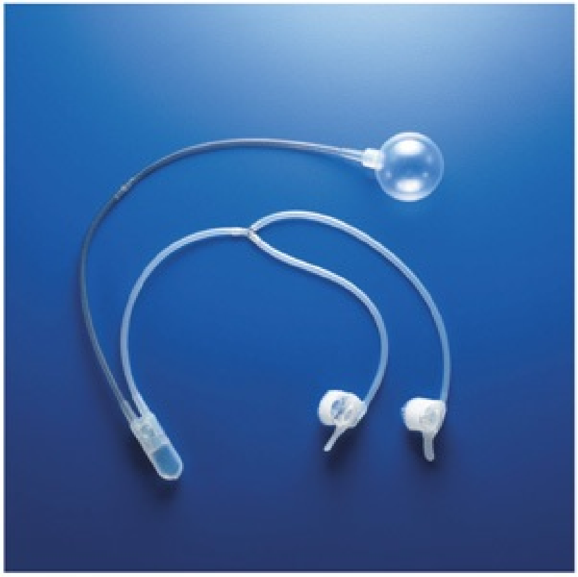

FIGURE 45.2 AUS with double cuff.

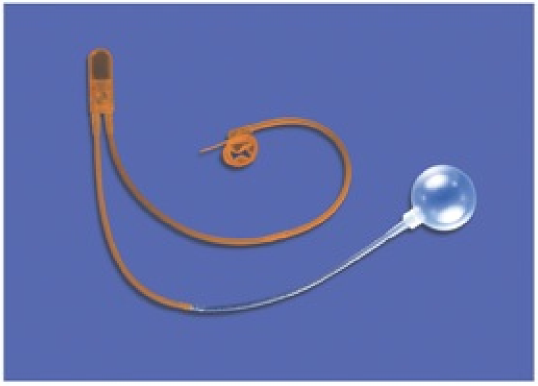

FIGURE 45.3 AUS with InhibiZone-coated cuff and control pump.

Since its first implantation by Brantley Scott in 1972 (2), the original model underwent several technical modifications and advances resulting in the current AUS implant. Notable advances in design include the narrow-backed cuff (1987) (3) to limit urethral erosion and color-coded kink-resistant tubing assuring secure device assembly and function. It was recently reported that learning curve for AUS placement was found to be approximately 25 cases based on complications and reoperation rates (4).

DIAGNOSIS

Identifying the source and type of the incontinence is the first step in determining the need for an AUS. Diagnosis of the etiology of incontinence can be determined using multichannel urodynamic testing such as videourodynamic studies. Such studies assess the intrinsic sphincter function, bladder capacity, and detrusor compliance as well as evaluate for detrusor overactivity and leak point pressures. This evaluation is especially important in patients with neurogenic etiologies because AUS placement in some of these patients can have potentially detrimental long-term effects to renal function.

Along with urodynamic evaluation, cystoscopic examination must be performed to evaluate the quality and health of the urethral tissue throughout, and especially at the level where an AUS is to be placed whether it is at the bladder neck or bulbar urethra. Most importantly, urethral stricture must be ruled out with cystoscopy.

A thorough physical exam should be performed. Specifically, a neurologic assessment is essential in determining patient eligibility for AUS placement. Traditionally, the pump is placed in the right hemiscrotum in a right-handed patient and on the left side in a left-handed patient. During physical exam, it is of paramount importance to confirm that the patient has the required manual dexterity, pincer grip, and finger strength necessary for the day-to-day manipulation of the pump to achieve satisfactory voiding. Evaluation of the genitalia is also important in identifying integumentary and microbial issues that may prevent placement of AUS. Sites of planned incisions must be examined carefully to assess for viability and integrity of the skin because this is important in operative planning and placement eligibility.

INDICATIONS FOR SURGERY

Indications for Artificial Urinary Sphincter Placement

Postprostatectomy incontinence due to intrinsic sphincter dysfunction is the most common indication for an AUS. Other indications include posterior urethral trauma leading to incompetent sphincter; persistent female incontinence refractory to all other incontinence therapies; and congenital abnormalities leading to persistent incontinence such as exstrophy-epispadias complex, spina bifida, and various other genitourinary abnormalities.

Contraindications for Artificial Urinary Sphincter Placement

As mentioned earlier, a key physical exam assessment is the patient’s neurologic status. AUS is absolutely contraindicated in patients with physical and/or mental disability whose conditions are severe enough to render them noncompliant and/or unreliable regarding management and use of the device.

Relative contraindications include female patients with prior history of pelvic radiation because they are at higher risk for erosion (both urethral and vaginal). Also included are patients with progressive neuromuscular disorders who may initially be deemed fit to use the device properly in the short term but will likely be unable to use the device in the long term. Lastly, patients with uncontrolled detrusor overactivity, noncompliant bladders, and/or small bladder capacity are also relatively contraindicated.

ALTERNATIVE THERAPIES

Given lack of sphincter function, aside from AUS placement, the patient may consider urethral bulking agents, bladder neck closure, male urethral sling placement, and/or urinary diversion. Selection of urethral sling versus AUS based on the measured Valsalva leak point pressure (e.g., AUS for very low leak point pressures of <40 cm H_2O pressure and sling for patients with moderate leak point pressures of 50 to 70 cm H_2O pressure) is a contentious issue. However, male urethral sling may be an option in patients with cystoscopically documented residual sphincter function, partial coaptation of the sphincteric urethra, and absence of any sectoral defects in the external urethral sphincter (Table 45.1).

SURGICAL TECHNIQUE

Preoperative Preparation

Infection of an implanted AUS device can have long-term detrimental effects for the patient. Therefore, it is important to be prudent regarding potentially modifiable preoperative and postoperative factors which may affect risk of infection. In a recent contemporary series, *Staphylococcus aureus* was the most common causative agent for AUS infection (5).

Preventive strategies must be employed to ensure the patient has the best chance for an infection-free outcome. Patients with urinary tract infections must be treated prior to surgery. Skin infections or irritation and breakdown in the area of the genitalia and planned incision sites must be addressed, and preventive measures must be taken in the perioperative period to prevent recurrences during the tissue healing process. If the genital skin involvement is secondary to urinary leakage, preoperative indwelling urethral or suprapubic catheter placement facilitates healing of the skin. Because catheters are potential sources for urinary tract infections, it is recommended removing catheter placed for this reason about 1 week prior to AUS implantation. If the patient had a catheter or intermittently catheterizes, prophylactic antibiotics may be considered starting a few days prior to the procedure.

Preoperative antibiotics that cover both aerobic and anaerobic organisms should be given approximately 1 hour before surgery or at time of induction. Antibiotic choice must have broad enough coverage for both skin and genitourinary flora.

Patient preparation also includes on-table shaving; patients must be instructed not to shave prior to arriving to the hospital on the day of the procedure. Shaving immediately prior to the start of the operation will reduce the chance of infection.

A recent randomized controlled trial evaluating the efficacy of chlorhexidine versus povidone-iodine–based antimicrobial scrubs in patients undergoing genitourinary prosthesis placement found that chlorhexidine prep was superior to povidone-iodine prep regarding positive postpreparation cultures of 8% versus 32%, respectively. They also concluded that there was no significant difference in urethral or genital skin irritation among the two skin preps. Chlorhexidine required a 2-minute prep time versus 5-minute prep time for povidone-iodine. Overall, this study found chlorhexidine to be a superior agent (6). The authors did not report any significant difference in the incidence of clinical complications between the two groups.

After anesthesia is induced and the patient has been shaved, the patient should be positioned in a dorsal lithotomy position and after being prepped should be draped in a such way to allow the surgeon access to both the perineum, genitalia, and suprapubic and lower abdominal area. Next, a 16Fr urethral catheter should be placed. Betadine mixed with normal saline is instilled in the urethra prior to the insertion of the urethral catheter because this is colonized in some patients.

ARTIFICIAL URINARY SPHINCTER PLACEMENT IN MEN

Perineal Cuff Placement

In men, proximal bulbar urethral cuff placement is optimal. For cuff placement around the bulbous urethra, a midline perineal incision should be made over the bulbar urethra. The incision should allow for dissection and exposure of approximately 2 cm length of urethra (Fig. 45.4). Great care must be taken in handling the corpus spongiosum, and every measure should be taken to prevent inadvertent entry into the urethral lumen. Electrocautery should be avoided in controlling bleeding associated with injuries to corpus spongiosum, which should be repaired with absorbable (4-0) suture instead.

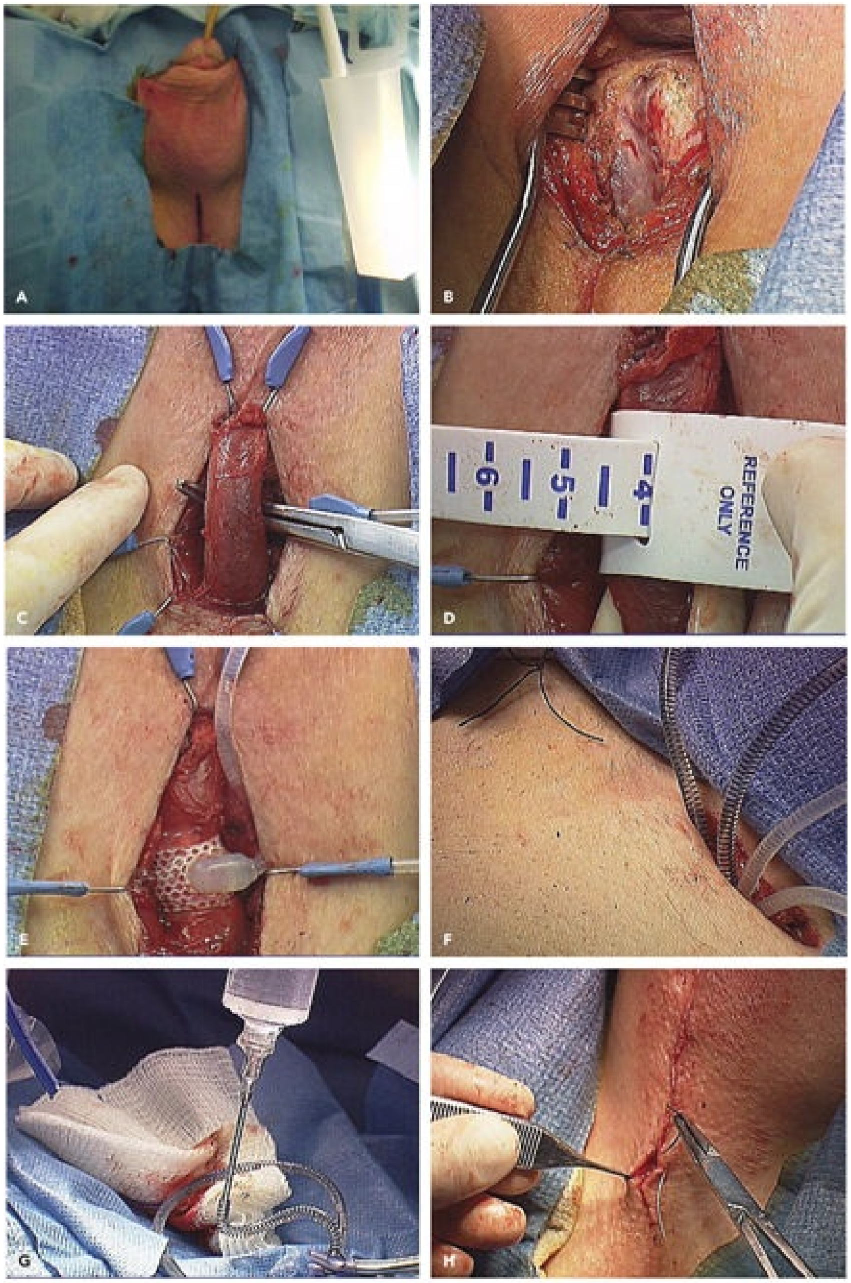

FIGURE 45.4 Various steps depicting perineal cuff placement in men. **A:** Perineal skin incision. **B:** Exposure of corpus spongiosum of the bulbar urethra after incising bulbospongiosus muscle. **C:** Circumferential mobilization of bulbar urethra. **D:** Measurement of the circumference of the bulbar urethra to select the appropriate cuff size. **E:** Appropriate size cuff placed around the proximal bulbar urethra. **F:** Clear and black tubing of the AMS 800. **G:** Filling of the reservoir with the "filling solution". **H:** Subcuticular closure of the perineal skin incision.

The urethral mobilization should be carried out circumferentially by freeing the attachments of the dorsal aspect of the urethra from its adjacently associated corpora. Once the urethra is freely mobilized, the circumference can be accurately determined using the sizer/measuring tool provided in the AUS surgical kit. When placing the sphincter, the cuff size should be such that it is neither too tight nor too loose. One of the hints to ensure determine appropriate cuff size is that one should be able to easily insert the closed jaws of a right-angle clamp between the urethra and the sizer/cuff. It is important to select the cuff about 2 to 3 mm longer than the measured size to prevent a tight fitting cuff over the urethra, thereby preventing possible erosion. Usually, the most common size for a man undergoing a bulbar urethra AUS implant is 4.0 to 4.5 cm. More recently, 3.5-cm cuffs are starting to gain favor for both primary and revision AUS placement (7).

After the cuff is placed, a 4- to 5-cm incision is made 2 to 3 cm above and just lateral to the pubic symphysis. This will be the planned reservoir (PRB) site. A transverse incision is then made in the fascia followed by blunt dissection to develop a space for the reservoir (PRB) between the transversalis fascia and the retropubic space. The PRB is then placed in the space developed and inflated to 23 to 25 mL. Intraperitoneal placement of the PRB is not recommended because the PRB is functional only in the relatively closed retropubic space (personal communication, December 2014, American Medical Systems, Minnetonka, Minnesota). The type of the PRB chosen (61 to 70 cm H_2O pressure versus 51 to 60 cm H_2O pressure) depends on the indication for AUS placement. PRB with a higher pressure (71 to 80 cm H_2O) may be used with a bladder neck cuff. If AUS placement is for postprostatectomy incontinence, then a 61- to 70-cm H_2O pressure PRB is acceptable. If the patient has any condition that may increase the chance of atrophy or erosion (such as prior radiation), a lower pressure PRB (51 to 60 cm of H_2O pressure) is indicated. The tubing from the cuff will need to be passed into the suprapubic incision to be connected to the reservoir.

Next, the control pump is placed in the subdartos pouch that is developed by spreading the ring clamp. The pump is placed in the right hemiscrotum in a right-handed person and vice versa. It is placed in the most anterior and dependent portion of the scrotum superficial enough with the deactivation button easily palpable. A path for the pump tubing is developed superiorly from the suprapubic incision into the perineal incision using a long clamp. It is important to secure the pump through the scrotal skin with a Babcock clamp to allow for optimal pump positioning while providing adequate tubing length until the end of the procedure.

Once all the tubing has been passed, excess tubing should be cut away and the remaining tubing should be connected using the connectors provided in the AUS accessory kit. Once all the tubing has been connected, the system should be cycled to test pump function. During the test, the urethral catheter should be removed, and urethroscopy should be used to visualize the cuff to assess for degree of occlusion of the activated cuff. Once the surgeon is satisfied, the cuff should be deactivated and remain deactivated for 4 to 6 weeks to allow for proper healing. Each layer of the wound is closed with absorbable sutures. The urethral catheter need not be reinserted unless there is suspicion regarding inadequate bladder emptying. The patient should be made aware that their incontinence will persist until the AUS is activated after an appropriate healing period. Patients can usually be discharged home 2 to 3 hours after surgery or on the first postoperative day with a 5- to7-day course of an oral antibiotic. The device is traditionally activated 6 weeks following implantation.

Transcorporeal Cuff Placement

This approach is usually reserved for patients who have had prior urethral erosion and/or an anatomically suboptimal urethra secondary to prior infected AUS or severe atrophy. Raj et al. (8) noted that comorbidities such as hypertension, coronary artery disease, and prior radiation predisposed the patient to a higher chance of erosion. Given that a more proximal placement of an AUS is sometimes not feasible, a more distal approach has been evaluated but not without its own set of challenges. Wall thickness of the corpus spongiosum of the urethra becomes an issue, as it becomes thinner distal to the bulbar urethra, putting the urethra at a higher risk of erosion.

Guralnick et al. (9) have reported success with transcorporeal cuff placement by using the tunica albuginea to bulk the urethral wall, thereby minimizing erosion and allowing for distal cuff placement in patients undergoing revision surgery.

Technique

A 2- to 3-cm portion of urethra distal to the bulbar urethra is selected, and under urethroscopic guidance, the skin incision made overlying the urethra and corporal bodies allowing for adequate exposure (Fig. 45.5). Next, 2.5-cm incisions are made bilaterally in the tunica albuginea of both corpora cavernosa after perforating the septum between the corpora cavernosa, creating a flap of corporal tissue over the dorsal roof of the urethra (Fig. 45.6A). This provides enough urethral buttress/protection to allow a larger than otherwise cuff to be placed, thus decreasing chance of erosion (Fig. 45.6B). The cuff is then inserted followed by repair of the corporotomies (Fig. 45.6C). It is important to note that there is a risk of decreased erectile function in potent men undergoing this procedure (9).

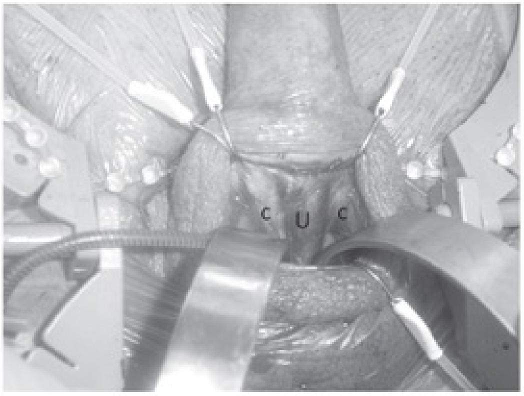

FIGURE 45.5 Initial dissection of the urethra, showing the urethra (*U*) and the corpora cavernosa (*C*) on either side.

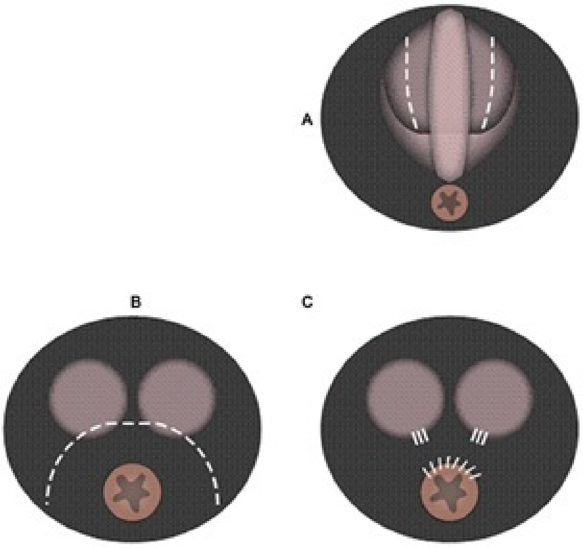

FIGURE 45.6 **A:** Transcorporeal cuff placement: Vertical corporotomies are made bilaterally. **B:** The tunica over the corpora is left attached to the urethra for extra support of urethral tissues. **C:** The remaining tunica albuginea is reconstituted behind the position of the cuff. The *broken lines* indicate incisions in the tunica albuginea of the right and left corpora cavernosa. (Adapted with permission from Guralnick ML, Miller E, Toh KL, et al. Transcorporal artificial urinary sphincter cuff placement in cases requiring revision for erosion and urethral atrophy. *J Urol* 2002;167(5):2075–2079. A more recent study by Wiedemann et al. (10) reviewed the existing literature along with their own cohort to better assess the role of transcorporeal cuff placement in the salvage setting to further elucidate outcomes with respect to erectile function and continence. They concluded that this method continues to be a useful alternative in the setting of urethral atrophy and/or erosion after prior AUS placement. Among six patients (*n* = 23) who had good preoperative erectile function and were sexually active, four had similar International Index of Erecticle Function (IIEF-5) score as before surgery with preservation of erectile function.

Transverse Scrotal Incision for Artificial Urinary Sphincter Placement

Traditional techniques usually use two incisions for placement of an AUS, one incision in the perineum and the other in the suprapubic area. Wilson et al. (11) introduced the concept of a single incision or transscrotal technique in 2003. This allowed all components of the AUS to be placed through a single incision with the patient in lithotomy or supine position (Fig. 45.7). A 3- to 4-cm transverse high scrotal incision is made near the penoscrotal junction. Self-retaining hook retractors can be used to optimize the exposure securing the base and shaft of the penis along with the glans superiorly on the anterior abdomen in mild stretch.

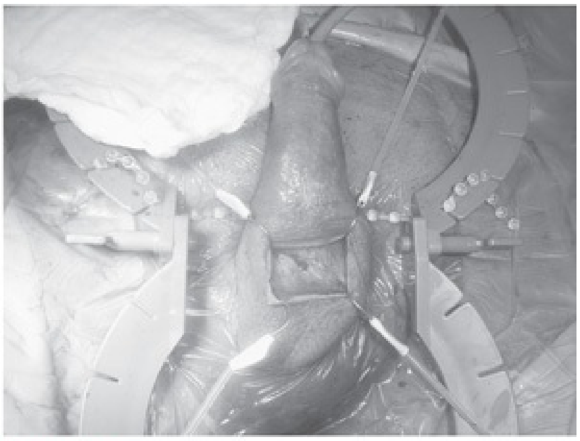

FIGURE 45.7 Transverse scrotal incision for placement of AUS with Lone Star ring retractor in place.

In this approach, the bulbar urethra is the target. To expose the bulbar urethra, both corpora cavernosa must both first be exposed proximally so that the attachment between the corpora spongiosum and the scrotal septum is clearly defined. Next, this attachment is sharply divided, and a pediatric Deaver retractor may be used to facilitate additional exposure. Next, the dissection is carried down to the level of the most proximal bulbar urethra. The bulbar urethra is then circumferentially freed for 2 to 3 cm around the targeted cuff position (Fig. 45.8). The cuff is then placed followed by blunt dissection to the level of the external ring. A pair of Metzenbaum scissors is used to perforate the transversalis fascia, and blunt dissection is used to develop the space for the PRB (Fig. 45.9). The reservoir is then placed and filled with 23 to 25 mL of filling solution (Fig. 45.10). A subdartos pouch is developed to place the control pump (Fig. 45.11). Excess tubing is excised, and connections between the reservoir, cuff, and pump are made using the connection kit provided by the AUS kit. The AUS is then cycled and tested as previously described.

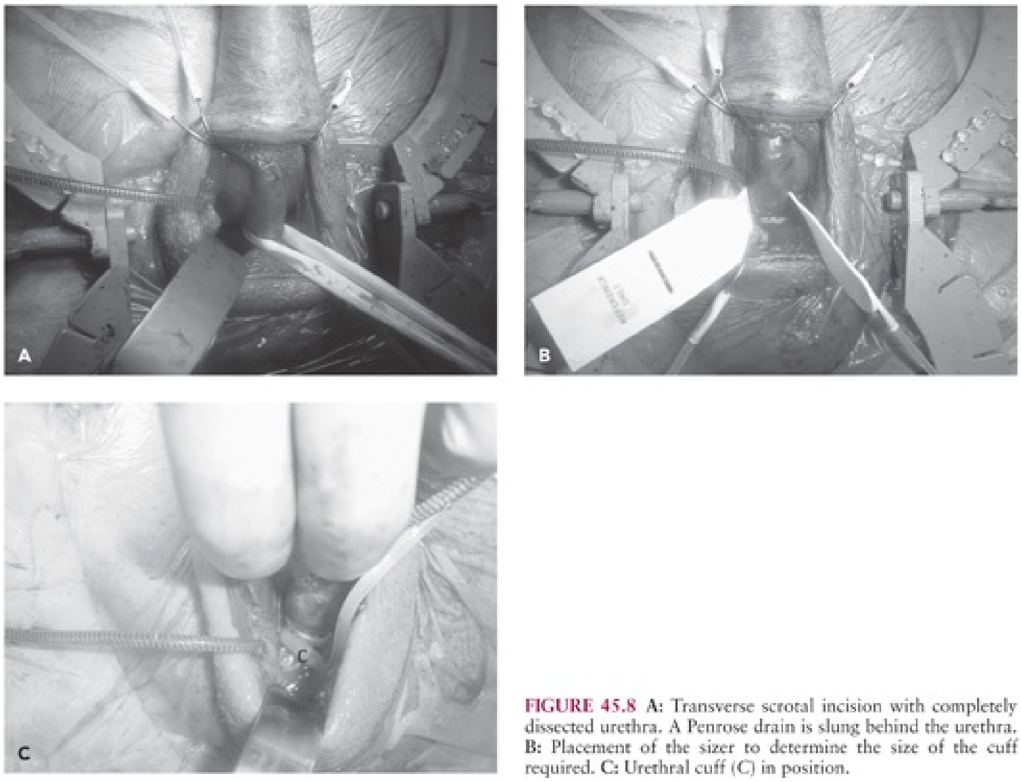

FIGURE 45.8 A: Transverse scrotal incision with completely dissected urethra. A Penrose drain is slung behind the urethra. B: Placement of the sizer to determine the size of the cuff required. C: Urethral cuff (C) in position.

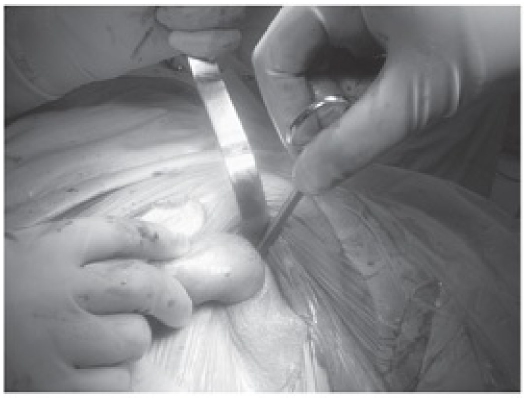

FIGURE 45.9 Through the same transverse scrotal incision, Metzenbaum scissors are used to perforate the transversalis fascia and develop the pocket for placement of the reservoir.

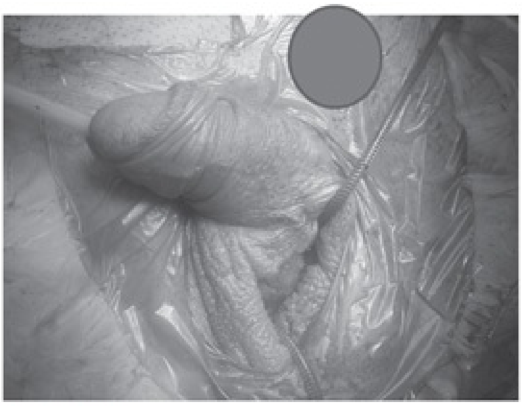

FIGURE 45.10 The reservoir is in position in the space of Retzius. The tubing connecting to the reservoir can be seen caudally. The *circle* represents the position of the reservoir.

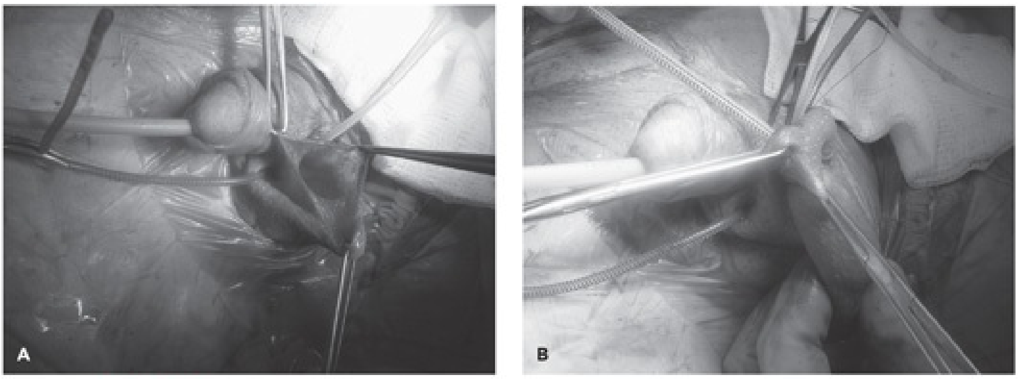

FIGURE 45.11 **A:** Creation of a subdartos pouch with the transverse scrotal incision for placement of the pump. **B:** The AUS pump is in position in the scrotum and is held by a Babcock clamp.

Bladder Neck Cuff Placement

AUS implantation with bladder neck cuff is indicated in women and poor quality of bulbar urethra after multiple prior failed attempts to achieve continence with bulbar urethral cuff placement. Bladder neck cuff is also used in conjunction with augmentation cystoplasty in patients with neurogenic bladder. Scarring at the bladder neck from prior surgery is an adverse factor to achieve optimal results with this technique. There is a risk of potential rectal injury with this approach especially in the presence of scarring.

A suprapubic incision is made to allow direct access to the prevesical space. Using blunt dissection, the prostate, bladder neck, and endopelvic fascia are exposed. A plane between the rectum and bladder is developed for the purposes of cuff placement. Incision of endopelvic fascia is surgeon-dependent and may help with mobilization especially if more space is required to complete mobilization of the bladder neck. When sizing the bladder neck, a larger cuff size (6 to 8 cm) may be used. A reservoir and pump are placed as described earlier; tubing is then trimmed and connected.

Artificial Urinary Sphincter Placement in Women

AUS placement in women is usually reserved for those with refractory stress incontinence or those with neurogenic bladder secondary to spina bifida. Topical estrogens may help improve urethral tissue quality and health preoperatively in postmenopausal women.

In women, it is generally accepted that the bladder neck is the only position to place the cuff. The bladder neck may be approached by either an abdominal or transvaginal approach. There is a higher risk of erosion in women due to the lack of a plane between the urethra and the vagina. In an abdominal approach, a low transverse-midline incision is used. A careful circumferential mobilization is performed around a 2-cm portion of the bladder neck (Fig. 45.12). Next, a sizer is used to determine the correct size cuff to place. The PRB is then placed in the paravesical space; the pump is placed in a developed subcutaneous pouch in the ipsilateral labia majora. The tubing is trimmed and connected in the usual fashion.

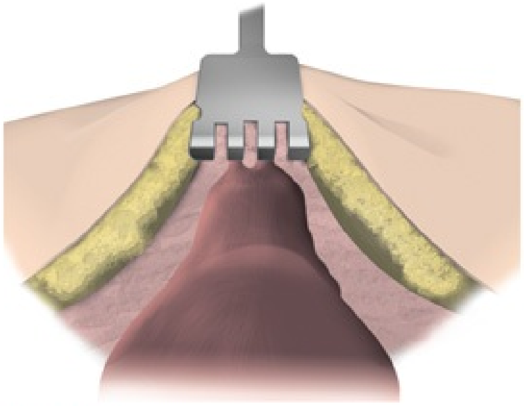

FIGURE 45.12 The abdominal approach to implantation of the AUS in women. The bladder neck region has been dissected ready for placement of the cuff.

The transvaginal approach closely resembles the perineal approach in men. An inverted U incision is used on the anterior aspect of the anterior vaginal wall at the level of the bladder neck. The bladder neck is circumferentially freed with care being taken to avoid entering the urethral lumen anteriorly. Once the urethra is freely dissected, the cuff is positioned. Next, a second incision is made transversely in the suprapubic area, and a reservoir is placed in a similar manner as described before. Tunneling to the labia majora is performed to allow placement of the pump in a subcutaneous pouch. The tubing is passed, trimmed, and connected. The vagina is packed to prevent bleeding until the following day when it is removed. The urethral catheter is left in place for 24 to 48 hours.

Synchronous Artificial Urinary Sphincter and Inflatable Penile Prosthesis Implantation

Combined implantation of both a penile implant and AUS is most commonly performed in the postprostatectomy setting. In the past, this has been performed as a staged procedure. However, with the advent of the transscrotal approach for placement of the AUS, it is possible to implant both AUS and inflatable penile prosthesis (IPP) via the same incision. Complication rates of the implantation including device erosion, infection, and/or malfunction were no different in combined versus staged procedures in one study (12).

After a high transverse scrotal incision is made, the scrotal septum is divided to free the corpora cavernosa and the corpus spongiosum of the urethra. The bulbar urethra is dissected-free and the AUS cuff is placed. Corporotomies are then performed for insertion of the cylinders of penile prosthesis. The respective reservoirs are placed via small transverse suprapubic incisions on each side. Their respective pumps are placed in the scrotum using developed subdartos pouches. After the tubing is connected and each implant tested, both should be deactivated. It has been recommended that AUS be placed before penile prosthesis. Patients requiring both AUS and IPP may be offered synchronous implantation, as this avoids a secondary procedure, which saves the patient both cost, recovery time, and potential morbidity (13). Both implants must be deactivated for a period of 4 to 6 weeks to allow time for healing.

Lee et al. (14) recently reported that combination therapy should be considered in all cases of erectile dysfunction and stress urinary incontinence, the latter from intrinsic sphincter deficiency. They evaluated both combinations of IPP/AUS versus IPP/male sling. Appropriate combination implants are recommended depending on the severity of stress urinary incontinence and the extent of intrinsic sphincter dysfunction.

Artificial Urinary Sphincter in the Pediatric Population: Simultaneous Artificial Urinary Sphincter with Bladder Augmentation

In patients with congenital neurogenic bladder and/or exstrophy-epispadias complex, the goals of treatment include preservation of renal function, prevention of recurrent urinary tract infections, and correction the underlying urinary incontinence. Although it is possible to undertake AUS implantation at the time of augmentation cystoplasty (for refractory neurogenic bladder dysfunction), this option may be considered on an individual basis as in a proportion of such patients the stress incontinence may abate or become less bothersome due to the low pressure in the augmented bladder.

Continence rates up to 80% or higher after the combined augmentation cystoplasty and AUS implant have been well documented. However, complications of AUS itself still raises concern for erosion, infection, and mechanical failure requiring explantation in up to 25% of patients in some cohorts (15). A recent review by Viers et al. (16) examined a cohort of patients undergoing cuff-only AUS versus complete AUS placement with augmentation cystoplasty (Table 45.2). The authors noted that cuff-only AUS placement was safe and efficacious in patients with neurogenic bladder, with decreased complication rates compared to a complete AUS implant.

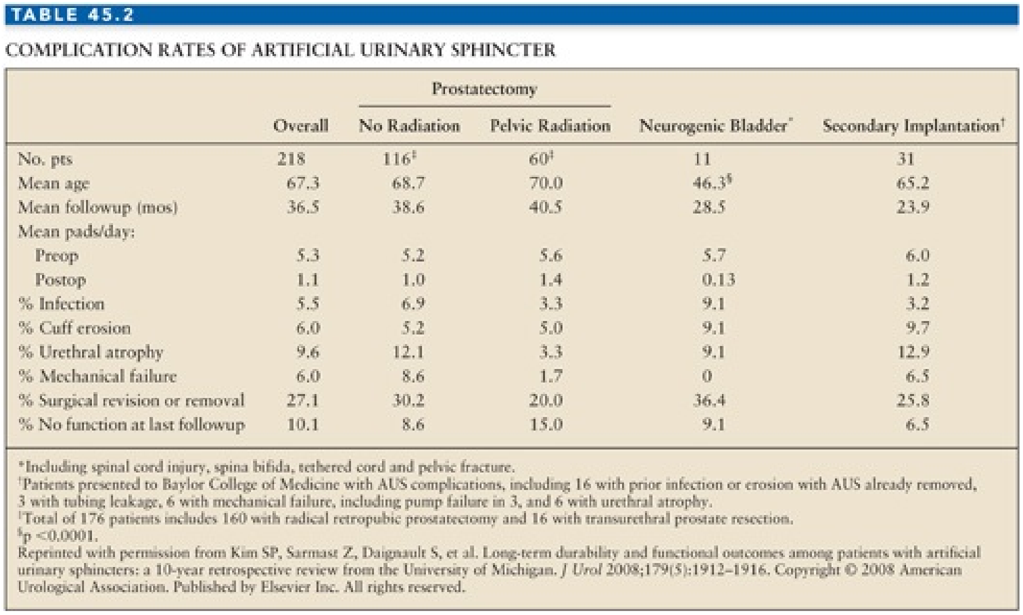

TABLE 45.2

COMPLICATION RATES OF ARTIFICIAL URINARY SPHINCTER

		Prostatectomy			
	Overall	No Radiation	Pelvic Radiation	Neurogenic Bladder[*]	Secondary Implantation[†]
No. pts	218	116[‡]	60[‡]	11	31
Mean age	67.3	68.7	70.0	46.3[§]	65.2
Mean followup (mos)	36.5	38.6	40.5	28.5	23.9
Mean pads/day:					
Preop	5.3	5.2	5.6	5.7	6.0
Postop	1.1	1.0	1.4	0.13	1.2
% Infection	5.5	6.9	3.3	9.1	3.2

Levesque et al. (17) noted in a 10-year study that it is important to educate the patient on the need for close follow-up. They noted that 11% of patients who developed renal failure and recurrent incontinence were lost to follow-up. It is also prudent to watch for post-AUS bladder dysfunction and educate the patient and parents that postprocedure self-catheterization may be necessary.

Tandem Cuff Placement for Artificial Urinary Sphincter

In the salvage setting, Guralnick et al. (9) previously reported the use of transcorporeal placement of the cuff. Recently, tandem-cuff placement has emerged as a viable option. In situations where the primary AUS has not resolved incontinence but was not shown to be infected or eroded thus not requiring explantation, tandem cuff placement is a reasonable option in lieu of revising the primary cuff and potentially incurring urethral injury. Placing a tandem cuff by the transcorporeal approach has shown promising results with lower complication rates. Magera and Elliott (18) have described this technique. This approach was noted to decrease pad use with 69% of patients reported feeling extremely improved. Other options in such patients include downsizing the cuff. Cuff downsizing is an option following cuff atrophy resulting in recurrent stress incontinence.

In the transcorporeal approach, as described earlier, the cuff is placed distal to the bulbar urethra; the tunica albuginea from the bilateral corporotomies is used to provide additional bulk around the thinner urethra. The corporotomies are closed prior to cuff placement, and the tubing is passed and delivered through a lower abdominal incision and connected into the existing system using Y connectors. A reservoir with 61- to 70-cm H_2O pressure should be used and the system deactivated for 4 to 6 weeks to allow for healing. The urethral catheter may be removed 24 hours after device implantation. Once the system is activated, nocturnal deactivation should be performed by the patient to prevent urethral atrophy (18).

COMPLICATIONS AND OUTCOMES

In the early postprocedure period, common complications include urinary retention and wound hematoma usually around the control pump. Retention is usually managed with temporary urethral catheter placement or intermittent catheterization, whereas hematomas are usually managed by supportive care. It is extremely important to be cognizant of the risk of urethral cuff erosion from the trauma and/or pressure necrosis of the indwelling catheter. Inappropriate catheter placement is a well-known cause for urethral cuff erosion. If at all an indwelling catheter becomes necessary, the AUS should be deactivated, and after intraurethral copious lubricant instillation, a small catheter is inserted by an experienced urologist for the shortest possible duration. In a 10-year outcomes study encompassing 124 patients, Kim et al. (19) reported 37% overall complication rate with 12.5% requiring explantation.

AUS infection has been reported in less than 2% of patients, with the most common organism being *Staphylococcus aureus*, followed by *Staphylococcus epidermidis* (5). In recent years, the antibiotic (rifampin and minocycline)-coated AUS has been introduced and is designed to release antibiotics over a period of 1 to 2 weeks in an effort to reduce infection rates. Currently, it is controversial on whether this significantly reduces infection rates (20).

However, in the 10-year outcomes study, the rate of infection in a cohort of 124 patients was noted to be 5.6%, whereas erosion was reported in 8% of patients (19). Lai et al. (21) also reported similar infection rates in their cohort of 270 patients with infection and erosion in 5.5% and 6%, respectively.

Following explantation, the standard waiting period until reimplantation of a new device is 3 to 6 months. Lai and Boone (22) recently reported that AUS reimplantation subsequent to removal of the AUS for infection or erosion, carried a fourfold increase in erosion of the reimplant. Linder et al. (23) reported similar results including 19% explantation rate of the secondary implant versus 6.4% with the primary AUS.

Mechanical failure is the most common complication noted with AUS placement usually attributed to wear and tear. Since the 11-year study in 2000 by Venn et al. (19,21,24) reporting 32% mechanical failure. Elliott et al. (25) published this decrease in the mechanical failure after the introduction of “narrow back design” of the cuff as a decrease from 21% to 7.6%. The improvement may be related to design modifications of the AUS including the narrow-backed cuff and kink-resistant tubing.

Patients with recurrent incontinence should be subjected to a full workup evaluating the bladder, urethra, and functioning of the implant to diagnose cuff-related urethral atrophy, mechanical malfunctioning, bladder neck contracture, urethral stricture, and/or detrusor overactivity. The workup may include physical examination, cystoscopy, and/or videourodynamic study. It is of paramount importance to ensure that the patient is properly using the implant and that appropriate patient instructions have been provided and are well understood. If urethral atrophy is noted, cuff downsizing may be performed. Tandem cuff placement may also be useful in this scenario. Detrusor overactivity and leak point pressure measurement are noted by urodynamic study and the appropriate treatment undertaken. Patients with neurogenic bladder dysfunction may need bladder augmentation.

A recent systematic review evaluated overall outcomes for patients undergoing AUS implant. Mean infection/erosion rate across all studies was noted to be 8.5%, whereas mechanical failure rate and urethral atrophy rate were found to be 6.2% and 7.9%, respectively. Seventy-nine percent of patients reported ≤1 pad use per day, whereas 43.5% of patients were noted to be completely dry (Table 45.3) (26). Mechanical failure rates were usually related to pump failure. Revision surgery varied from 0% to 41.3% (27).

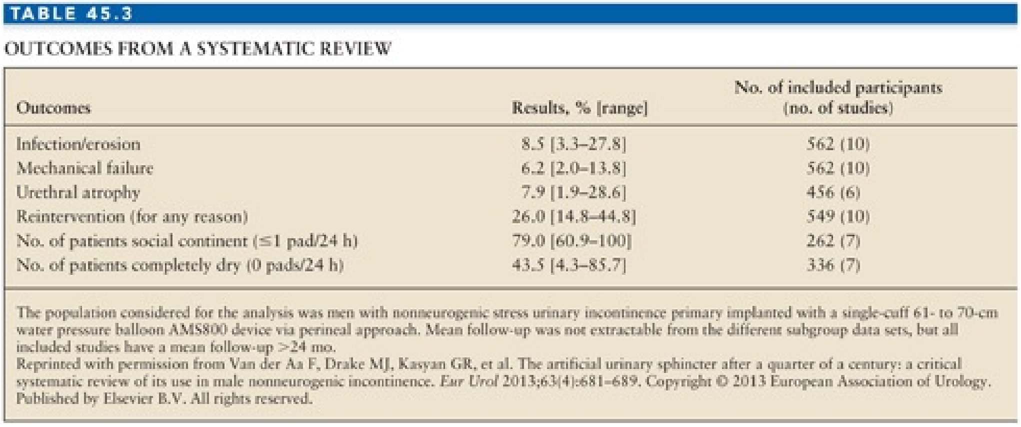

TABLE 45.3

OUTCOMES FROM A SYSTEMATIC REVIEW

Outcomes	Results, % [range]	No. of included participants (no. of studies)
Infection/erosion	8.5 [3.3–27.8]	562 (10)
Mechanical failure	6.2 [2.0–13.8]	562 (10)
Urethral atrophy	7.9 [1.9–28.6]	456 (6)
Reintervention (for any reason)	26.0 [14.8–44.8]	549 (10)
No. of patients social continent (≤1 pad/24 h)	79.0 [60.9–100]	262 (7)
No. of patients completely dry (0 pads/24 h)	43.5 [4.3–85.7]	336 (7)

The population considered for the analysis was men with nonneurogenic stress urinary incontinence primary implanted with a single-cuff 61- to 70-cm water pressure balloon AMS800 device via perineal approach. Mean follow-up was not extractable from the different subgroup data sets, but all included studies have a mean follow-up >24 mo.

Outcomes of Artificial Urinary Sphincter Placement after Prior Failed Male Sling

In a recent cohort study of 29 men with failed male sling placement in the setting of postprostatectomy incontinence that subsequently underwent AUS placement, 96% of men were found to be using ≤1 pad at 3 months follow-up (28). Men with AUS implant following prior failed male sling had comparable outcomes to men who received primary AUS implantation. Long-term continence rates of over 90% were reported following AUS implant for postprostatectomy urinary incontinence (24).

Artificial Urinary Sphincter Implantation Following Prior Radiotherapy for Prostate Cancer

Prior radiation therapy was in the past considered to result in higher complication rates following AUS placement. Kim et al. (19) reported a higher rate of bladder neck contracture in radiated patients relative risk (RR 2.1). However, recent studies have shown no significant difference in the rates of erosion, infection, and urethral atrophy between groups of men that were irradiated versus nonradiated. However, larger studies need to be performed to determine if there is a significant difference in the AUS outcomes in patients that received radiation (29).

CHAPTER 46 ■ THE MALE SLING FOR POSTPROSTATECTOMY INCONTINENCE: CURRENT CONCEPTS AND CONTROVERSIES

YING H. JURA AND CRAIG V. COMITER

PREVALENCE OF POSTPROSTATECTOMY INCONTINENCE

The most common cause of stress urinary incontinence (SUI) in men is iatrogenic injury during prostate surgery. The rate of incontinence following surgery for benign prostatic hyperplasia is approximately 2% (1). In contrast, the risk of urinary incontinence is significantly higher following surgery for prostate cancer. In a questionnaire-based study by Stanford et al. (2), postprostatectomy patients were evaluated using a self-administered questionnaire. Only 32% claimed total urinary control, 40% had occasional leakage, 7% had frequent leakage, and 2% suffered from no control at 2 years postoperatively (2). Although reports of postprostatectomy incontinence (PPI) vary, contemporary cohort studies demonstrate that 1% to 5% of patients will ultimately undergo surgery for the management of their incontinence after radical prostatectomy (2–5).

RISK FACTORS FOR POSTPROSTATECTOMY INCONTINENCE

The surgical technique for radical prostatectomy (RP) has become relatively standardized, with improved instrumentation and visualization, especially following the adoption of robotic assistance. There are, however, recognized risk factors for PPI. These risk factors include age, preoperative continence status, preoperative voiding dysfunction, tumor stage, obesity, prior radiation or transurethral resection of the prostate, vascular disease, preoperative membranous urethral length, and postoperative radiation or cryotherapy (6–14). Although many of these risks may not be modifiable, they may alter cancer treatment choice.

The most predictive risk factors for PPI are preoperative urinary incontinence and voiding dysfunction. Stress incontinence in men who have not had prostate cancer surgery occurs at a baseline prevalence of 1.3% to 4.8% (15). Whereas urgency and overflow incontinence associated with bladder outlet obstruction may indeed resolve following surgery for this condition, preoperative SUI typically will not improve postoperatively (6). Rather, baseline intrinsic sphincteric deficiency (ISD), demonstrated either by the preexisting clinical sign of SUI or the urodynamic finding of low maximal urethral closure pressure, strongly predicts postoperative SUI (13,14). Preoperative bladder dysfunction also increases the risk of PPI, especially in those with neurogenic detrusor overactivity secondary to Parkinson disease, dementia, or spinal cord injury (7).

DIAGNOSIS

Evaluation of the patient with PPI should begin with a detailed history of lower urinary tract symptoms. As the pathophysiology of PPI is variable and history alone is not sufficient to distinguish between bladder causes (poor compliance, detrusor overactivity, detrusor underactivity) and outlet causes (sphincteric insufficiency or bladder outlet obstruction) of incontinence, a micturition diary is useful for quantifying frequency, incontinence episodes, and functional bladder capacity. It is important to demonstrate leakage on physical examination to confirm the diagnosis of SUI. Leakage should occur during cough or Valsalva and cease at the end of the straining maneuver. Although this confirms the presence of ISD, it is not a definitive test of bladder storage or voiding function.

Urodynamic evaluation is strongly recommended prior to consideration of invasive therapy. Filling cystometry can assess bladder storage, and antegrade or retrograde leak point pressure may provide information on outlet function. The majority of men with PPI suffer from ISD, but only 25% to 50% will have ISD alone on urodynamics. Approximately 15% of patients with PPI demonstrate only bladder dysfunction without ISD, and 40% of patients with ISD will demonstrate concomitant bladder dysfunction (16). Bladder dysfunction may result from preexisting outlet obstruction, or age-related detrusor overactivity, or may occur de novo after prostatectomy as a result of bladder denervation. Impaired detrusor contractility, which occurs in 29% to 61% of patients (de novo in approximately 47%), and poor compliance, which occurs in 8% to 39% of patients (de novo in approximately 50%), have traditionally been thought to resolve within 8 months (17,18).

Although pad use, bother from leakage, and patient preference typically dictate the implementation of surgical treatment, it is important to quantify the degree of sphincteric incompetence, as this factor may affect the type of treatment recommended for the management of the stress incontinence. For example, patients with higher abdominal leak point pressure (ALPP), and therefore more preserved sphincteric function, tend to respond better to periurethral bulking agents than do patients with a lower ALPP (19).

INDICATIONS FOR SURGERY

Surgical intervention is indicated for treating bothersome SUI due to ISD that fails to adequately improve following 12 months of conservative management. Most patients will experience improvement in leakage for up to 1 year following surgery, regardless of active (pelvic floor physiotherapy) or passive (observation) management (20).

Severity, effect on quality of life, and the ability of the patient to conservatively manage incontinence must be balanced against the risks of surgery. In addition, reasonable physician and patient expectations based on clinical efficacy, acceptable morbidity (severity, duration, and need for additional therapy), and the avoidance of serious complications are essential. Implantation of a surgical device should be undertaken with caution in patients with uncontrolled detrusor overactivity or decreased bladder compliance. In addition, those conditions that may require future transurethral management (i.e., urethral stricture or bladder neck contracture) are relative contraindications to outlet surgery because repeated instrumentation may put the patient at risk for device infection or erosion.

Due to lack of U.S. Food and Drug Administration (FDA)–approved pharmacotherapy for ISD, and generally poor efficacy of periurethral bulking agents (21), surgery remains the primary treatment modality for the management of PPI. Surgical approaches include implantation of an artificial urinary sphincter (AUS), or placement of a male sling (MS). This chapter will focus on the surgical technique of the most popular MS surgeries.

ARTIFICIAL URINARY SPHINCTER

In contrast to the low-pressure coaptation of periurethral bulking, the AUS relies on circumferential occlusion of the urethra using a pressurized inflatable cuff. For more than three decades, the AUS has represented the most efficacious treatment for male SUI treatment, with satisfaction rates typically greater than 80%, regardless of the degree of incontinence. The majority of men with PPI are appropriate candidates for AUS placement, with exception of those who may lack the mental faculties and manual dexterity to cycle the scrotal pump and properly work the system.

The AUS has been reported to have a predictably high success rate regardless of the degree of incontinence, even in the setting of detrusor dysfunction such as overactivity, or diminished vesical compliance (22). In men who had presumably normal storage function prior to RP, the urodynamic findings of detrusor overactivity or diminished compliance are most likely due to a supraphysiologic infusion rate of filling medium into a bladder that has experienced a prolonged underfilled state secondary to continual urinary leakage. Preoperative detrusor overactivity does not adversely affect resolution of SUI following AUS implantation, but persistent overactive bladder symptoms are common, and patients must be counseled accordingly (22). Detrusor hypocontractility does not adversely affect surgical success because the AUS is cycled to an "open" phase during voiding, with relief of urethral occlusion.

The AUS, however, has a nontrivial complication rate. It has revision rates of 8% to 45% and explantation rates of 7% to 17% due to mechanical failure, urethral atrophy, infection, and erosion (23,24). Despite high success rates, the high cost and high revision rates have inspired the search for less expensive, less invasive, and less complicated devices. In addition, patients are often apprehensive about a mechanical device that requires manipulation prior to voiding. The modern MS has been actively studied and refined over the past decade in an effort to minimize invasiveness and overcome these hurdles.

MALE SLING

Various slings are currently available for the treatment of PPI. With the recent withdrawal of the bone-anchored sling from the market, the most commonly used devices are the retrourethral transobturator sling (RTS), the quadratic sling, and the adjustable pubourethral sling.

RATIONALE FOR THE MALE SLING

The impetus for the design of the modern MS was to decrease the risk of device infection, urethral erosion, and urethral atrophy that can be associated with a circumferential urethral compression and to allow for spontaneous voiding without the need for device manipulation. The MS is a noncircumferential suburethral device that is placed with the aim of applying sufficient urethral occlusive pressure to prevent leakage yet permit normal spontaneous voiding without the need for device manipulation. Recent experience with the MS has taught several lessons regarding the management of PPI with sling surgery: (a) Adequate but not excessive tension is necessary for urethral compression and continence; (b) well-designed synthetic materials have an acceptably low rate of infection and erosion; (c) adequate detrusor contractility is necessary to overcome the fixed resistance of certain slings; (d) various methods of sling fixation can achieve successful urethral compression; (e) there is no "best" sling for all patients—rather different patient types may be best treated with different slings; and (f) patients with more severe or total urinary incontinence appear to have a lower success rate with the MS than do patients with more mild to moderate degrees of incontinence (25,26).

RETROURETHRAL TRANSOBTURATOR SLING

Surgical Technique

The most commonly performed sling procedure for the treatment of PPI is currently the RTS. As the mechanism of action of this sling is thought to rely more on repositioning the prolapsed sphincteric urethra than on direct compression of the bulbar urethra, it is recommended that preoperative evaluation include the "repositioning" test to verify the presence of adequate residual sphincter function. Rehder's group demonstrated that the ALPP increases on gently pushing the perianal midperineum in a cephalad direction (avoiding direct compression of the urethral bulb). Men with sufficient residual sphincter function (i.e., mild ISD) demonstrate passive sphincter closure with cystoscopically visible contraction of the striated sphincter on perineal elevation (27). This provocative maneuver, by increasing the “zone of coaptation,” augments pressure transmission within the functional sphincteric unit, and when demonstrated preoperatively, is predictive of a successful surgical outcome (28,29). In those men with adequate residual sphincter function, a retroluminal transobturator sling is appropriate.

The surgery is performed under general anesthesia with the patient in a lithotomy position. A negative urine culture is required prior to surgery. Intravenous cephazolin (or vancomycin plus gentamicin, if allergic) is given within 1 hour of surgery.

After the patient is prepared and draped in a sterile fashion, a 14Fr Foley catheter is passed per urethra to help identify the perineal portion of the urethra. A 3- to 4-cm midline incision centered over the bulbar urethra is made. The bulbospongiosus muscle is typically divided and dissected off the bulbospongiosum. The central tendon can be found after the bulbar urethral is exposed and a retractor is placed to isolate the urethra. By gently pulling the perineal urethra cephalad, the central perineal tendon is evident as it spans from the inferior aspect of the bulbar urethra to the perineum. With retraction of the inferior aspect of the perineal incision caudal, and countertraction of the perineal urethra cephalad, the central tending should be readily visualized. After the central tendon is identified, the fibrous portion is divided to allow approximately 2 to 4 cm of mobility of the urethral bulb (Fig. 46.1).

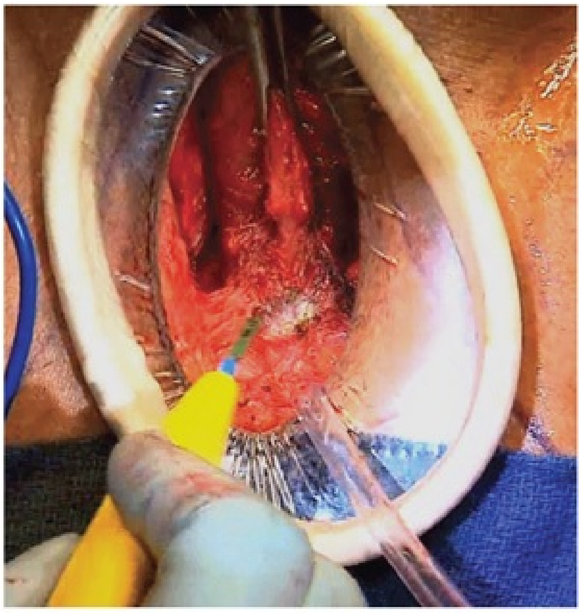

FIGURE 46.1 Identification of the central perineal tendon, aided by upward traction of the perineal portion of the urethra. Detachment of this tendon permits proximal urethral relocation.

Small stab incisions are made in each groin/thigh crease, approximately 1 cm inferior and lateral to the insertion of the adductor longus tendon at the medial border of the obturator foramen. Helical needle passers are then passed through the stab incisions, through the obturator membrane, around the inferior pubic ramus, and out at the apex of the triangle formed by the bulbar urethra medially and the ischiopubic ramus laterally. The mesh sling is then connected to the needle passers. The needle passers are rotated back along the insertion pathway to pull the sling back through the obturator foramen and out the stab incisions. The sling should be centered over the urethra. Four interrupted 3-0 polyglycolic acid sutures are then placed to secure the midportion of the sling to the bulbospongiosum just distal to the central tendon. Fixation of the sling to the periurethral tissue prevents "slippage" of the sling too far proximally and actually *off* the posterior aspect of the urethra, which can reduce sling efficacy.

To tension the sling, both arms of the sling are pulled laterally. This should be done after removal of the Foley catheter. The bulbar urethra should be repositioned 2 to 3 cm proximally (Fig. 46.2). The arms of the sling may be tunneled back into the perineal incision and then trimmed. The catheter is then replaced into the bladder, and the wound is irrigated with antibiotic solution. The bulbospongiosus muscle should be reapproximated and then the wound is closed in multiple layers with running suture, using 2-0 polyglycolic acid suture for the deep layer, 3-0 polyglycolic acid suture for the dartos layer, and 4-0 polyglycolic acid suture for the skin. A trial of voiding is performed when the patient is able to stand comfortably to void, usually within 6 to 36 hours postoperatively.

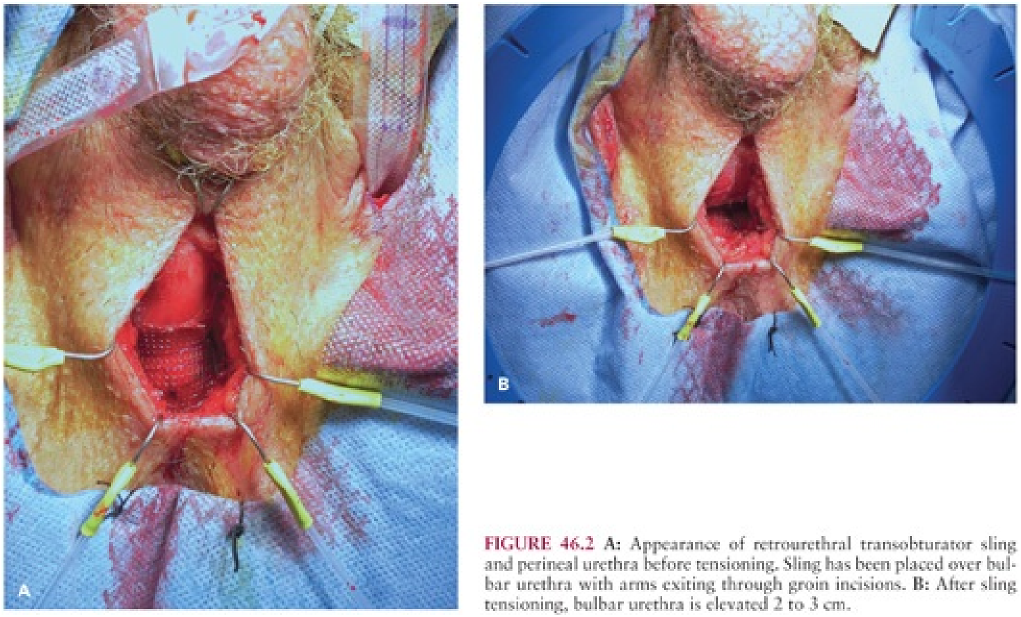

FIGURE 46.2 A: Appearance of retrourethral transobturator sling and perineal urethra before tensioning. Sling has been placed over bulbar urethra with arms exiting through groin incisions. B: After sling tensioning, bulbar urethra is elevated 2 to 3 cm.

Mechanism of Action

The retroluminal sling was introduced in 2005. It was designed to be placed through a minimally invasive transobturator (TO) placement. Its mechanism of action relies on proximal urethral relocation rather than any significant compression of the bulbar urethra. The sling is placed *retrourethrally*, under the proximal urethral bulb. Upon tensioning, a 2- to 3-cm proximal relocation of the bulbar urethra is achieved.

It is hypothesized that laxity of posterior support predisposes to misalignment of the proximal urethra and thereby contributes to ineffective coaptation of the urethral sphincter complex (28). The retroluminal sling can remedy the abnormal anatomy and proximal urethral prolapse that may occur following prostate extirpation. Once the sling is appropriately tensioned, the urethral bulb is proximally relocated 2 to 3 cm into the higher pressure pelvic outlet and can function as a "backstop" during straining (30). Risk factors for failure of the TO sling include those conditions associated with poor residual sphincter function and/or a lack of urethral mobility—such as poor coaptive response to perineal elevation, a high preoperative pad weight, and a history of prior external beam radiation (29,31).

Outcomes

Surgical success can vary with the definition of continence, the method of evaluation, the length of follow-up, and the experience of the surgeon. In addition, the method of sling fixation may also contribute to the outcome of the procedure. Most series report the results of the AdVance sling (American Medical Systems, Minnetonka, Minnesota) or the TOMS (CL Medical, Lyon, France). Success is most commonly defined as cure (no pads or one security pad) or improvement (two or less pads or >50% reduction in pad use).

The cure/improved rates from prospective series have ranged from 54% to 80% at 1 year, with success remaining 75% to 78% for studies with follow-ups of up to 3 years (32). A recent prospective multicenter trial by Rehder et al. (33) with 156 patients undergoing the AdVance sling for PPI found a cure rate of 53.8% at 1 year and a cure rate of 53.0% at 3 years. Improvement rate was an additional 23.1% and 23.8% at 1 and 3 years. In multivariate analysis, pretreatment pad usage was the only independent predictor of success. Patients with mild/moderate incontinence (five or less pads per day) had a cure rate of 58.6% and an improvement rate of 23.2% compared to 42.3% cure and 25% improved for those with severe incontinence (less than five pads per day) (33). In those patients with limited residual sphincter function and restricted urethral mobility, a sling that provides a greater degree of urethral compression may be more efficacious.

The urodynamic effects of the RTS have been reported (34,35). In another prospective study by Rehder et al. (36), 115 men underwent urodynamic evaluation before and 12 months after sling surgery. There were no significant differences in detrusor voiding pressure, postvoid residual urine volume, and maximal urine flow rates. The only urodynamic variable with a significant change was the Valsalva leak point pressure at 19.3 cm H_2O before sling placement versus 42.1 cm H_2O after sling placement (36). In a smaller study with 13 patients, Davies et al. (35) reported similar findings. One patient (8%) in this series developed de novo detrusor overactivity.

Reported rates of transient urinary retention have ranged from 3% to 23%. Perineal pain ranges widely from 0% to >50%, likely due to differences in the definition of postoperative pain. Serious complications requiring revision or removal of the RTS are rare with only a few reports in the literature (32,37). Rehder et al. (33) in their 3-year multicenter prospective trial reported the following complication rates: 50% mild perineal pain, 9% transient urinary retention (resolving within 6 months), 0.6% superficial wound infection, 0.6% sling explantation due to symphysitis (33).

QUADRATIC SLING

Efforts to improve the efficacy of MS by combining the ventral elevation of the RTS with a more distal urethral compression against the perineal membrane and pubis (such as with the previously popular bone-anchored sling) led to the design of the Virtue (Coloplast, Humlebaek, Denmark) quadratic sling. This four-armed, large-pore, knitted monofilament polypropylene mesh provides *both* proximal urethral relocation via a TO component and bulbar and perineal urethral compression via a superior prepubic (PP) component (38) (Fig. 46.3).

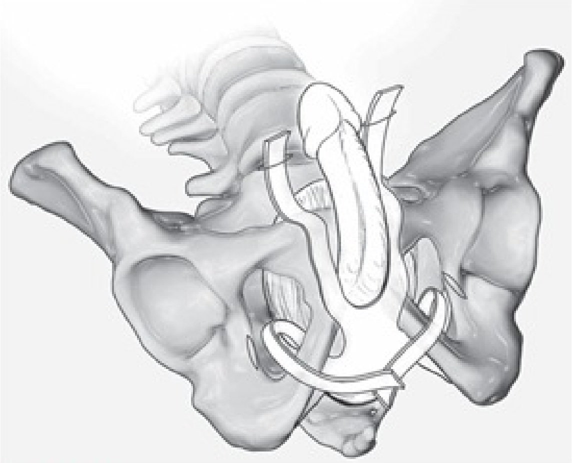

FIGURE 46.3 The quadratic sling with two transobturator arms and two PP arms.

Surgical Technique

Patients are anesthetized, given intravenous preoperative antibiotics, prepared, and draped sterilely. After inserting a 14Fr urethral catheter, a 5-cm midline perineal incision is made, and the bulbous urethra and pubic rami are exposed. The bulbospongiosus muscle is left intact to minimize the risk of urethral injury during dissection. The urethra is partially detached from the perineal body to permit the urethral bulb to move proximally similar to the RTS.

Transobturator Passage

On each side, the inferior sling extension (TO) is attached to the curved introducer and passed from the medial aspect of the descending ramus through the obturator foramen and out through a skin incision in the ipsilateral groin crease, just inferior to the adductor longus tendon. The sling is then removed from the introducer and pulled through the tissue from medial to lateral (inside to outside).

Prepubic Passage

Through two stab incisions 3 cm from the midline and 2 cm above the pubic symphysis, the curved introducer is passed from superior to inferior, staying anterior to the pubic symphysis, and out the perineal incision, lateral to the urethra on each side. The superior sling extension is attached to the introducer and pulled up through the stab incision on either side.

Sling Tensioning

The TO extensions are pulled laterally until the bulbar urethra is relocated 2 to 3 cm proximally, similar to the RTS. The TO suture tips and plastic sleeves are removed such that only mesh remains in contact with tissue. Using a long hemostat, the TO arms are then tunneled medially through the subcutaneous tissue of the perineum back to the midline incision. This permits maintenance of tension while the PP arms are manipulated upward to provide visual compression of the sling against the bulbar and perineal urethra. Retrograde leak point pressure (RLPP) is measured via perfusion sphincterometry with a 14Fr catheter in the penile urethra (38) and PP sling tension is adjusted sufficiently to increase the RLPP to 60 to 70 cm H_2O. The PP suture tips and plastic sleeves are removed, and the PP mesh is cut flush to the suprapubic skin.

Sling Fixation

After the TO extensions are tunneled subcutaneously back to the midline perineal incision, they are sutured together in the midline with a 0-polypropylene suture. Following PP passage, fixation of the superior sling arms is accomplished by suturing the superior extensions, just above their attachment to the body of the sling, to the soft tissue overlying the pubic bone (Fig. 46.4).

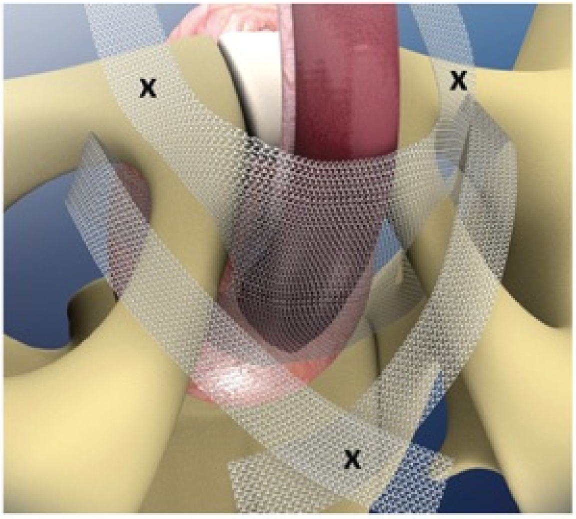

FIGURE 46.4 The quadratic sling is fixed by suturing the superior arms, just above their attachment to the body of the sling (*X*), to the soft tissue over the pubis and by suturing the transobturator extensions in the midline (*X*).

Finally, the perineal incision and stab wounds are irrigated and closed. The urethral catheter is maintained overnight and removed the following morning at home. Patients are instructed to refrain from strenuous activity for 8 weeks.

Mechanism of Action

This hybrid device is based on the combination of proximal urethral relocation (similar to RTS) and perineal urethral compression (similar to bone-anchored slings). Comiter et al. (38) investigated the urethral resistance exerted by the sling in 22 men using RLPP, measured by perfusion sphincterometry, at various steps during the surgical procedure. They found that RLPP increased from a mean baseline value of 33.4 ± 8.8 cm H_2O to 43.3 ± 6.8 cm H_2O after TO tensioning and to 55.8 ± 8.7 after PP tensioning. The final RLPP after TO and PP fixation increased to 68.8 ± 6.0 cm H_2O. Each mean RLPP value was significantly higher than the preceding value (38).

Outcomes

Results of the quadratic sling demonstrate improvements in urinary continence that are similar to those reported for the bone-anchored sling and the RTS. In the initial cohort of 100 men that underwent VIRTUE sling placement in a multinational clinical trial with an unfixed device, despite early success, sling efficacy deteriorated over time due to a lack of surgical fixation of the sling (39). However, with a straightforward sling fixation of the TO arms (tunneled back to the midline) and the PP arms (to the soft tissue over the pubic symphysis), excellent efficacy has been maintained over a 12-month period. In a multinational FDA-monitored clinical trial, success (>50% reduction in pad weight) was achieved by 79% at 1 year, with an overall 88% decrease in pad weight from a median of 147 g preoperatively to 18 g postoperatively. There were no cases of prolonged urinary retention, infection, or sling erosion, and 12.9% experienced temporary perineal pain, which resolved in all but one patient at 1 year postoperatively. In addition, the efficacy of the quadratic sling did not significantly differ among patients with mild (<100 g per day), moderate (100 to 400 g per day), or severe (>400 g per day) SUI (40). In addition, there was no significant change in postvoid residual urine following sling placement in this cohort.

ADJUSTABLE MALE SLINGS

Adjustable slings allow for sling tensioning intraoperatively, and retensioning postoperatively, if deemed necessary. Although not available in the United States, they are available in Canada and Europe. The Argus (Argus, Promedon SA, Cordoba, Argentina) consists of a silicone foam pad placed under the bulbar urethra that is attached to retropubically passed silicone columns. These columns are secured over the rectus fascia with silicone washers. A small suprapubic incision is needed to access the washers for adjusting tension postoperatively. The Remeex (Neomedic, Barcelona, Spain) bulbourethral sling, another adjustable device, consists of a synthetic mesh that is placed under the bulbar urethra and suspended by retropubically passed sutures. The sutures are secured to a "varitensor" device anterior to the rectus fascia. A "manipulator" is used to tighten or loosen the sling to the desired tension. The varitensor may be reaccessed with local anesthesia to adjust tension.

Both slings have shown to have good long-term success rates but also high complication rates. The success rates of the Argus have ranged from 72% to 79% at a mean follow-up of 26 to 45 months (41–43). The Remeex was evaluated in a multicenter trial with 51 patients followed for 32 months. The success rate was 85% (44). Complications with the Argus include erosion (13%) and sling infection requiring explant (11%) (41–43). Complications with the Remeex include bladder perforation (10%), varitensor infection requiring explant (4%), and erosion (2%) (44). It does not appear that the adjustable slings provide a markedly improved outcome compared to the RTS and the quadratic sling but may have substantially greater morbidity.

WHICH PROCEDURE IS BEST FOR WHICH PATIENT

Adequate tissue compliance is necessary for successful urethral compression and/or proximal repositioning with a sling. Not surprisingly, radiation, previous AUS explantation, and prior MS—all of which may result in poorly compliant and relatively noncompressible fibrotic urethra—are associated with diminished efficacy for the noncircumferential MSs. Because the AUS can provide the circumferential urethral compression necessary for adequate coaptation in such cases, it is the treatment of choice for patients who have had prior radiation or previous AUS or MS.

Full-course external beam radiotherapy reduces the efficacy of sling surgery. In a prospective series with 24 radiated patients followed for a median of 18 months after placement of an RTS, Bauer et al. (45) found only a 25% cure rate and a 25% improvement rate. In another series with both nonradiated (86%) and radiated patients (14%), Bauer et al. (45) found a history of radiotherapy to be a risk factor for sling failure. This has also been found to be true in other series with RTS (36,46,47). Radiation has also been shown to adversely affect the success of the original pubourethral sling (48) and the BAS (25).

In men who have failed prior MS surgery, placement of the AUS remains a straightforward procedure. With prior RTS, the surgeon may elect to place the AUS cuff transscrotally, and the previous sling neither renders the operation more difficult nor decreases AUS efficacy (3,25). With the quadratic sling, the polypropylene sling may be readily identified and dissected off the underlying muscle. The bulbospongiosus may then be split and dissected off the underlying spongy urethra, and the AUS may be placed in routine fashion (Fig. 46.5).

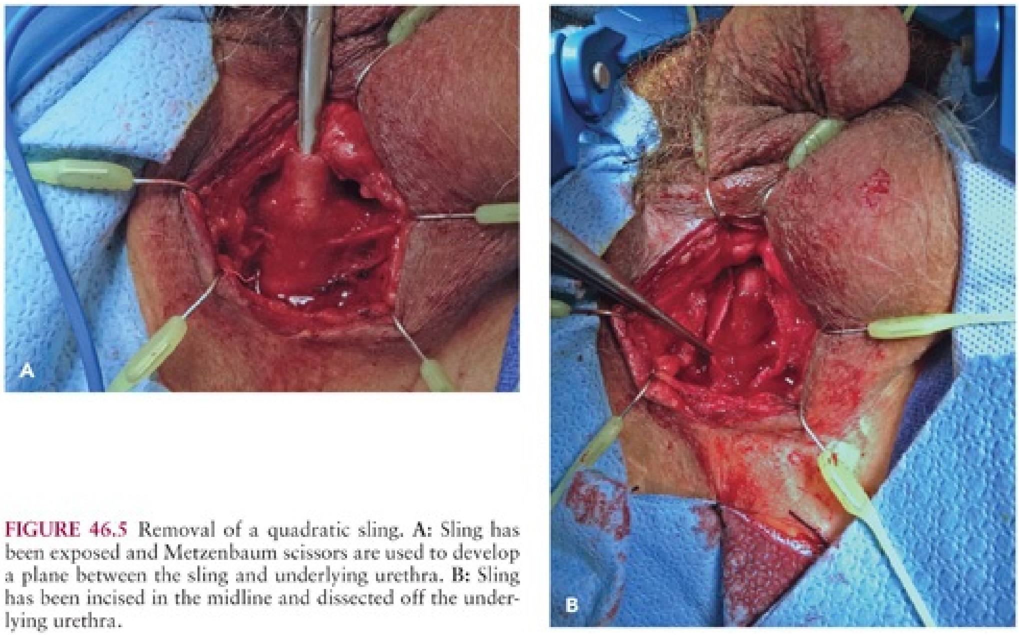

FIGURE 46.5 Removal of a quadratic sling. A: Sling has been exposed and Metzenbaum scissors are used to develop a plane between the sling and underlying urethra. B: Sling has been incised in the midline and dissected off the underlying urethra.

Maintaining sling tension and position along the urethra is critical for sustained efficacy. The last decade has taught us that sling tension (and therefore efficacy) is more adequately maintained with a permanent synthetic material compared to a resorbable allograft or xenograft (49). Additionally, the adequacy of sling fixation strongly affects continence rates regardless of the particular type of sling. Early sling slippage will typically result in recurrent SUI. This problem, however, has been overcome with improvements in sling fixation. With respect to the RTS, inadequate fixation of the sling to the urethra and insufficient sling tunneling are associated with a higher rate of recurrent incontinence (31). Similarly, inadequate fixation of the quadratic sling has been associated with a higher risk of early sling failure (40).

Finally, the degree of incontinence has been shown to impact efficacy. Multiple reports demonstrated that patients with more severe incontinence preoperatively are at higher risk for postoperative incontinence following sling surgery (33,47,50). In a prospectively evaluated cohort of 62 patients with PPI, Fischer et al. (50) demonstrated that men with <423 g leakage per day were 6 times more likely to achieve satisfactory continence compared to those with a higher preoperative pad weight tests. Thus, AUS is the treatment of choice for most men with high-volume SUI, as AUS success rates are generally independent of the degree of leakage.

In men with mild to moderate SUI (<400 g per day) and normal bladder contractility, the MS may be preferable as an initial procedure because an AUS can still be offered after sling failure, whereas previous placement of an AUS is a relative contraindication to sling surgery. In addition, the MS has emerged as the preferred surgical option among patients with PPI. When offered a choice between MS and AUS, the majority of patients will opt for the MS in order to avoid a mechanical device (51). For those with milder leakage, the TO approach has reported efficacy of 60% to 85% with very few complications. For men with more moderate incontinence, the quadratic sling may have better efficacy based on a broader area of urethral compression in addition to proximal urethral elevation.

SUMMARY

Male SUI is usually iatrogenic and can be a bothersome complication of prostate cancer surgery, causing approximately 10% of patients to seek further treatment. After 12 months of active conservative management, surgical intervention is often indicated. Transurethral injection of bulking agents, although minimally invasive, has no proven short- or long-term success. The AUS and suburethral sling are both safe and efficacious treatments for PPI secondary to ISD.

For high volume incontinence, including total urinary incontinence due to severe sphincteric insufficiency, the AUS appears to have higher efficacy than does the MS. For mild to moderate SUI, the success rates for MS and AUS appear more or less equivalent. In these patients, the MS may be the preferred option in many patients due to lower complication and revision rates and ability to void without device manipulation. In fact, if given the choice between MS and AUS surgery, the majority of patients will choose sling placement in order to avoid a mechanical device (51). Although spontaneous voiding is a relative advantage of the MS, the patient requires adequate detrusor contractility to overcome the resistance of a compressive sling. Thus, both the AUS and the MS represent efficacious and acceptably safe methods for the treatment of PPI, but each has its specific role in managing patients with different degrees of leakage and bladder voiding function.

CHAPTER 47 SACRAL NEUROMODULATION

CHRISTOPHER F. TENGGARDJAJA AND SANDIP VASAVADA

Overactive bladder (OAB) symptoms are projected to affect 34 million people in the United States, with a projected national cost of $76 billion in 2015 (1,2). OAB is defined as urinary urgency with or without incontinence commonly associated with frequency and nocturia (3). Patients treated for OAB symptoms undergo behavioral modification in addition to pharmacotherapy. By the time these patients reach the urologist, they usually have refractory symptoms. Sacral neuromodulation (SNM) has proven to be a durable and successful treatment for refractory OAB patients.

Our knowledge of electrical stimulation for neuromodulation is dependent on prior neurophysiologic studies. In the 1800s, work in canine models localized preservation of sensation versus motor function to respective intact dorsal or ventral spinal nerve roots. Selective transection of pelvic and hypogastric nerves helped to further determine their effects on bladder function and micturition. These physiologic observations laid the foundation for our present day techniques. By 1960, several studies began exploring the feasibility of selective nerve root activation with electrical activity. Schmidt et al. (4) demonstrated the ability to induce voiding in canine models with stimulation of sacral nerve roots. Brindley et al. (5) demonstrated improved voiding in spinal cord injury patients with implantation of sacral anterior root stimulators. The placement of neurostimulators has evolved from morbid open cut-down procedures involving laminectomies to minimally invasive percutaneous image-guided techniques. First approved in Europe in 1994, SNM was approved by the U.S. Food and Drug Administration (FDA) for urgency urinary incontinence

(UUI) in 1997 followed by urgency-frequency syndrome and nonobstructive urinary retention (UR) in 1999. Most recently, SNM was approved for the treatment of fecal incontinence (FI) in 2011 (InterStim, Medtronic, Inc). This chapter focuses on the indications, techniques, and outcomes for implantation.

MECHANISMS OF ACTION OF SACRAL NEUROMODULATION

Urinary storage and emptying are facilitated by complex interactions between the central and peripheral nervous systems. Urinary storage is facilitated by lumbar sympathetics and pudendal efferent activation. Micturition is activated by sacral parasympathetics and pudendal relaxation of the external urinary sphincter. SNM is thought to affect both afferent and efferent activity to allow for detrusor relaxation and also cause selective inhibition at the spinal and supraspinal levels (6). Given that SNM is effective in both OAB and nonobstructive UR, it is thought that different pathways are modulated in each patient group with a return to “normal neurophysiology.” For patients with OAB who possibly have an unmasking of a primitive reflex or abnormal sensory afferent discharge, SNM may act on pudendal nerve afferents regulating abnormal activation and inhibiting interneuronal transmission leading to a modulation of sensory outflow to the pontine micturition center. This subsequently prevents involuntary detrusor contractions by modulating the abnormal activation of the micturition reflex. Patients with nonobstructive UR are hypothesized to have an erroneous disinhibition of the spinal guarding and bladder afferent loop reflexes. SNM restores a normal voiding pattern by inhibiting the constant activation of these guarding reflexes (7).

DIAGNOSIS

An initial visit includes a comprehensive history and physical examination. Important aspects of the history include onset and duration of symptoms, exacerbating factors, prior failed therapies, and an assessment of quality of life. Questionnaires such as Urogenital Distress Inventory Short Form (UDI-6) and Incontinence Impact Questionnaire Short Form (IIQ-7) can aid in establishing baseline symptom scores of severity and bother. Age of the patient and onset of symptoms play an important role in the initial assessment. A young patient with sudden onset of symptoms accompanied by other neurologic complaints may warrant further workup for underlying neurologic disease such as multiple sclerosis. Past medical and surgical history are noted because these may be contributing factors to the patient’s problems. OAB symptoms can often be traced to other comorbidities such as poorly controlled diabetes or history of a stroke. UR can be preceded by radical pelvic surgery or a long-standing history of voiding dysfunction.

Physical examination focuses on evaluation of concurrent anatomic abnormalities such as demonstrable pelvic organ prolapse and/or stress urinary incontinence (SUI) during a supine stress test in female patients. These issues can complicate successful treatment of urgency by SNM, which is rendered moot by profound SUI. Saddle sensation should be evaluated and anal sphincter tone assessed. Testing of the bulbocavernosus reflex evaluates the S2–S4 pelvic nerve root. Absence suggests an underlying neurogenic process that may need further evaluation (8). In male patients, a digital rectal exam can suggest a prostatic etiology for outlet obstruction. Initial evaluation tests include a urinalysis to screen for infection and a postvoid residual in patients who complain of incomplete emptying. A 3-day voiding diary is very useful in identifying patients who are candidates for SNM as well as educating patients on their fluid intake and habits. This also serves as an objective measure of urgency and incontinence. If the patient performs clean intermittent catheterization, a voiding/catheterization diary gives a baseline of the patient's symptoms as well as the patient's storage capacity. Urodynamics is reserved for cases where mixed urinary incontinence and abnormal compliance in a neurogenic bladder confound the diagnosis. Fluorourodynamics evaluates whether the patient has obstructive voiding amenable to surgical correction versus non-neurogenic voiding dysfunction, which may be ameliorated by pelvic floor training or SNM. Cystoscopy is selectively performed if there is a concern for bladder outlet pathology.

INDICATIONS FOR SURGERY

After a thorough workup, patients diagnosed with either refractory UUI, urgency-frequency or nonobstructive UR can be considered candidates for SNM. Contraindications exist for SNM. Although SNM can be done in short outpatient staged procedures or with an in-office peripheral nerve evaluation followed by one-stage implantation, all patients should be cleared for surgery. Candidates for therapy must be able to lie in the prone position throughout the duration of the procedure. SNM is not currently recommended in patients who need to undergo spinal magnetic resonance imaging (MRI) due to the theoretical risk of lead heating/dislocation and/or implantable pulse generator (IPG) torquing/malfunction/displacement. Nevertheless, a retrospective review of nine patients who underwent 15 MRIs including that of the lumbar spine showed no adverse effects to MRI interpretation or device functioning (9). Although this review had similar results to other studies, SNM placement in patients with known neurologic disease necessitating frequent spinal MRIs cannot be advocated at this time. Magnetic resonance (MR) of the head at 1.5 Tesla is conditionally approved in patients with InterStim. MR studies should not be performed in patients who are in the testing phase (10). Given the unknown risk of teratogenicity, SNM is relatively contraindicated during pregnancy. Patients with a functioning SNM should have their IPG turned off for the duration of their pregnancy. All patients should have cognition which allows them to properly operate the iCon controller. Performing a mini-mental status exam or clock test to evaluate baseline cognition can be helpful in evaluation for candidacy. Lastly, complex anatomy or prior history of surgery or trauma in the area of the sacral foramina may preclude a patient from being a candidate for lead placement.

ALTERNATIVE THERAPY

All patients are counseled on therapy options based on their initial complaint. For those with UUI or urgency-frequency, first-line therapy consists of behavioral modification. Second-line therapy for OAB includes pharmacotherapy. Alternative third-line therapy options such as percutaneous tibial nerve stimulation (PTNS) and onabotulinumtoxinA injection into the detrusor should be discussed. PTNS is a minimally invasive stimulation of the posterior tibial nerve with weekly 30-minute sessions for an initial period of 12 weeks. OnabotulinumtoxinA has been approved for use in both idiopathic and neurogenic detrusor overactivity patients. For the patient who has failed all therapy options, augmentation cystoplasty exists as a fourth-line treatment. Treatment options for patients with nonobstructive UR include intermittent catheterization or surgical management with urinary diversion when appropriate (11). Conservative treatment with fecal incontinence includes physical therapy with biofeedback. For the refractory patient, surgical management including sphincteroplasty, artificial sphincter, and SNM can be considered as other options.

SURGICAL TECHNIQUE

The implantation of SNM has evolved with time. In 2002, the tined lead was introduced, which obviated the need for larger incisions to anchor the lead to the thoracolumbar fascia.(Fig. 47.1) The IPG was originally placed in the lower anterior abdominal wall and now is placed in the gluteal region. The size of the InterStim II 3058 IPG is also smaller with the trade-off of decreased battery longevity (Fig. 47.2).

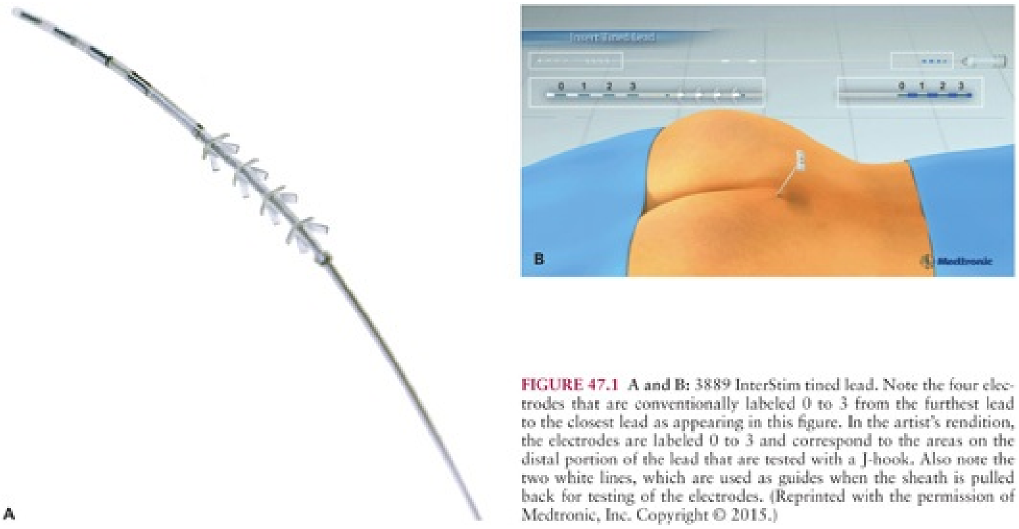

FIGURE 47.1 **A and B:** 3889 InterStim tined lead. Note the four electrodes that are conventionally labeled 0 to 3 from the furthest lead to the closest lead as appearing in this figure. In the artist's rendition, the electrodes are labeled 0 to 3 and correspond to the areas on the distal portion of the lead that are tested with a J-hook. Also note the two white lines, which are used as guides when the sheath is pulled back for testing of the electrodes. (Reprinted with the permission of Medtronic, Inc. Copyright © 2015.)

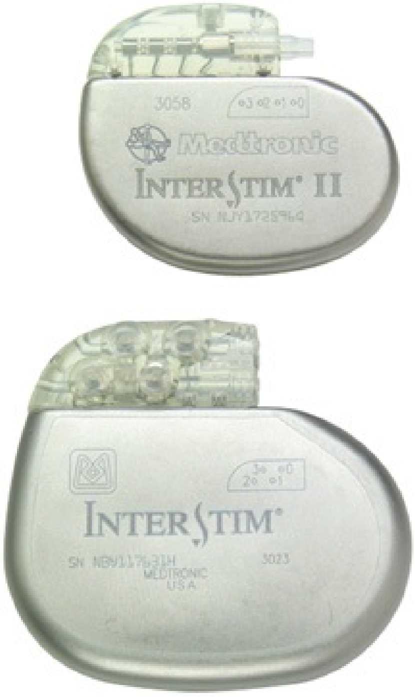

FIGURE 47.2 InterStim I IPG (*bottom*) versus the current InterStim II IPG (*top*). Although smaller in size, the InterStim II IPG has a shorter battery life. (Reprinted with the permission of Medtronic, Inc. Copyright © 2015.)

SNM involves test stimulation and then implantation. This is one of the benefits of SNM as a therapeutic option. The patient tests the therapy prior to proceeding to implantation. The test stimulation can be done with either peripheral nerve evaluation (PNE) or implantation of a tined lead. The PNE involves placement of a nonpermanent lead followed by a single operation for permanent lead and IPG implantation. The staged operation consists of test stimulation with a tined lead placed in the operating room and then subsequent IPG implantation if successful.

Peripheral Nerve Evaluation Test Stimulation

PNE is an office-based procedure that can be used to test patients prior to implantation of the tined lead and IPG during a single surgery. PNE offers the evaluation of efficacy without the risks and inconvenience of two separate operating room anesthetic procedures. In addition, the standard placement of a PNE lead in the right and left foramen during the trial allows the surgeon to test both sides. Efficacy needs to be seen on only one side to lead to single-stage implantation. Historically, initial permanent lead placement required a morbid cutdown procedure to the thoracolumbar fascia or sacrum for securing the lead. Patient selection is important prior to justifying PNE versus a staged implantation due to the increased risk of lead migration with a non-tined lead and shorter trial period. The PNE lead is placed under local anesthetic. Fluoroscopy may or may not be used. Sensory and motor responses are evaluated. Given the non-tined lead, the trial is set for 6 to 7 days versus the longer trial period in a staged evaluation. Although up to 50% of patients will have a successful PNE trial, numerous patients fail either due to lead migration, accidental lead discontinuation, inappropriate length of trial, or inability to perform complex programming (12). Thus, patients who fail PNE or have equivocal results may still undergo a test stimulation with a tined lead.

We prefer to perform PNE in our office setting with local anesthetic. The patient is asked to shower with a chlorhexidine scrub the night before. In the office, the patient changes into a gown and is placed in the prone position with flexion at the hips and knees. A towel roll or support can be used to aid with flexion. The lower back, presacral area, and buttock are prepped with a skin prep solution. The patient is then draped with the anus exposed to evaluate for bellows. If the patient’s body habitus makes bellows difficult to observe, taping of the buttocks prior to prepping can aid with visualization. It is often useful to have an assistant in the room to help the patient and the surgeon. A grounding pad for the lead is placed on the calf or heel of the patient. The red cord from the screener cable is connected to the grounding pad. The white connector to the screener cable is connected to the screener box. The black plug of the screener cable is then connected to the patient cable.

Localization of the S3 Foramen

The procedure can be performed with or without fluoroscopic localization. If no fluoroscopy is used, palpable bony landmarks include the tip of the coccyx, the sciatic notches, and the curve of the sacrum. The approximate location of the S3 foramen is found by measuring 9 cm cephalad from the tip of coccyx in the midline and 2 cm lateral from the midline to identify the foramen on either side. An additional mark is made at a level 11 cm from the tip of the coccyx because this will allow for a perpendicular entry of the finder needle to the sacrum and optimal positioning of the finder needle through the S3 foramen (Fig. 47.3). Another method of localizing the S3 foramen is based on the sciatic notch. The S3 foramen is typically at the level of the sciatic notch and a line can be drawn from the left and right notches if they can be palpated. The sacrum defines midline and the foramina should be 2 cm lateral on either side of the midline. A less reliable landmark that can be used for localization is the curve of the sacrum. Theoretically, the sacral crest is S4. Thus, 2 cm cephalad of S4 would be the plane for the S3 foramen.

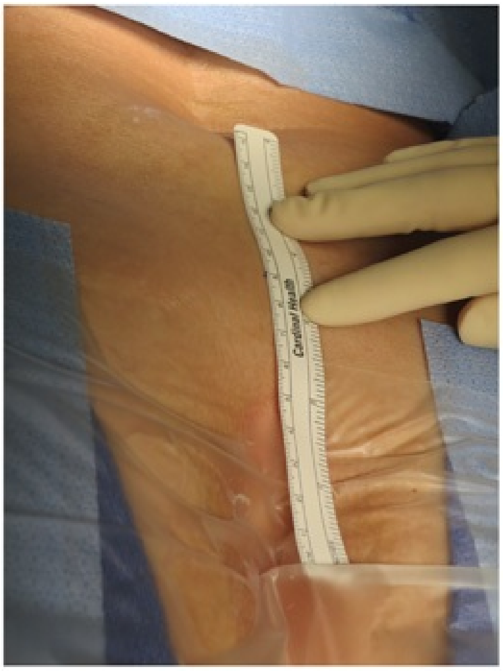

FIGURE 47.3 Using landmarks such as the anal verge to estimate the location of the S3 foramen. This ruler demonstrates the 9 and 11 cm marks measured out midline from the anal verge.

If fluoroscopy is used during the procedure, a “cross-hair” technique has been described by Chai and Mamo (13). In an anteroposterior (AP) view, the inferior border of the sacroiliac joints is identified. A foramen needle is placed over this area. The spinous process is then marked midline with a directional guide (Fig. 47.4). A mark is made, and the foramen should be 2 cm lateral to the mark on either side. The finder needle should be inserted into the dermis above this marking to achieve an angle of entry perpendicular to the bony plate. This equates to a 60-degree angle placement through the skin. In contrast, if the finder needle were placed directly at the mark on fluoroscopy, a 90-degree angle through the skin would correlate to a more difficult entry into the foramen given the curve of the sacrum (Fig. 47.5).

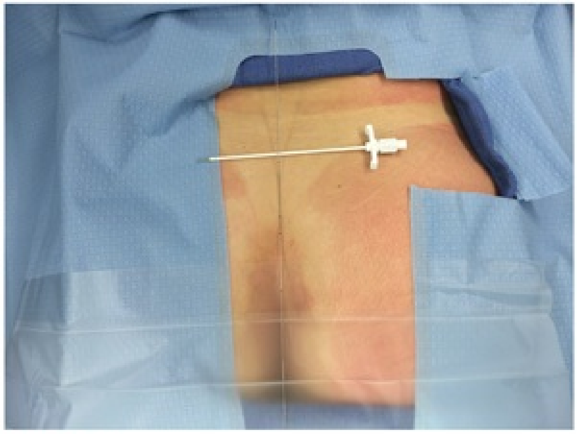

FIGURE 47.4 Cross-hair technique demonstrated with placing the radiopaque directional guide in the midline and either a finder needle or obturator/sheath in the transverse direction sitting on the most inferior border of the sacroiliac joints. The S3 foramen should be 2 cm lateral of midline on either side.

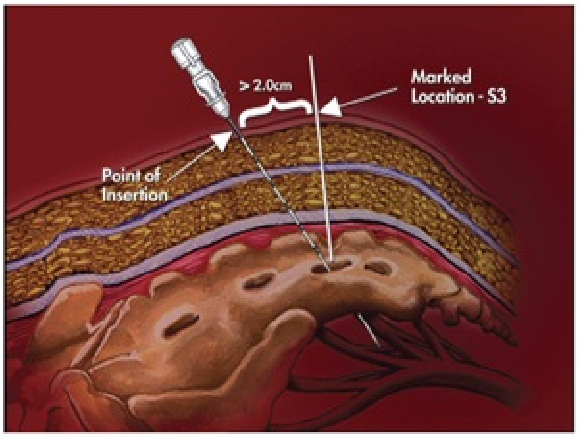

FIGURE 47.5 Proper insertion and angle of the finder needle in the S3 foramen. A 60-degree angle enables the needle to properly enter the S3 foramen given the curve of the sacrum versus a 90-degree angle that may lead to a less than optimal placement of the lead next to the sacral nerve as it exits the foramen.
